Printed and bound in Finland

THE FIRST EDITION OF THIS WORK

WAS DEDICATED TO

SIR BENJAMIN COLLINS BRODIE, BART.

F.R.S., D.C.L.

IN ADMIRATION OF

HIS GREAT TALENTS

AND IN REMEMBRANCE OF

MANY ACTS OF KINDNESS SHOWN TO THE ORIGINAL AUTHOR OF THE BOOK

FROM AN

EARLY PERIOD OF HIS PROFESSIONAL CAREER

PREFACE

TO

THE SIXTEENTH EDITION

THE text of this edition has been carefully revised and in part rewritten. Many additional drawings have been introduced, more especially in connection with the chapters on Embryology, the Nervous System, and the Organs of Sense, while at the same time care has been taken to keep the size of the book within reasonable limits. A further use of colour has been employed in order to render the drawings more effective and instructive.

The half-tone illustrations which were utilised to a considerable extent in recent editions, and which required for their successful reproduction a highly glazed heavy paper, have been replaced by woodcuts and line drawings. These not only harmonise more closely with Carter's original figures, but have permitted of a lighter paper being used for printing purposes, with the result that the present volume weighs considerably less than the last.

The Editors desire to express their indebtedness to Dr. R. A. Bolam, Lecturer on Physiology and Histology in the University of Durham College of Medicine, Newcastle-upon-Tyne, who has revised the chapter on Histology and furnished it with several new illustrations.

It is hoped that the present edition will maintain and enhance the reputation which the work has enjoyed during the past forty-seven years.

PREFACE

TO

THE SIXTEENTH EDITION

THE text of this edition has been carefully revised and in many places rewritten. Many additional drawings have been introduced, more especially in connection with the chapters on Histology, the Nervous System, and the Organs of Sense, while at the same time care has been taken to keep the size of the book within reasonable limits. A further use of colour has been employed in order to render the drawings more effective and instructive.

The half-tone illustrations which were utilised to a considerable extent in recent editions, and which required for their successful reproduction a highly glazed heavy paper, have been replaced by woodcuts and line drawings. These not only harmonise more closely with Carter's original figures but have permitted of a lighter paper being used for printing purposes, with the result that the present volume weighs considerably less than the last.

The Editors desire to express their indebtedness to Dr. [illegible], Lecturer on Physiology and Histology in the University of Durham College of Medicine, Newcastle-upon-Tyne, who has revised the chapter on Histology and furnished it with several new illustrations.

It is hoped that the present edition will maintain and increase the reputation which the work has enjoyed during the past [illegible] years.

GENERAL ANATOMY OR HISTOLOGY

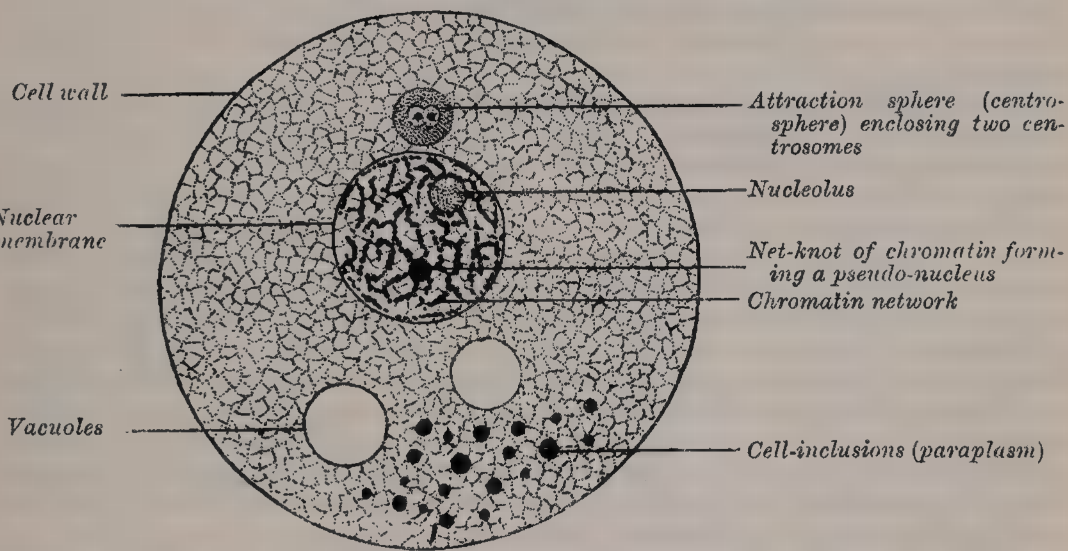
THE ANIMAL CELL (fig. 1)

ALL the tissues and organs of which the body is composed were originally developed from a microscopic structure (the *ovum*), consisting of a soft jelly-like granular material enclosed in a membrane, and containing a vesicle, or small spherical body, inside which are one or more solid spots. This may be regarded as a perfect cell. Moreover, all the solid tissues can be shown to consist largely of similar cells, differing, it is true, in external form, but essentially similar to an ovum.

In the higher organisms all such cells may be defined as 'nucleated masses of protoplasm of microscopic size.' The two essentials, therefore, of an animal cell in the higher organisms are: the presence of a soft jelly-like granular material, similar to that found in the ovum, and which is usually styled *protoplasm*; and

FIG. 1.—Diagram of a cell. (Modified from Wilson.)



a small spherical body embedded in it, and termed a *nucleus*;* the remaining constituents of the ovum, viz. its limiting membrane and the solid spot contained in the nucleus, called the *nucleolus*, are not considered essential to the cell, and in fact many cells exist without them.

Protoplasm (*cytoplasm*) is a material probably of variable constitution, but yielding to the chemist on its disintegration bodies chiefly of proteid nature. Lecithin and cholesterin are constantly found in it, as well as inorganic salts, chief among which are the phosphates and chlorides of the alkali metals and calcium. It is of a semi-fluid, viscid consistence, and appears either as a hyaline substance, homogeneous and clear, or else it exhibits a granular appearance. This granular appearance, under a high power of the microscope, is seen to be due to the fact that protoplasm consists of an elastic and refractile network or honeycombed

* In certain lower forms of life, masses of protoplasm without any nuclei have been described by Huxley and others, as cells.

reticulum, containing in its meshes a clear, semi-fluid homogeneous substance. The former is known as *spongioplasm*, the latter as *hyaloplasm*. The granular appearance is often caused by the knots of the network being mistaken for granules; but, in addition to this, protoplasm often contains true granules, some of which are proteid in nature and probably essential constituents; others are fat, glycogen or pigment granules, and are regarded as adventitious material taken in from without, and hence are styled cell-inclusions or *paraplasm*. The size and shape of the meshes of the spongioplasm vary in different cells and in different parts of the same cell. In many fixed cells, e.g. epithelial cells, the external layer becomes denser than the rest, and often altered by the deposition in it of some chemical substance, so as to constitute a membrane which encloses the rest of the protoplasm and forms the *cell wall*. The relative amount of spongioplasm and hyaloplasm varies in different cells; the latter preponderating in the young cell and the former increasing in amount, at the expense of the hyaloplasm, as the cell grows.

The most striking characteristics of protoplasm are its vital properties of *motion* and *nutrition*. By motion is meant the property which protoplasm has of changing its shape and position by some intrinsic power, which enables it to thrust out from its main body an irregular process, into which the whole of the protoplasmic substance is gradually drawn, so that the mass comes to occupy a new position. This, on account of its resemblance to the movements observed in the Amœba or Proteus animalcule, has been termed 'amœboid movement.' Ciliary movement, or the vibration of hair-like processes from the surface of any structure, may also be regarded as a variety of the motion with which protoplasm is endowed.

Nutrition is the power which protoplasm has of attracting to itself the materials necessary for its growth and maintenance from surrounding matter. When any foreign particle comes in contact with the protoplasmic substance, it becomes incorporated in it, being enwrapped by one or more processes projected from the parent mass which enclose it. When thus taken up, it may remain in the substance of the protoplasm for some time without change, or may be again extruded.

The **Nucleus** is a minute body, embedded in the protoplasm, and usually of a spherical or oval form, its size having little relation to the size of the cell. It is surrounded by a well-defined wall, the *nuclear membrane*, which encloses the nuclear contents. These are known as the *nuclear substance* (nuclear matrix), which is composed of a homogeneous material and a stroma or network. The former is probably of the same nature as the hyaloplasm of the cell; but the latter, which forms also the wall of the nucleus, differs from the spongioplasm of the cell substance. It is sometimes known as the *chromoplasm* or *intranuclear network*, and consists of a network of fibres or filaments arranged in a reticular manner. These filaments stain very readily with certain dyes; they are therefore named *chromatin*; while the interstitial substance does not stain readily, and is hence called *achromatin*. In some resting nuclei, i.e. nuclei which are not undergoing subdivision, the nuclear filaments do not form a network, but present the appearance of a convoluted skein, similar to that found in a nucleus about to undergo division, which will be immediately described.

Within the nuclear matrix are one or more highly refracting bodies, termed *nucleoli*, connected with the nuclear membrane by the nuclear filaments. They are regarded as being of two kinds. Some are mere local condensations ('net-knots') of the chromoplasm; these are irregular in shape and are termed *pseudo-nucleoli*; others are distinct bodies differing from the pseudo-nucleoli both in nature and chemical composition; they may be termed *true nucleoli*, and are usually found in resting cells.

The nuclear substance differs chemically from ordinary protoplasm in containing *nuclein*, in its power of resisting the action of acids and alkalies, in its imbibing more intensely the stain of carmine, hæmatoxylin, &c., and in its remaining unstained by some reagents which colour ordinary protoplasm.

Recent investigations tend to show that most living cells contain, in addition to their protoplasm and nucleus, a minute particle which, on account of the power it appears to possess of attracting the surrounding protoplasmic granules, is termed the *attraction particle* or *centrosome*; it usually lies near the nucleus. The spherical arrangement of fibrillar rows of granules surrounding the central

particle is termed the *attraction-sphere* or *centrosphere*. These spheres are as a rule double, and are connected by a spindle-shaped system of delicate fibrils (*achromatic spindle*). They are best seen in young cells which are about to undergo the process of division, a process believed to commence in these bodies.

The process of reproduction of cells is described as being brought about by *indirect* or by *direct division*. *Indirect division* or *karyokinesis* (*karyomitosis*) has been observed in all the tissues—generative cells, epithelial tissue, connective tissue, muscular tissue, and nerve tissue, and probably it will ultimately be shown that the division of cells always takes place in this way, and that the process of reproduction of cells by direct division is, as some observers believe, merely a sort of imperfect or abnormal karyokinesis.

The process of indirect cell division is characterised by a series of complex changes in the nucleus, leading to its subdivision; this being followed by cleavage of the cell protoplasm. Starting with the nucleus in the quiescent or *resting* stage, these changes may be briefly grouped under the four following phases:

1. *Prophase.*—The nuclear network of chromatin filaments assumes the form of a twisted *skein* or *spirem*, while the nuclear membrane and nucleolus disappear. The convoluted skein of chromatin divides into a definite number of V-shaped loops or *chromosomes*. The number of chromosomes varies in different animals—in man it is believed to be always sixteen. Coincident with or preceding these changes the centrosome, or attraction particle, which usually lies by the side of the nucleus, undergoes subdivision, and the two resulting centrosomes, each surrounded by a centrosphere, are seen to be connected by a spindle of delicate achromatic fibres, the *achromatic spindle*. These centrosomes move away from each other—one towards each extremity of the nucleus—and the fibrils of the achromatic spindle are correspondingly lengthened. The centrosomes are now situated one at either extremity or pole of the elongated spindle, and each is surrounded by a centrosphere, from which fibrils radiate into the investing protoplasm. A line encircling the spindle midway between its poles is named the *equator*, and around this the V-shaped chromosomes arrange themselves in the form of a star, thus constituting the *mother star* or *monaster*.

2. *Metaphase.*—Each V-shaped chromosome now undergoes longitudinal cleavage into two equal halves or *daughter chromosomes*, the cleavage commencing at the apex of the V and extending along its divergent limbs. The daughter chromosomes, thus separated, travel in opposite directions along the fibrils of the achromatic spindle towards the centrosomes, around which they group themselves, and thus two star-like figures are formed, one at either pole of the achromatic spindle. This is termed the *diaster*.

3. *Anaphase.*—The V-shaped daughter chromosomes now arrange themselves into a *skein* or *spirem*, and eventually form the network of chromatin which is characteristic of the resting nucleus. The nuclear membrane and nucleolus are also differentiated during this phase. The cell protoplasm begins to appear constricted around the equator of the achromatic spindle, where double rows of granules are also sometimes seen. The constriction deepens and the original cell gradually becomes divided.

4. *Telophase.*—In this stage the cell is completely divided into two new cells, each with its own nucleus, centrosome and centrosphere, which assume the ordinary positions occupied by such structures in the resting stage.

The series of diagrams (fig. 2), by Professor S. Delépine, is intended to explain the formation of some of the most important changes observed in nuclei of cells during karyokinesis (mitosis); it is based chiefly on the work of Flemming, Strasburger, E. van Beneden, Rabl, O. Hertwig, Henneguy, &c. A. *Resting nucleus*. Nucleolus and nuclear membrane visible. A centrosome is represented near the nucleus. B and C. *Skein* or *spirem*. Chromatic filaments much convoluted. Evidence of longitudinal splitting begins to be distinct in several parts. The centrosome has divided; the nuclear membrane is becoming indistinct. The two centrosomes are widely separated, and the space between them is occupied by the achromatic spindle. (Two arrows point to the positions which the centrosomes will ultimately occupy; during their passage to these points the achromatic spindle seems to be within the nucleus.) The nuclear membrane has disappeared. D. *Mother star, monaster*. The nuclear segments (chromosomes) resulting from the breaking-up of the chromatic filament into fragments of nearly equal length have moved towards the equator of the spindle, where they now form an equatorial

FIG. 2.—Karyokinesis: or indirect cell-division.

plate. These segments are all split longitudinally. E. *Metaphase.* One half of each chromosome moves in the direction of one pole and the other half in that of the other pole, being guided towards the centrosomes by the achromatic filaments. F. *Daughter stars* or *diaster*. G. *Daughter skeins* or *dispirem*, beginning to form. Segments in the form of thick loops not closely packed. H. *Daughter skeins* or *dispirem*, formed. Segments more closely packed and less distinct, owing to the formation of anastomoses. I. *Resting daughter nuclei.* Cell completely divided into two, but bridges remain between them in the region previously occupied by the achromatic filaments, these being specially distinct in certain cells (e.g. prickle cells). The nucleus has a distinct nuclear membrane and a nucleolus.

In the reproduction of cells by *direct* division the process is brought about either by segmentation or by gemmation. In reproduction by *segmentation* or *fission*, the nucleus becomes constricted in its centre, assuming an hour-glass shape, and then divides into two. This leads to a cleavage or division of the whole protoplasmic mass of the cell; and thus two daughter cells are formed, each containing a nucleus. These daughter cells are at first smaller than the original mother cell; but they grow, and the process may be repeated in them, so that multiplication may take place rapidly. In reproduction by *gemmation*, a budding-off or separation of a portion of the nucleus and parent cell takes place, and, becoming separated, forms a new organism.

The **cell-wall,** which is not an essential constituent, and in fact is often absent, is merely the external layer of the protoplasm, firmer than the rest of the cell, and often thickened by the deposit in it of certain chemical substances. It forms a flexible, transparent, finely striated membrane, sometimes furnished with minute pores, so as to be permeable to fluids.

THE NUTRITIVE FLUIDS

The **circulating fluids** of the body, which subserve its nutrition, are the blood, the lymph, and the chyle.

THE BLOOD

The blood is an opaque, rather viscid fluid, of a bright red or scarlet colour when it flows from the arteries, of a dark red or purple colour when it flows from the veins. It is salt to the taste, and has a peculiar faint odour and an alkaline reaction. Its specific gravity is about 1·060, and its temperature is generally about 99° F., though varying slightly in different parts of the body.

General Composition of the Blood.—Blood consists of a faintly yellow fluid, the *plasma* or *liquor sanguinis*, in which are suspended numerous minute particles, the *blood corpuscles*, the majority of which are coloured and give to the blood its red tint. If a drop of blood is placed in a thin layer on a glass slide and examined under the microscope, a number of these corpuscles will be seen immersed in the clear fluid plasma.

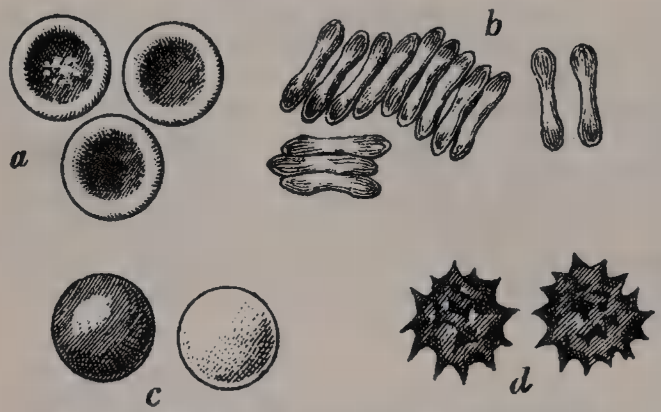
The **Blood Corpuscles** are chiefly of two kinds: (1) Coloured corpuscles or Erythrocytes, (2) Colourless corpuscles or Leucocytes. A third variety, the Blood platelets, are of subsidiary importance.

1. **Coloured or Red Corpuscles** (*erythrocytes*), when examined under the microscope, are seen to be circular discs, biconcave in profile. They have no nuclei, but, in consequence of their biconcave shape, present, according to the alteration of focus under an ordinary high power, a central part, sometimes bright, sometimes dark, which has the appearance of a nucleus (fig. 3, *a*). It is to their aggregation that the blood owes its red hue, although when examined by transmitted light their colour appears to be only a faint reddish-yellow. Their size varies slightly even in the same drop of blood, but it may be stated that their ordinary diameter is about $\frac{1}{3200}$ of an inch, while their thickness is about $\frac{1}{12000}$ of an inch or nearly one quarter of their diameter. Besides these there are found, especially in disease (e.g. anæmic conditions), certain smaller corpuscles of about one-half or one-third of the size just indicated; these are termed *microcytes*, and are very scarce in normal blood. The number of red corpuscles in the blood is enormous; between 4,000,000 and 5,000,000 are contained in a cubic millimetre. Power states that the red corpuscles of an adult would present an aggregate surface of about 3,000 square yards. Each corpuscle consists of

a colourless elastic spongework or stroma, condensed at the periphery to form an investing membrane, and uniformly diffused throughout this are the coloured fluid contents. The stroma is composed mainly of *nucleo-proteid* and of the fatty substances, *lecithin* and *cholesterin*, while the coloured material consists chiefly of the respiratory proteid, *hæmoglobin*, which contains a proportion of iron in addition to the ordinary proteid elements. This proteid has a great affinity for oxygen, and, when removed from the body, crystallises readily under certain circumstances. It is very soluble in water, the addition of which to a drop of blood speedily dissolves out the hæmoglobin from the corpuscles.

If the web of a frog's foot be spread out and examined under the microscope, the blood is seen to flow in a continuous stream through the vessels, and the corpuscles show no tendency to adhere to each other or to the wall of the vessel. Doubtless the same is the case in the human body; but when the blood is drawn and examined on a slide without reagents, the corpuscles often collect into heaps like rouleaux of coins (fig. 3, *b*). It has been suggested that this phenomenon may be explained by alteration in surface tension. During life the red corpuscles may be seen to change their shape under pressure so as to adapt themselves, to some extent, to the size of the vessel. They are, however, highly elastic, and speedily recover their shape when the pressure is removed. They are readily influenced by the medium in which they are placed and by the specific gravity of the medium. In water they swell up, lose their shape, and become globular (fig. 3, *c*). Subsequently the hæmoglobin becomes dissolved out, and the envelope can barely be distinguished as a faint circular outline. Solutions of salt or sugar, denser than the plasma, give them a stellate or crenated appearance (fig. 3, *d*), but the usual shape may be restored by diluting the solution to the same specific gravity as the plasma. The crenated outline may be produced as the first effect of the passage of an electric shock: subsequently, if sufficiently strong, the shock ruptures the envelope. A solution of salt or sugar, of the same specific gravity as the plasma, merely separates the blood corpuscles mechanically, without changing their shape.

Fig. 3.—Human red blood-corpuscles. Highly magnified.



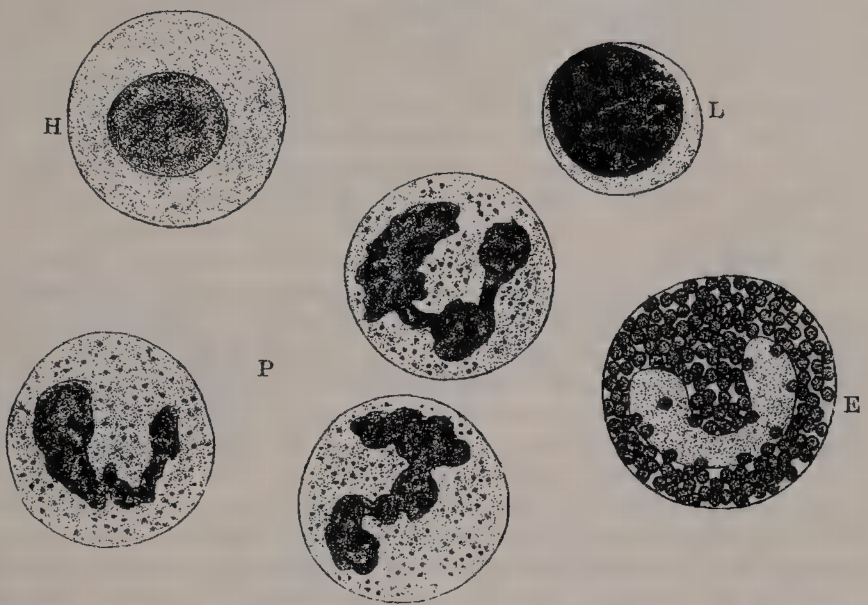
a. Seen from the surface. *b.* Seen in profile and forming rouleaux. *c.* Rendered spherical by water. *d.* Rendered crenate by salt solution.

The **Colourless Corpuscles** or *leucocytes* are of various sizes, some no larger, others even smaller, than the red corpuscles. In human blood, however, the majority are rather larger than the red corpuscles, and measure about $\frac{1}{2000}$ to $\frac{1}{2500}$ of an inch in diameter. On the average from 10,000 to 12,000 leucocytes are found in each cubic millimetre of blood.

They consist of minute masses of nucleated protoplasm, and exhibit several varieties, which are differentiated from each other chiefly by the occurrence or non-occurrence of granules in their protoplasm and by the staining reactions of these granules when present (fig. 4). (1) The most numerous and important are spherical in shape, and are characterised by a nucleus, which often consists of two or three parts (multipartite) connected together by fine threads of chromatin. The protoplasm is clear, and contains a number of very fine granules, which stain with acid dyes, as eosin (fig. 4, P). These cells are termed the *polymorphonuclear* leucocytes. (2) A second variety comprises from 2 to 4 per cent. of the leucocytes; they are larger than the previous kind, and are made up of a coarsely granular protoplasm, the granules being highly refractile and grouped round a single nucleus of horse-shoe shape (fig. 4, E). These granules stain deeply with eosin, and the cells are therefore often termed *eosinophile* corpuscles. (3) The third variety is called the *hyaline* cell (fig. 4, H). This is usually about the same size as the eosinophile cell, and, when at rest, is spherical in shape and contains a single round or oval nucleus. The protoplasm is free from granules,

but is not quite transparent, having the appearance of ground glass. (4) The fourth kind of colourless corpuscle is designated the *lymphocyte* (fig. 4, L), because it is identical with the lymphoid cell derived from the lymphatic glands, the spleen, tonsil, and thymus. It is the smallest of the leucocytes, and consists chiefly of a spheroidal nucleus with very little surrounding protoplasm of a

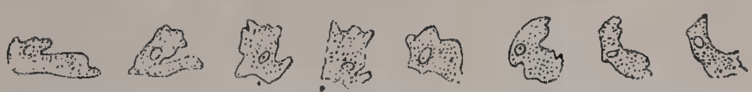
FIG. 4.—Varieties of leucocytes found in human blood.



homogeneous nature; it is regarded as the immature form of the hyaline cell. The third and fourth varieties together constitute from 20 to 30 per cent. of the colourless cells, but of these two varieties the lymphocytes are by far the more numerous. Leucocytes having in their protoplasm granules which stain with basic dyes (basophile) have been described as occurring in human blood, but they are rarely found except in disease.

The white corpuscles are very various in shape in living blood (fig. 5), because many of them have the power of constantly changing their form by protruding finger-shaped or filamentous processes of their own substance, by which they move, and take up granules from the surrounding medium. In locomotion the corpuscle pushes out a process of its substance—a *pseudopodium*, as it is called—and then shifts the rest of the body into it. In the same way when any granule or particle

FIG. 5.—Human colourless blood-corpuscle, showing its successive changes of outline within ten minutes when kept moist on a warm stage. (Schofield.)



comes in its way it wraps a pseudopodium round it, and then withdrawing it, lodges the particle in its own substance. By means of these amœboid properties the cells have the power of wandering or emigrating from the blood-vessels by penetrating their walls and thus finding their way into the extra-vascular spaces. A chemical investigation of the protoplasm of the leucocytes shows the presence of nucleo-proteid and of a globulin. The occurrence of small amounts of fat and glycogen may also be demonstrated.

The **Blood platelets** are discoid or irregularly shaped, colourless, refractile bodies, much smaller than the red cells. Considerable discussion has arisen as to their significance. Recent observers have shown that under the action of certain stains the centrally situated portion of the blood platelet takes on an appearance suggestive of a nucleus. In spite of this, and of the fact that they have been observed in the blood-vessels during life, there is still a tendency to regard them as products of disintegration of the white cells, or as precipitates, possibly of nucleo-proteid, and not as living elements of the blood.

Origin of the Blood Corpuscles.—In the embryo the red corpuscles are developed from mesoblastic cells in the vascular area of the blastoderm. These cells unite

with one another to form a network, their nuclei multiply in number, and around some of the nuclei an aggregation of coloured protoplasm takes place. After a time the network becomes hollowed out by an accumulation of fluid, and forms capillary blood-vessels, and in the fluid those nuclei which are surrounded by coloured protoplasm float as the first red blood cells.* The embryonic corpuscles are thus nucleated, and, further, they have the power of amœboid movement. These cells disappear in later embryonic life, to be replaced by smaller non-nucleated corpuscles, having all the characters of the adult erythrocytes, which, according to Schäfer, are formed within certain cells of the connective tissue. Small globules of reddish colouring matter appear in the protoplasm of these cells, and these eventually becoming larger, more uniform in size and disc-shaped, float in a cavity which results from the coalescence of numerous vacuoles. The cells, becoming more hollowed, join with neighbouring cells to form new blood-vessels, and these become connected with previously existing vessels. In post-embryonic life the important source of the red corpuscles is the red marrow in the ends of the long bones and especially in the ribs and sternum. Here are found special, nucleated, coloured cells, termed *erythroblasts*, which are probably direct descendants of the nucleated, embryonic red cells. These erythroblasts by atrophy and disappearance of their nuclei (or, as some observers maintain, by their extrusion) and by assumption of the biconcave form are transformed into the adult red corpuscles. Of the white corpuscles of the blood, the lymphocytes are derived from lymphatic tissue generally, and from the lymphatic glands especially, and enter the blood by way of the lymph stream; the hyaline cells probably develop from the lymphocytes, while the eosinophile cells are believed to originate mainly in the bone marrow and possibly also in the connective tissues.

The **Plasma or Liquor Sanguinis,** the fluid portion of the blood, has a yellowish tint, is alkaline in reaction, and of a specific gravity of 1·028. It contains in solution about 10 per cent. of solids, of which four-fifths are proteid in nature; the remainder being salts, chiefly chlorides, phosphates, and sulphates of the alkali metals; carbohydrates, chiefly sugar; fats and soaps; cholesterin, urea, and other nitrogenous extractives. The proteids are three in number, *serum albumin, serum globulin,* and *fibrinogen.* Fibrinogen is a body of the globulin class, but differs from serum globulin in several respects. It is the substance from which the *fibrin,* which plays so important a part in the clotting of the blood, is derived.

Coagulation of the Blood.—When blood is drawn from the body and allowed to stand, it solidifies in the course of a very few minutes into a jelly-like mass or *clot,* which has the same appearance and volume as the fluid blood, and, like it, looks quite uniform. Soon, however, drops of a transparent yellowish fluid, the *serum,* begin to ooze from the surface of the mass and to collect around it. Coincidently the clot begins to contract, so that in the course of about twenty-four hours, having become considerably smaller and firmer than the first formed jelly-like mass, it floats in a quantity of yellowish serum. The clotting of the blood is due to the formation of a fine meshwork of the insoluble material, *fibrin,* which entangles and encloses the blood corpuscles. It is supposed that when blood is drawn a nucleo-proteid, termed *prothrombin,* appears in the plasma, probably as the result of disintegration of some of the white cells and perhaps also the blood platelets. This substance interacts with soluble lime salts in the blood, and a fresh body, *thrombin* or *fibrin ferment,* is the result. The thrombin then acts on the fibrinogen in solution in the plasma, converting it into insoluble fibrin, while at the same time a very small amount of a new proteid of the globulin type passes into solution.

Fibrin may be obtained, practically free from corpuscles, by whipping the blood, after it has been withdrawn from the body, with a bundle of twigs, to which the fibrin adheres as it is formed. By various means the clotting of the blood may be retarded so that the plasma may be obtained free from corpuscles; from this plasma there may be derived fibrin and serum, without the cellular elements. Fibrin thus obtained is a white or buff-coloured stringy substance, and when observed, in the course of formation, under the microscope, shows a meshwork of fine fibrils. After exposure to the air for some time it becomes

* Recent observations tend to show that the endothelial lining of the vessels and the blood corpuscles are of hypoblastic origin.

hard, dry, brown and brittle. It is one of the class of coagulated proteids, insoluble in hot or cold water, saline solution, alcohol, or ether. Under the action of dilute hydrochloric acid it swells up but does not dissolve, but, when thus swollen, is readily dissolved by a solution of pepsin.

Serum, with the exception of its proteids, has a composition identical with that of plasma. The fibrinogen, characteristic of plasma, has disappeared, and the fibrin ferment or thrombin is found instead, together with the serum albumin and serum globulin which are not involved in the process of coagulation.

The relation of the various constituents of the blood to each other may be easily understood by a reference to the subjoined plan.

$$\text{Blood}\left\{\begin{array}{l}\text{Corpuscles} \\ \text{Plasma}\left\{\begin{array}{l}\text{Fibrin} \\ \text{Serum}\end{array}\right.\end{array}\right. \qquad \left.\begin{array}{l}\text{Corpuscles} \\ \text{Fibrin}\end{array}\right\}\text{Clot}$$

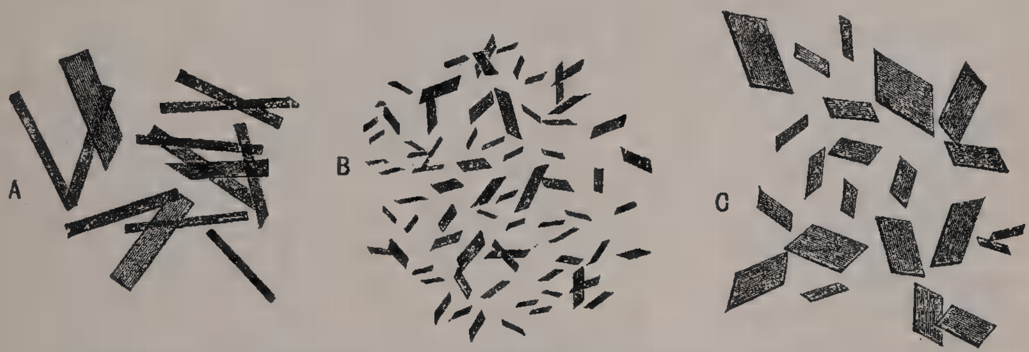
Gases of the Blood.—When blood is exposed to the vacuum of an air-pump, 100 volumes are found to yield about 60 volumes of gas. The gases present are carbon dioxide, oxygen and nitrogen, and they occur in the following proportions in arterial and venous blood:

	Carbon dioxide	Oxygen	Nitrogen
Arterial blood . .	40 vols.	20 vols.	1 to 2 vols.
Venous blood . .	46 to 50 vols.	10 to 12 vols.	1 to 2 vols.

The greater quantity of the oxygen is in loose chemical combination with the hæmoglobin of the red corpuscles. The carbon dioxide exists in combination for the most part as sodium bicarbonate and carbonate. The nitrogen is in simple solution in the plasma.

Blood Crystals.—Hæmoglobin, as already stated, readily crystallises when separated from the blood corpuscles. In human blood the crystals are elongated prisms (fig. 6, A), and in the majority of animals belong to the rhombic system, though in the squirrel hexagonal plates are met with. Small brown prismatic

Fig. 6.—Blood-crystals.



A. Hæmoglobin crystals from human blood. B. Hæmin crystals from blood treated with acetic acid. C. Hæmatoidin crystals from an old apoplectic clot.

crystals of *hæmin* (fig. 6, B) may be obtained by mixing dried blood with common salt and boiling with a few drops of glacial acetic acid. A drop of the mixture on a slide will show the characteristic crystals on cooling. *Hæmatoidin* crystals (fig. 6, C) occur sometimes in old blood clots.

Lymph and Chyle

Lymph is a transparent, colourless or slightly yellow fluid, which is conveyed by a set of vessels, named *lymphatics*, into the blood. These vessels arise in nearly all parts of the body as *lymph capillaries*. They take up the blood plasma which has exuded from the blood capillaries into the tissue spaces where it has nourished the tissue elements, and return it into the veins close to the heart, there to be mixed with the mass of blood. The greater number of these lymphatics empty themselves into one main duct, the *thoracic duct*, which passes upwards along the front of the spine and opens into the large veins on the left

side of the root of the neck. The remainder empty themselves into a smaller duct which terminates in the corresponding veins on the right side of the neck.

Lymph, as its name implies, is a watery fluid of sp. gr. about 1·015, closely resembling the blood plasma, but more dilute, containing only about 5 per cent. of proteids and 1 per cent. of salt and extractives. When examined under the microscope, leucocytes of the lymphocyte class are found floating in the transparent fluid. They are always increased in number after the passage of the lymph through lymphoid tissue, as in lymphatic glands. They are constantly furnishing a fresh supply of colourless corpuscles to the blood.

Chyle is an opaque, milky-white fluid, absorbed by the villi of the small intestine from the food, and carried by a set of vessels similar to the lymphatics, named *lacteals*, to the commencement of the thoracic duct, where it is intermingled with the lymph and poured into the circulation through the same channels. It must be borne in mind that these two sets of vessels, lymphatics and lacteals, though differing in name, are identical in structure, and that the character of the fluid they convey is different only while digestion is going on. At other times the lacteals convey a transparent, nearly colourless lymph.

Chyle exactly resembles lymph in its physical and chemical properties, except that it has, in addition to the other constituents of lymph, a quantity of finely divided fatty particles, the so-called 'molecular basis of chyle' to which the milky appearance is due. It contains a little more proteïd than lymph, but the chief difference lies in the large quantity of fats, soaps, lecithin and cholesterin which are found in the chyle. Lymph and chyle, containing, as they do, fibrinogen in solution and leucocytes, clot on removal from the body, the coagulum being free from red cells, and presenting a clear or whitish jelly-like appearance.

EPITHELIUM

All the surfaces of the body—the external surface of the skin, the internal surface of the digestive, respiratory, and genito-urinary tracts, the closed serous cavities, the inner coat of the vessels, the acini and ducts of all secreting and excreting glands, the ventricles of the brain and the central canal of the spinal cord—are covered by one or more layers of simple cells, called *epithelium* or *epithelial cells*. These cells are also present in the terminal parts of the organs of special sense, and in some other structures, as the pituitary and thyroid bodies. They serve various purposes, forming in some cases a protective layer, in others acting as agents in secretion and excretion, and again in others being concerned in the elaboration of the organs of special sense. Thus, in the skin, the main purpose served by the epithelium (here called the *epidermis*) is that of protection. As the surface is worn away by the agency of friction or change of temperature new cells are supplied, and thus the surface of the true skin and the vessels and nerves which it contains are defended from damage. In the gastro-intestinal mucous membrane and in the glands, the epithelial cells appear to be the principal agents in separating the secretion from the blood or from the alimentary fluids. In other situations (as the nose, fauces, and respiratory passages) the chief office of the epithelial cells appears to be to maintain an equable temperature by the moisture with which they keep the surface always slightly lubricated. In the serous cavities they also keep the opposed layers moist, and thus facilitate their movements on each other. Finally, in all internal parts they insure a perfectly smooth surface.

Fig. 7.—Simple pavement epithelium.

Epithelium consists of one or more layers of cells, united together by an interstitial cement substance, supported on a basement membrane, and is naturally grouped into two classes according as to whether there is a single layer of cells (*simple epithelium*) or more than one (*stratified epithelium*). A third variety (*transitional epithelium*) is that in which cells, in three or four layers, are so fitted together that the appearance is not one of distinct stratification. The different varieties of simple epithelium

are generally spoken of as squamous or pavement, columnar, glandular or spheroidal, and ciliated.

The *pavement* epithelium (fig. 7) is composed of flat, nucleated scales of different shapes, usually polygonal, and varying in size. These cells fit together by their edges, like the tiles of a mosaic pavement. The nucleus is generally flattened, but may be spheroidal. The flattening depends upon the thinness of the cell. The protoplasm of the cell presents a fine reticulum or honeycombed network, which gives to the cell the appearance of granulation. This kind of epithelium forms the lining of the air-cells of the lungs. The *endothelium*, which covers the serous membranes, and which lines the heart, blood-vessels, lymphatics, and the anterior chamber of the eye, is also of the pavement type, being composed of a single layer of flattened transparent squamous cells, joined edge to edge in such a manner as to form a membrane of cells. Endothelium differs from epithelium in that it originates from the embryonic mesoblast, while epithelium arises, as a rule, from the epiblast or hypoblast.

The *columnar* or *cylindrical* epithelium (fig. 8) is formed of cylindrical or rod-shaped cells set together so as to form a complete layer, resembling, when viewed in profile, a palisade. The cells have a prismatic figure, more or less

Fig. 8.—Columnar epithelium from an intestinal villus.

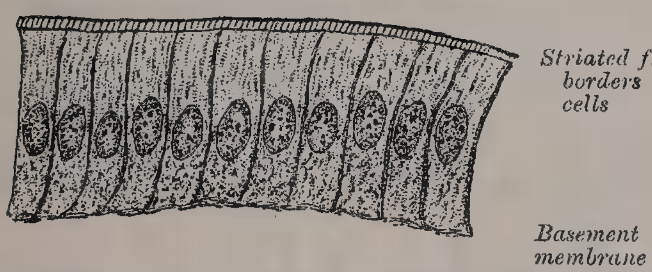


Fig. 9.—Goblet cells. (From Kirke's 'Physiology.')

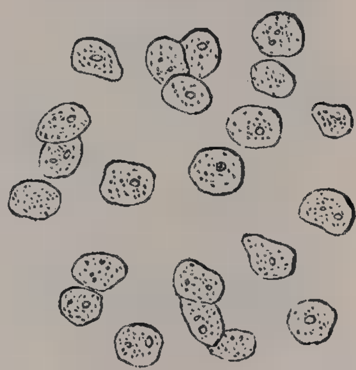
flattened from mutual pressure, and are set upright on the surface on which they are supported. Their protoplasm is always more or less reticulated, and fine longitudinal striæ may be seen in it. They possess a nucleus which is oval in shape and contains an intranuclear network.

This form of epithelium covers the mucous membrane of nearly the whole gastro-intestinal tract and the glands of that part, the greater part of the urethra, the vas deferens, the prostate, Cowper's glands, Bartholini's glands, and a portion of the uterine mucous membrane. In a modified form it also covers the ovary.

Goblet or *chalice* cells are a modification of the columnar cell. They appear to be formed by an alteration in shape of the columnar epithelium (ciliated or otherwise) consequent on the formation of granules which consist of a substance called *mucigen* in the interior of the cell. This distends the upper part of the cell, while the nucleus is pressed down towards its deep part, until the cell bursts and the mucus is discharged on to the surface of the mucous membrane (as shown in fig. 9), the cell then assuming the shape of an open cup or chalice.

Fig. 10.—Spheroidal epithelium. Magnified 250 times.

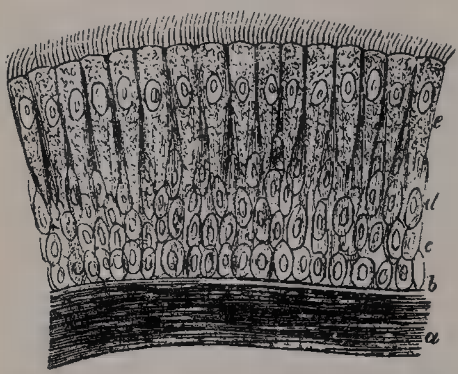


The *glandular* or *spheroidal* epithelium (fig. 10) is composed of spheroidal or polyhedral cells, but the cells may be columnar or cubical in shape in some situations. Like other forms of epithelial cells, the protoplasm is a fine reticulum, which gives to the cells the appearance of granulation. They are found in the terminal recesses of secreting glands, and the protoplasm of the cells usually contains the materials which the cells secrete.

Ciliated epithelium (fig. 11) may be of any of the preceding forms, but generally inclines to the columnar shape. It is distinguished by the presence of minute processes, which are direct prolongations of the cell-protoplasm, like hairs or eyelashes (cilia) standing up from the free surface. If the cells are examined

during life or immediately on removal from the living body (for which in the human subject the removal of a nasal polypus offers a convenient opportunity) in a weak solution of salt, the cilia will be seen in lashing motion; and if the cells are separate, they will often be seen to be moved about in the field by this motion.

FIG. 11.—Ciliated epithelium from the human trachea. Magnified 350 times.

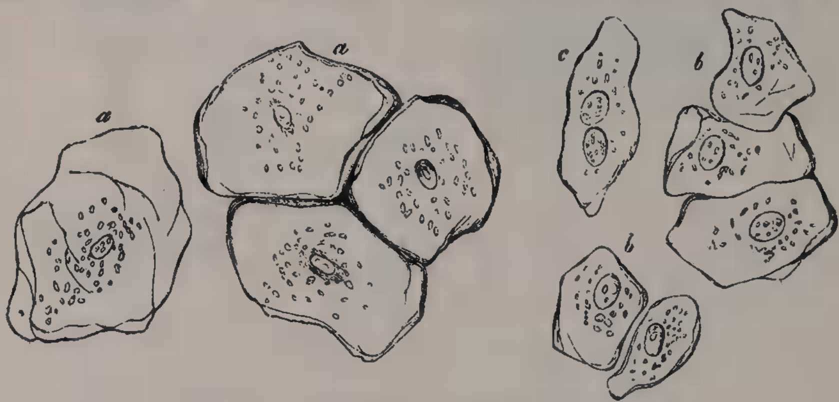


a. Innermost layers of the elastic longitudinal fibres. *b.* Homogeneous innermost layer of the mucous membrane. *c.* Deepest round cells. *d.* Middle elongated cells. *e.* Superficial cells, bearing cilia.

The situations in which ciliated epithelium is found in the human body are: the respiratory tract from the nose downwards to the smallest ramifications of the bronchial tubes, except a part of the pharynx and the surface of the vocal cords; the tympanum and Eustachian tube; the Fallopian tube and upper portion of the uterus; the vasa efferentia, coni vasculosi and the first part of the excretory duct of the testicle; and the ventricles of the brain and central canal of the spinal cord.

Stratified epithelium (fig. 13) consists of several layers of cells superimposed one on the top of the other and varying greatly in shape. The cells of the deepest layer are for the most part columnar

FIG. 12.—Epithelial cells from the oral cavity of man. Magnified 350 times.



a. Large. *b.* Middle sized. *c.* The same with two nuclei.

FIG. 13.—Stratified epithelium from the œsophagus.

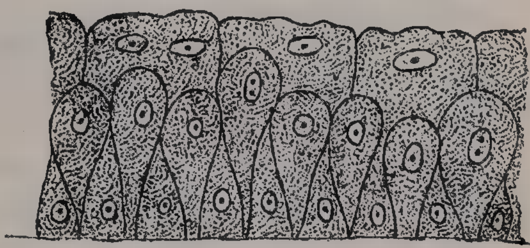
in shape, and as a rule form a single layer, placed vertically on the supporting membrane; above these are several layers of spheroidal cells, which as they approach the surface become more and more compressed, until the superficial layers are found to consist of

flattened scales (fig. 12), the margins of which overlap one another so as to present an imbricated appearance. They here undergo a chemical change from the conversion of their protoplasm into a horny substance (keratin).

Certain cells found in the deeper layers of stratified epithelium, and termed *prickle cells* (fig. 14), constitute a variety of squamous epithelium. These cells possess short, fine fibrils, which pass from their margins to those of neighbouring cells, serving to connect them together. They are not closely connected together by cement-substance, but are separated from each other by intercellular channels, across which these fine fibrils may be seen bridging, and this gives to the cell, when isolated, the appearance of being covered over with a number of short spines, in consequence of the fibrils being broken through. They were first described by Max Schultze and Virchow, and it was believed by them that the cells were dovetailed together. Subsequently this was shown not to be so by Martyn, who pointed out that the prickles were attached to each other by their apices; and recently Delépine has stated that he believes the prickles of prickle cells are parts of fibrils forming internuclear bundles between the nuclei of the cells of an epithelium in a state of active growth (see page 5, and fig. 2).

FIG. 15.—Transitional epithelium.



Transitional epithelium occurs in the ureters and urinary bladder. Here the cells of the most superficial layer are cubical, with depressions on their under surfaces, which fit on to the rounded ends of the cells of the second layer, which are pear-shaped, the apices touching the basement-membrane. Between their tapering points is a third variety of cells, filling in the intervals between them, and of smaller size than those of the other two layers (fig. 15).

CONNECTIVE TISSUES

The term **connective tissue** includes a number of tissues which possess this feature in common, viz. that they serve the general purpose in the animal economy of supporting and connecting the tissues of the body. These tissues may differ considerably from each other in appearance, but they present nevertheless many points of relationship, and are moreover developed from the same layer of the embryo, the mesoblast. They are divided into three great groups: (1) the connective tissues proper, (2) cartilage, and (3) bone. Blood, which has already been described, is, strictly speaking, a form of connective tissue, and is so dealt with by many histologists.

The Connective Tissues Proper

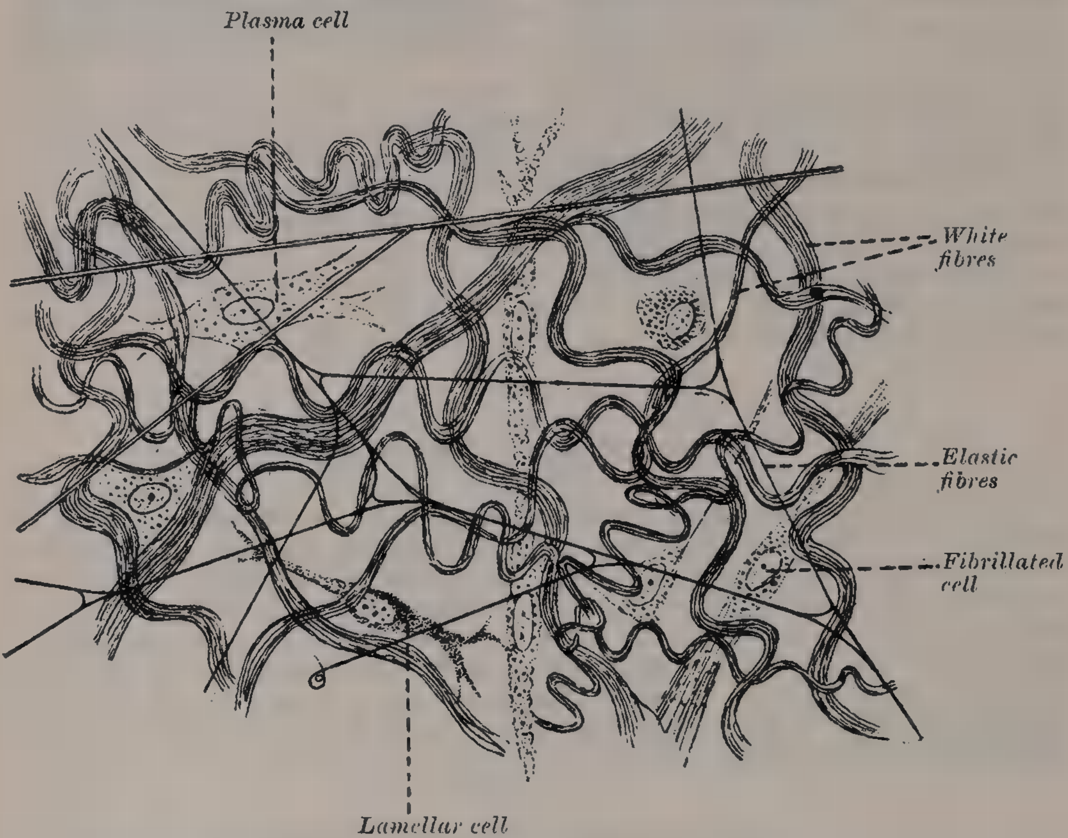
Several forms or varieties of connective tissue are recognised: (1) Areolar tissue. (2) White fibrous tissue. (3) Yellow elastic tissue. (4) Mucous tissue. (5) Retiform tissue. They are all composed of a homogeneous matrix, in which are embedded cells and fibres—the latter of two kinds, white and yellow or elastic. The distinction between the different forms of tissue depends upon the relative preponderance of one or other kind of fibre, of cells, or of matrix.

Areolar tissue (fig. 16) is so called because its meshes are easily distended, and thus separated into areolæ or spaces, which open freely into each other, and are consequently easily blown up with air, or permeated by fluid, when injected into any part of the tissue. Such spaces, however, do not exist in the natural condition of the body, but the whole tissue forms one unbroken membrane composed of a number of interlacing fibres, variously superimposed. Hence the term 'the cellular membrane' is in many parts of the body more appropriate than its more modern equivalent. The chief use of the areolar tissue is to bind parts together; while by the laxity of its fibres, and the permeability of its areolæ, it allows them to move on each other, and affords a ready exit for inflammatory and other effused fluids. It is one of the most extensively distributed of all the tissues.

It is found beneath the skin, in a continuous layer all over the body, connecting it to the subjacent parts. In the same way it is situated beneath the mucous and serous membranes. It is also found between muscles, vessels, and nerves, forming investing sheaths for them, and connecting them with surrounding structures. In addition to this, it is found in the interior of organs, binding together the various lobes and lobules of the compound glands, the various coats of the hollow viscera, and the fibres of muscles &c., and thus forms one of the most important connecting media of the various structures or organs of which the body is made up. In many parts the areolæ or interspaces of areolar tissue are occupied by fat-cells, constituting *adipose tissue,* which will presently be described.

Areolar tissue presents to the naked eye a flocculent appearance, somewhat like spun-silk. When stretched out, it is seen to consist of delicate soft elastic threads interlacing with each other in every direction, and forming a network of extreme delicacy. When examined under the microscope (fig. 16) it is found to be

FIG. 16.—Subcutaneous tissue from a young rabbit. Highly magnified. (Schäfer.)



composed of white fibres and yellow elastic fibres intercrossing in all directions, and united together by a homogeneous cement or ground substance, the *matrix,* showing cell-spaces wherein lie many cellular elements, the *connective tissue corpuscles*; these contain the protoplasm out of which the whole is developed and regenerated.

The *white fibres* are arranged in waving bands or bundles of minute transparent homogeneous filaments or fibrillæ. The bundles have a tendency to split up longitudinally or send off slips to join neighbouring bundles and receive others in return, but the individual fibres are unbranched and never join other fibres; the *yellow elastic fibres* have a well-defined outline and are considerably larger in size than the white fibrillæ. They vary much, being from the $\frac{1}{24000}$ to the $\frac{1}{4000}$ of an inch in diameter. The fibres form bold and wide curves, branch, and freely anastomose with each other. They are homogeneous in appearance, and tend to curl up, especially at their broken ends.

Connective tissue corpuscles.—The cells of areolar tissue are of three principal kinds: (1) Flattened lamellar cells, which may be either branched or unbranched. The branched lamellar cells are composed of clear cell substance, in which is

contained an oval nucleus. The processes of these cells unite so as to form an open network, as in the cornea. The unbranched cells are joined edge to edge like the cells of an epithelium. The 'tendon cells,' presently to be described, are an example of this variety. (2) Granule cells, which are ovoid or spheroidal in shape, and formed of a soft protoplasm, containing granules which are albuminous in character and stain deeply with eosin. (3) Plasma cells of Waldeyer, varying greatly in size and form, but always to be distinguished from the other two varieties by containing a largely vacuolated protoplasm. The vacuoles are filled with fluid, and the protoplasm between the spaces is clear, with occasionally a few scattered granules.

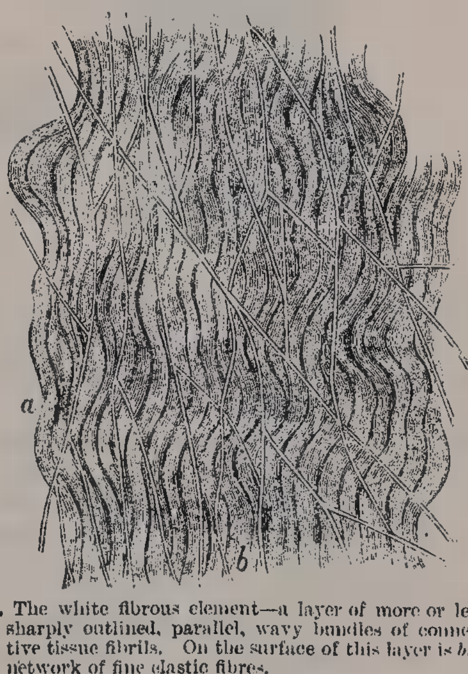
In addition to these three typical forms of connective tissue corpuscles, areolar tissue may be seen to possess *wandering cells,* i.e. leucocytes which have emigrated from the neighbouring vessels, and in some instances, as in the choroid coat of the eye, cells filled with granules of pigment (*pigment-cells*).

FIG. 17.—White fibrous tissue. High power.

The connective tissue corpuscles lie in spaces in the ground substance between the bundles of fibres, and these spaces may be brought into view by treating the tissue with nitrate of silver and exposing it to the light. This will colour the ground substance and leave the cell-spaces unstained.

White fibrous tissue (fig. 17) is a true connecting structure, and serves three purposes in the animal economy. In the form of ligaments it serves to bind bones together; in the form of tendons it serves to connect muscles to bones or other structures; and it forms an investing or protecting structure to various organs in the form of membranes. Examples of where it serves this latter office are to be found in the muscular fasciæ or sheaths, the periosteum, and perichondrium; the investments of the various glands (such as the tunica albuginea testis, the capsule of the kidney, &c.), the investing sheath of the nerves (epineurium), and of various organs, as the penis and the eye (sheath of the corpora cavernosa and corpus spongiosum and of the sclerotic). In white fibrous tissue, as its name implies, the white fibres predominate, the matrix being apparent only as a cement substance, the yellow elastic fibres comparatively few, while the tissue-cells are arranged in a special manner. It presents to the naked eye the appearance of silvery white glistening fibres, covered over with a quantity of loose flocculent tissue which binds the fibres together and carries the blood-vessels (fig. 18). It is not possessed of any elasticity, and only the very slightest extensibility; it is exceedingly strong, so that upon the application of any external violence the bone with which it is connected will fracture before the fibrous tissue will give way. In ligaments and tendons the bundles of fibres run parallel with each other; in membranes they intersect one another in different places. The cells found in white fibrous tissue are often called 'tendon-cells.' They are situated on the surface of groups of bundles and are quadrangular in shape, arranged in rows, in single file, each cell being separated from its neighbours by a narrow line of cement-substance. The nucleus is generally situated at one end of the cell, the nucleus of the adjoining

FIG. 18.—Connective tissue. (Klein and Noble Smith.)



a. The white fibrous element—a layer of more or less sharply outlined, parallel, wavy bundles of connective tissue fibrils. On the surface of this layer is *b*, a network of fine elastic fibres.

cell being in close proximity to it (fig. 19). Upon the addition of acetic acid to white fibrous tissue it swells up into a glassy-looking indistinguishable mass. When boiled in water it is converted almost completely into gelatin, the white fibres being composed of the albuminoid *collagen*, which is often regarded as the anhydride of gelatin.

Yellow elastic tissue.—In certain parts of the body a tissue is found which when viewed in mass is of a yellowish colour, and is possessed of great elasticity; so that it is capable of considerable extension, and when the extending force is withdrawn returns at once to its original condition. This is *yellow elastic tissue*, which may be regarded as a connective tissue in which the yellow elastic fibres have developed to the practical exclusion of the other elements. It is found in the ligamenta subflava, in the vocal cords, in the longitudinal coat of the trachea and bronchi, in the inner coats of the blood-vessels, especially the larger arteries, and to a very considerable extent in the thyro-hyoid, crico-thyroid, and stylo-hyoid ligaments. It is also found in the ligamentum nuchæ of the lower animals (fig. 20). In some parts where the fibres are broad and large and the network close, the tissue presents the appearance of a membrane, with gaps or perforations corresponding to the intervening spaces. This is to be found in the inner coat of the arteries, and to it the name of *fenestrated membrane* has been given by Henle. The yellow elastic fibres remain unaltered by acetic acid. Chemically they are composed of the albuminoid body, *elastin*.

FIG. 19.—Tendon of mouse's tail, stained with logwood, showing chains of cells between the tendon-bundles. (From Quain's 'Anatomy.' E. A. Schäfer.)

FIG. 20.—Yellow elastic tissue. High power.

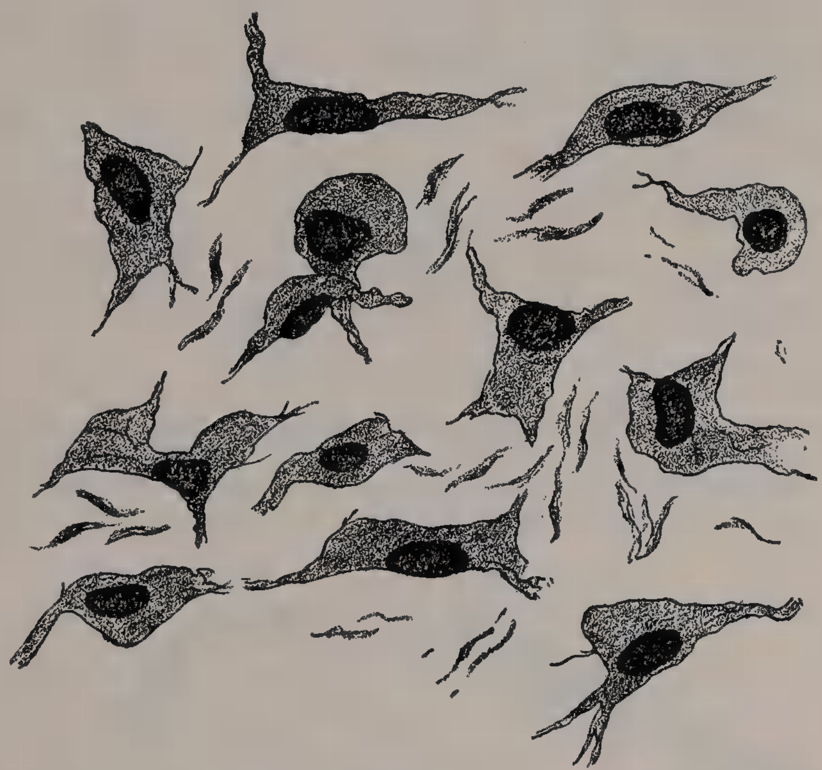
Vessels and Nerves of Connective Tissue.—The *blood-vessels* of connective tissue are very few—that is to say, there are few actually destined for the tissue itself, although many vessels may permeate one of its forms, the areolar tissue, carrying blood to other structures. In white fibrous tissue the blood-vessels usually run parallel to the longitudinal bundles and between them, sending transverse communicating branches across; in some forms, as in the periosteum and dura mater, they are fairly numerous. In yellow elastic tissue, the blood-vessels also run between the fibres, and do not penetrate them. *Lymphatic* vessels are very numerous in most forms of connective tissue, especially in the areolar tissue beneath the skin and the mucous and serous surfaces. They are also found in abundance in the sheaths of tendons, as well as in the tendons themselves.

Nerves are to be found in the white fibrous tissue, where they terminate in a special manner; but it is doubtful whether any nerves terminate in areolar tissue; at all events, they have not yet been demonstrated, and the tissue is possessed of very little sensibility.

Development of Connective Tissue.—Connective tissue is developed from embryonic connective-tissue cells derived from the mesoblast. These cells, at first rounded, become fusiform and branched, and ultimately connective-tissue corpuscles. A mucinous intercellular substance or matrix, partly derived from the cells themselves and partly from the lymph exuded by the neighbouring blood-vessels, gradually separates the cells. In the matrix the fibres are deposited, probably under the influence of the cells, but not by any transformation of the cell protoplasm. In the case of yellow elastic fibres, rows of granules of elastin are first laid down; these eventually fuse into the fully developed fibre.

Mucous tissue exists chiefly in the 'jelly of Wharton,' which forms the bulk of the umbilical cord, but is also found in other situations in the fœtus, chiefly as a stage in the development of connective tissue. It consists of a matrix, largely made up of mucin, in which are nucleated cells with branching

FIG. 21.—Mucous tissue from the umbilical cord of the human fœtus (four months).



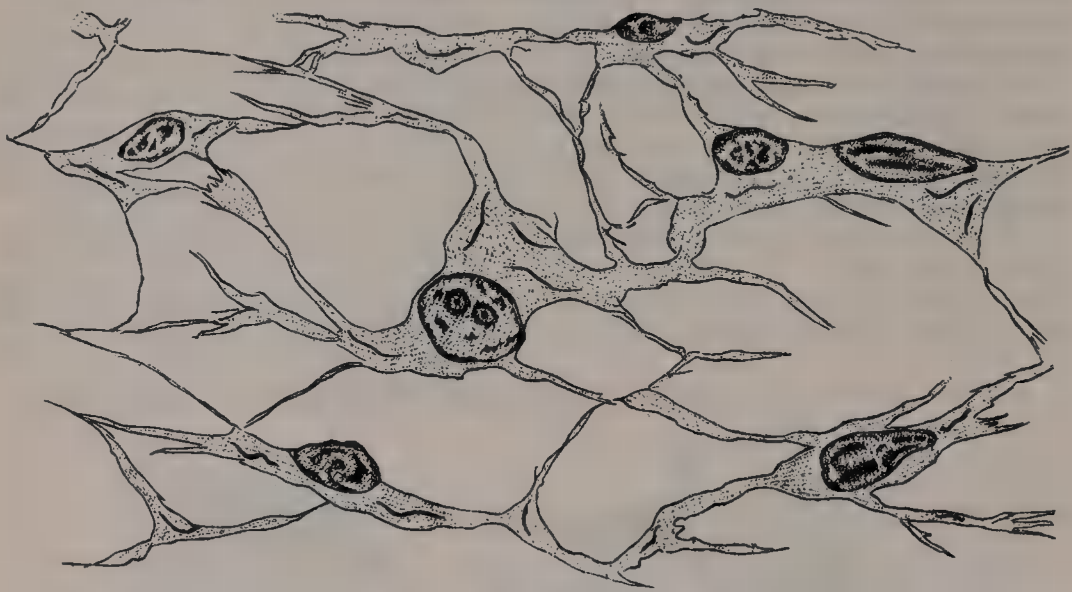
and anastomosing processes (fig. 21). Few fibres are seen in typical mucous tissue, though, at birth, the umbilical cord shows considerable development of fibres. In the adult the vitreous humour of the eye is a persistent form of mucous tissue, in which there are no fibres, and from which the cells have disappeared, leaving only the mucinous ground substance.

Retiform or **reticular** connective tissue (fig. 22) is found extensively in many parts of the body, constituting the framework of some organs and entering into the construction of many mucous membranes. It is a variety of connective tissue, in which the intercellular or ground substance has, in a great measure, disappeared, and has been replaced by fluid. It is apparently composed almost entirely of extremely fine bundles of white fibrous tissue, forming an intricate network, and chemically it yields gelatin. The fibres are covered and concealed in places by flattened branched connective-tissue cells. In many situations the interstices of the network are filled with rounded lymph-corpuscles, and the tissue is then termed **lymphoid** or **adenoid tissue** (see fig. 78).

Basement membranes, formerly described as homogeneous membranes, are really a form of connective tissue. They constitute the supporting membrane, or *membrana propria,* on which is placed the epithelium of mucous membranes or

secreting glands, and are also found in other situations. By means of staining with nitrate of silver they may be shown to consist of flattened cells in close apposition, and joined together by their edges, thus forming an example of an epithelioid arrangement of connective-tissue cells. In some situations the cells,

FIG. 22.—Retiform connective tissue, from a lymphatic gland.

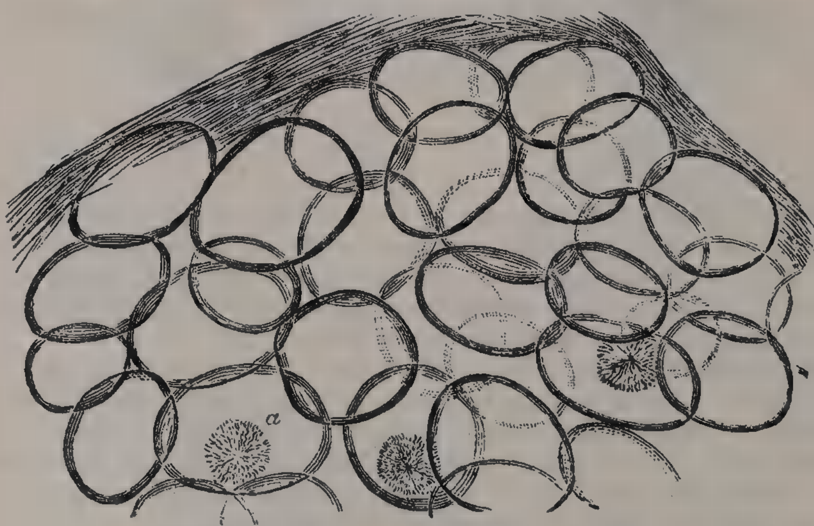


instead of adhering by their edges, give off branching processes, which join with similar processes of other cells and so form a network, rather than a continuous membrane. In other instances basement membranes are composed of elastic tissue, as in the cornea, or, again, in other cases, of condensed ground substance.

ADIPOSE TISSUE

In almost all parts of the body the ordinary areolar tissue contains a variable quantity of fat. The principal situations where it is not found are the subcutaneous tissue of the eyelids, the penis and scrotum, the nymphæ, within the cavity of the cranium, and in the lungs, except near their roots. Nevertheless its

FIG. 23.—Adipose tissue. High power.



a. Starlike appearance, from crystallisation of fatty acids.

distribution is not uniform; in some parts it is collected in great abundance, as in the subcutaneous tissue, especially of the abdomen; around the kidneys; on the surface of the heart between the furrows, and in some other situations. Lastly, fat enters largely into the formation of the marrow of bones. A distinction must be made between fat and adipose tissue; the latter being a distinct tissue, the

former an oily matter, which in addition to forming adipose tissue is also widely present in the body, as in the fat of the brain and liver, and in the blood, chyle, &c.

Adipose tissue consists of small vesicles, *fat-cells*, lodged in the meshes of areolar tissue. The fat-cells (fig. 23) vary in size, but are of about the average diameter of $\frac{1}{500}$ of an inch. They are formed of an exceedingly delicate protoplasmic membrane, filled with fatty matter, which is liquid during life, but becomes solidified after death. They are round or spherical where they have not been subjected to pressure; otherwise they assume a more or less angular outline. A nucleus is always present and can be easily demonstrated by staining with hæmatoxylin; in the natural condition it is so compressed by the contained oily matter as to be scarcely recognisable. These fat-cells are contained in clusters in the areolæ of fine connective tissue, and are held together mainly by a network of capillary blood-vessels, which are distributed to them.

Fig. 24.—Development of fat. (Klein and Noble Smith.)

a. Minute artery. *v.* Minute vein. *c.* Capillary blood-vessels in the course of formation; they are not yet completely hollowed out, there being still left in them protoplasmic septa. *d.* The ground substance, containing numerous nucleated cells, some of which are more distinctly branched and flattened than others, and appear therefore more spindle-shaped.

Chemically the oily material in the cells is composed of the fats, olein, palmitin, and stearin, which are glycerin compounds with fatty acids. Sometimes fat crystals form in the cells after death (fig. 23, *a*). By boiling the tissue in ether or strong alcohol, the fat may be extracted from the vesicle, which is then seen empty and shrunken.

Fat is said to be first detected in the human embryo about the fourteenth week. The fat-cells are formed by the transformation of connective-tissue corpuscles, in which small droplets of oil are formed; these coalesce to produce a larger drop, and this increases until it distends the corpuscle, the remaining protoplasm and the nucleus being displaced towards the periphery of the cell (fig. 24).

Pigment

In various parts of the body **pigment** is found; most frequently in epithelial cells and in the cells of connective tissue. Pigmented *epithelial cells* are found in the external layer of the retina and on the posterior surface of the iris. Pigment is likewise found in the epithelial cells of the deeper layers of the cuticle in some parts of the body—such as the areola of the nipple and in coloured patches of skin and especially in the skin of the coloured races, and in hair. It is also found in the epithelial cells of the olfactory region, and of the membranous labyrinth of the ear.

Fig. 25.—Pigment-cells from the choroid coat of the eyeball.

In the *connective-tissue cells* pigment is frequently met with in the lower vertebrates. In man it is found in the choroid coat of the eye (fig. 25), and in the iris of all but the light blue eyes and the albino. It is also occasionally met with in the cells of retiform tissue and in the pia mater of the upper part of the spinal cord. These cells are characterised by their large size and branched processes, which, as well as the body of the cells, are filled with

granules. The pigment consists of dark brown or black granules of very small size closely packed together within the cells, but not invading the nucleus. Occasionally the pigment is yellow, and when occurring in the cells of the cuticle constitutes 'freckles.'

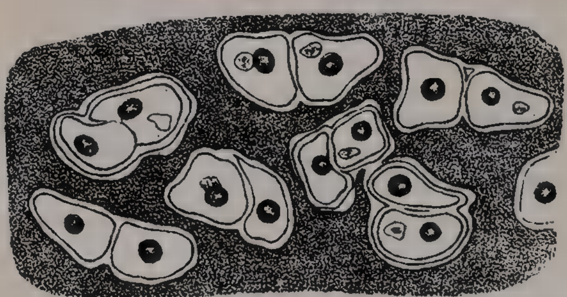
Cartilage

Cartilage is a non-vascular structure which is found in various parts of the body—in adult life chiefly in the joints, in the parietes of the thorax, and in various tubes, such as the air-passages, nostrils, and ears, which are to be kept permanently open. In the fœtus, at an early period, the greater part of the skeleton is cartilaginous. As this cartilage is afterwards replaced by bone, it is called *temporary*, in contradistinction to that which remains unossified during the whole of life, and which is called *permanent*.

Cartilage is divided, according to its minute structure, into hyaline cartilage, white fibro-cartilage, and yellow or elastic fibro-cartilage. Besides these varieties met with in the adult human subject, there is a variety called *cellular cartilage*, which consists entirely, or almost entirely, of cells, united in some cases by a network of very fine fibres, in other cases apparently destitute of any intercellular substance. This is found in the external ear of rats, mice, and some other animals, and is present in the chorda dorsalis of the human embryo, but is not found in any other human structure. The various cartilages in the body are also classified, according to their function and position, into articular, interarticular, costal, and membraniform.

Hyaline cartilage, which may be taken as the type of this tissue, consists of a gristly mass of a firm consistence, but of considerable elasticity and of a pearly-bluish colour. Except where it coats the articular ends of bones, it is covered externally by a fibrous membrane, the *perichondrium*, from the vessels of which it imbibes its nutritive fluids, being itself destitute of blood-vessels. It contains no nerves. Its intimate structure is very simple. If a thin slice is examined under the microscope, it will be found to consist of cells of a rounded or bluntly angular form, lying in groups of two or more in a granular or almost homogeneous matrix (fig. 26). The cells, when arranged in groups of two or more, have generally a straight outline where they are in contact with each other, and in the rest of their circumference are rounded. The cell-contents consist of clear translucent protoplasm, in which fine interlacing filaments and minute granules may sometimes be seen; embedded in this are one or two round nuclei, having the usual intranuclear network. The cells are embedded in cavities in the matrix, called *cartilage lacunæ*; around these the matrix is arranged in concentric lines, as if it had been formed in successive portions around the cartilage cells. This constitutes the so-called *capsule* of the space. Each lacuna is generally occupied by a single cell, but during the division of the cells it may contain two, four, or eight cartilage-cells. By exposure to the action of an electric shock the cell assumes a jagged outline and shrinks away from the interior of the capsule.

Fig. 26.—Human cartilage-cells from the cricoid cartilage. × 350.

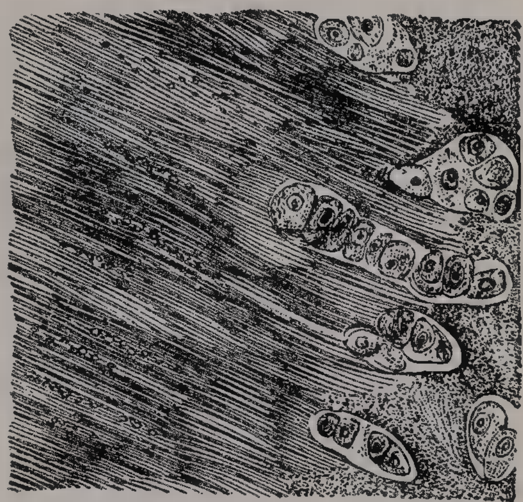


The matrix is transparent and apparently without structure, or else presents a dimly granular appearance, like ground glass. Some observers have shown that the matrix of hyaline cartilage, and especially the articular variety, after prolonged maceration, can be broken up into fine fibrils. These fibrils are probably of the same nature, chemically, as the white fibres of connective tissue. It is believed by some histologists that the matrix is permeated by a number of fine channels, which connect the lacunæ with each other, and that these canals communicate with the lymphatics of the perichondrium, and thus the structure is permeated with a current of nutrient fluid. This, however, is somewhat doubtful.

Articular cartilage, costal cartilage, and temporary cartilage are all of the hyaline variety. They present minute differences in the size and shape of their cells and in the arrangement of their matrix. In **articular cartilage**, which shows no tendency to ossification, the matrix is finely granular under a high power; the cells and nuclei are small, and are disposed parallel to the surface in the superficial part, while nearer to the bone they become vertical. Articular cartilages have a tendency to split in a vertical direction; in disease this tendency becomes very manifest. Articular cartilage is not covered by perichondrium, on its free surface, where it is exposed to friction, though a layer of connective tissue can be traced in the adult over a small part of its circumference continuous with that of the synovial membrane, and here the cartilage-cells are more or less branched and pass insensibly into the branched connective-tissue corpuscles of the synovial membrane.

Articular cartilage forms a thin incrustation upon the joint-surfaces of the bones, and its elasticity enables it to break the force of any concussion, while its smoothness affords ease and freedom of movement. It varies in thickness according to the shape of the articular surface on which it lies; where this is convex the cartilage is thickest at the centre, where the greatest pressure is received; and the reverse is the case on the concave articular surfaces. Articular cartilage appears to derive its nutriment partly from the vessels of the neighbouring synovial membrane, partly from those of the bone upon which it is implanted. Toynbee has shown that the minute vessels of the cancellous tissue as they approach the articular lamella dilate and form arches, and then return into the substance of the bone.

Fig. 27.—Costal cartilage from a man seventy-six years of age, showing the development of fibrous structure in the matrix. In several portions of the specimen two or three generations of cells are seen enclosed in a parent cell-wall. High power.



In **costal cartilage** the cells and nuclei are large, and the matrix has a tendency to fibrous striation, especially in old age (fig. 27). In the thickest parts of the costal cartilages a few large vascular channels may be detected. This appears, at first sight, to be an exception to the statement that cartilage is a non-vascular tissue, but is not so really, for the vessels give no branches to the cartilage substance itself, and the channels may rather be looked upon as involutions of the perichondrium. The ensiform cartilage may be regarded as one of the costal cartilages, and the cartilages of the nose and of the larynx and trachea (except the epiglottis and cornicula laryngis, which are composed of elastic fibro-cartilage) resemble them in microscopical characters.

Temporary cartilage and the process of its ossification will be described with bone.

The hyaline cartilages, especially in adult and advanced life, are prone to calcify—that is to say, to have their matrix permeated by the salts of lime without any appearance of true bone. The process of calcification occurs also and still more frequently, according to Rollett, in such cartilages as those of the trachea and in the costal cartilages, which are prone afterwards to conversion into true bone.

White fibro-cartilage consists of a mixture of white fibrous tissue and cartilaginous tissue in various proportions; it is to the first of these two constituents that its flexibility and toughness are chiefly owing, and to the latter its elasticity. When examined under the microscope it is found to be made up of fibrous connective tissue arranged in bundles, with cartilage-cells between the bundles; these to a certain extent resemble tendon-cells, but may be distinguished from them by being surrounded by a concentrically striated area of cartilage matrix and by their being less flattened (fig. 28). The fibro-cartilages admit of arrangement into four groups—interarticular, connecting, circumferential, and stratiform.

1. The *interarticular fibro-cartilages* (*menisci*) are flattened fibro cartilaginous plates, of a round, oval, triangular, or sickle-like form, interposed between the articular cartilages of certain joints. They are free on both surfaces, thinner towards their centre than at their circumference, and held in position by the attachment of their margins and extremities to the surrounding ligaments. The synovial membrane of the joint is prolonged over them a short distance from their attached margins. They are found in the temporo-mandibular, sterno-clavicular, acromio-clavicular, wrist and knee joints. These cartilages are usually found in those joints which are most exposed to violent concussion and subject to frequent movement. Their use is—to maintain the apposition of the opposed surfaces in their various motions; to increase the depth of the articular surfaces and give ease to the gliding movement; to moderate the effects of great pressure and deaden the intensity of the shocks to which the parts may be subjected. Humphry has pointed out that these interarticular fibro-cartilages serve an important purpose in increasing the variety of movements in a joint. Thus, in the knee-joint, there are two kinds of motion, viz. angular movement and rotation, although it is a hinge joint, in which, as a rule, only one variety of motion is permitted; the former movement takes place between the condyles of the femur and the interarticular cartilage, the latter between the cartilage and the head of the tibia. So, also, in the temporo-mandibular joint, the upward and downward movement of opening and shutting the mouth takes place between the fibro-cartilage and the jaw-bone, the grinding movement between the glenoid cavity and the fibro-cartilage, the latter moving with the jaw-bone.

Fig. 28.—White fibro-cartilage from an intervertebral disc.

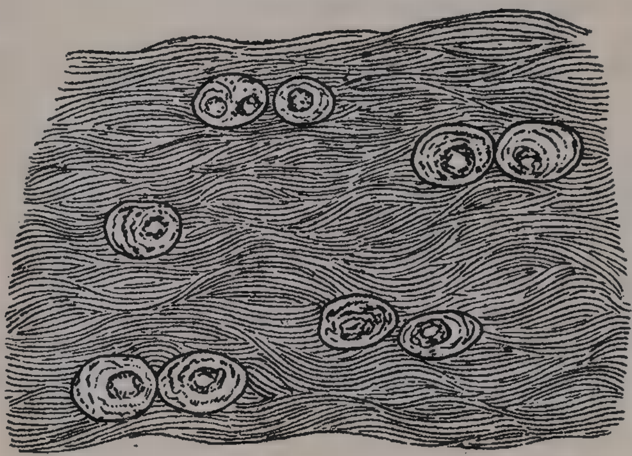


Fig. 29.—Yellow cartilage, ear of horse. High power.

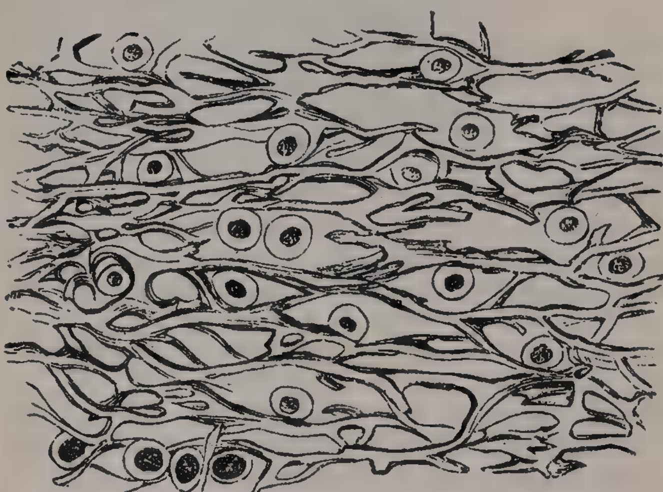


2. The *connecting fibro-cartilages* are interposed between the bony surfaces of those joints which admit of only slight mobility, as between the bodies of the vertebræ and between the pubic bones. They form discs, which adhere closely to both of the opposed surfaces, and are composed of concentric rings of fibrous tissue, with cartilaginous laminæ interposed, the former tissue predominating towards the circumference, the latter towards the centre.

3. The *circumferential fibro-cartilages* consist of a rim of fibro-cartilage, which surrounds the margin of some of the articular cavities, as the cotyloid cavity of the hip, and the glenoid cavity of the shoulder; they serve to deepen the articular surface, and to protect its edges.

4. The *stratiform fibro-cartilages* are those which form a thin coating to osseous grooves through which the tendons of certain muscles glide. Small masses of fibro-cartilages are also developed in the tendons of some muscles, where they glide over bones, as in the tendons of the Peroneus longus and the Tibialis posticus.

Yellow or **elastic fibro-cartilage** is found in the human body in the auricle of the external ear, the Eustachian tubes, the cornicula laryngis, and the epiglottis. It consists of cartilage-cells and a matrix, the latter being pervaded in every direction, except immediately around each cell, where there is a variable amount of non-fibrillated hyaline, intercellular substance, by a network of yellow elastic fibres, branching and anastomosing in all directions (fig. 29). The fibres resemble those of yellow elastic tissue, both in appearance and in being unaffected by acetic acid; and according to Rollett their continuity with the elastic fibres of the neighbouring tissue admits of being demonstrated.

The distinguishing feature of cartilage as to its chemical composition, is that it yields on boiling a substance called *chondrin*, very similar to gelatin, but differing from it in several of its reactions. It is now believed that chondrin is not a simple body, but a mixture of gelatin with mucinoid substances, chief among which, perhaps, is a compound termed *chondro-mucoid*.

BONE

Structure and Physical Properties of Bone.—Bone is one of the hardest structures of the animal body; it possesses also a certain degree of toughness and elasticity. Its colour, in a fresh state, is pinkish white externally, and deep red within. On examining a section of any bone, it is seen to be composed of two kinds of tissue, one of which is dense in texture, like ivory, and is termed *compact tissue*; the other consists of slender fibres and lamellæ, which join to form a reticular structure; this, from its resemblance to lattice-work, is called *cancellous tissue*. The compact tissue is always placed on the exterior of the bone; the cancellous is always internal. The relative quantity of these two kinds of tissue varies in different bones, and in different parts of the same bone, as strength or lightness is requisite. Close examination of the compact tissue shows it to be extremely porous, so that the difference in structure between it and the cancellous tissue depends merely upon the different amount of solid matter, and the size and number of spaces in each; the cavities being small in the compact tissue and the solid matter between them abundant, while in the cancellous tissue the spaces are large and the solid matter is in smaller quantity.

Bone during life is permeated by vessels and is enclosed, except where it is coated with articular cartilage, in a fibrous membrane, the *periosteum*, by means of which many of these vessels reach the hard tissue. If the periosteum is stripped from the surface of the living bone small bleeding points are seen, which mark the entrance of the periosteal vessels; and on section during life, every part of the bone will be seen to exude blood from the minute vessels which ramify in it. The interior of the bones of the limbs presents a cylindrical cavity filled with marrow and lined by a highly vascular areolar structure, called the *medullary membrane* or *internal periosteum*, which, however, is rather the areolar envelope of the cells of the marrow, than a definite membrane.

The **periosteum** adheres to the surface of the bones in nearly every part, excepting at their cartilaginous extremities. When strong tendons or ligaments are attached to the bone, the periosteum is incorporated with them. It consists of two layers closely united together, the outer one formed chiefly of connective tissue, containing occasionally a few fat-cells; the inner one, of elastic fibres of the finer kind, forming dense membranous networks, which can be again separated into several layers. In young bones the periosteum is thick and very vascular, and is intimately connected at either end of the bone with the epiphysial cartilage, but less closely with the shaft, from which it is separated by a layer of soft tissue, containing a number of granular corpuscles or 'osteoblasts,' in which ossification proceeds on the exterior of the young bone. Later in life the periosteum is thinner, less vascular, and the osteoblasts have become converted into an epithelioid layer, separated from the rest of the periosteum in many places by cleft-like spaces, which are supposed to serve for the transmission of lymph. The periosteum serves as a nidus for the ramification of the vessels previous to their distribution in the bone; hence the liability of bone to exfoliation or necrosis, when denuded of this membrane by injury or disease. Fine nerves and lymphatics, which generally accompany the arteries, may also be demonstrated in the periosteum.

The **marrow** not only fills up the cylindrical cavity in the shafts of the long

bones, but also occupies the spaces of the cancellous tissue and extends into the larger bony canals (Haversian canals) which contain the blood-vessels. It differs in composition in different bones. In the shafts of adult long bones the marrow is of a *yellow* colour, and contains, in 100 parts, 96 of fat, 1 of areolar tissue and vessels, and 3 of fluid, with extractive matter, and consists of a basis of connective tissue, supporting numerous blood-vessels and cells, most of which are fat-cells, but some are 'marrow-cells,' such as occur in the red marrow, to be immediately described. In the flat and short bones, in the articular ends of the long bones, in the bodies of the vertebræ, in the cranial diploë, and in the sternum and ribs, it is of a *red* colour, and contains, in 100 parts, 75 of water and 25 of solid matter, consisting of cell-globulin, nucleo-proteid, extractives, salts, and only a small proportion of fat. The red marrow consists of a small quantity of connective tissue, blood-vessels, and numerous cells (fig. 30), some few of which are fat-cells, but the great majority are roundish nucleated cells, the true 'marrow-cells' of Kölliker. These marrow-cells proper, or *myelocytes*, resemble in appearance lymphoid corpuscles, and like them are amœboid; they generally have a hyaline protoplasm, though some show granules either oxyphile or basophile in reaction.

FIG. 30.—Human bone-marrow.

A number of *eosinophile* cells are also present. Among the marrow-cells may be seen smaller cells, which possess a slightly pinkish hue; these are the *erythroblasts* or *normoblasts*, from which, as we have seen, the red corpuscles of the adult are derived, and which may be regarded as descendants of the nucleated coloured corpuscles of the embryo. *Giant-cells* (*myeloplaxes*, *osteoclasts*), large, multi-nucleated, protoplasmic masses, are also to be found in both sorts of adult marrow, but more particularly in red marrow. They were believed by Kölliker to be concerned in the absorption of bone-matrix, and hence the name which he gave to them—*osteoclasts*. They excavate small shallow pits or cavities in the bone, which are named *Howship's lacunæ*, in which they are found lying.

Vessels of Bone.—The blood-vessels of bone are very numerous. Those of the compact tissue are derived from a close and dense network of vessels ramifying in the periosteum. From this membrane, vessels pass into the minute orifices in the compact tissue, and run through the canals which traverse its substance. The cancellous tissue is supplied in a similar way, but by less numerous and larger vessels, which, perforating the outer compact tissue, are distributed to the cavities of the spongy portion of the bone. In the long bones, numerous apertures may be seen at the ends near the articular surfaces, some

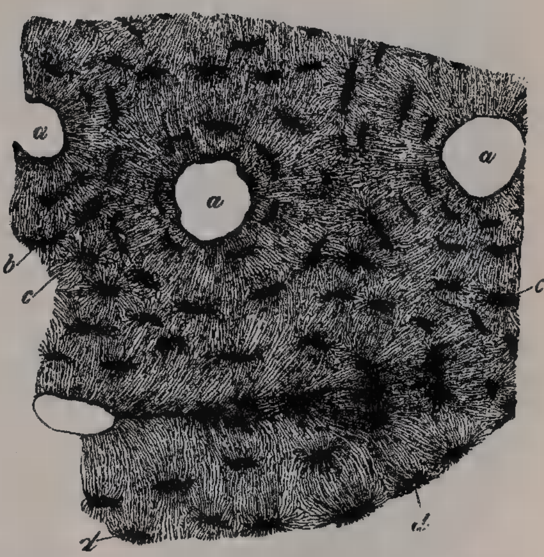
of which give passage to the arteries of the larger set of vessels referred to; but the most numerous and largest apertures are for the veins of the cancellous tissue, which run separately from the arteries. The medullary canal in the shafts of the long bones is supplied by one large artery (or sometimes more), which enters the bone at the nutrient foramen (situated in most cases near the centre of the shaft), and perforates obliquely the compact structure. The *medullary* or *nutrient* artery, usually accompanied by one or two veins, sends branches upwards and downwards, to supply the medullary membrane, which lines the central cavity and the adjoining canals. The ramifications of this vessel anastomose with the arteries both of the cancellous and compact tissues. In most of the flat, and in many of the short spongy bones, one or more large apertures are observed, which transmit, to the central parts of the bone, vessels corresponding to the medullary arteries and veins. The veins emerge from the long bones in three places (Kölliker)—(1) by one or two large veins, which accompany the artery; (2) by numerous large and small veins at the articular extremities; (3) by many small veins which arise in the compact substance. In the flat cranial bones the veins are large, very numerous, and run in tortuous canals in the diploic tissue, the sides of the canals being formed by a thin lamella of bone, perforated here and there for the passage of branches from the adjacent cancelli. The same condition is also found in all cancellous tissue, the veins being enclosed and supported by osseous structure, and having exceedingly thin coats. When the bony structure is divided, the vessels remain patulous, and do not contract in the canals in which they are contained. Hence the occurrence of purulent absorption after amputation, in those cases where the stump becomes inflamed, and the cancellous tissue is infiltrated and bathed in pus.

Lymphatic vessels, in addition to those found in the periosteum, have been traced by Cruikshank into the substance of bone, and Klein describes them as running in the Haversian canals.

Nerves are distributed freely to the periosteum, and accompany the nutrient arteries into the interior of the bone. They are said by Kölliker to be most numerous in the articular extremities of the long bones, in the vertebræ, and the larger flat bones.

Minute Anatomy.—The intimate structure of bone, which in all essential particulars is identical in the compact and in the cancellous tissue, is most easily studied in a transverse section from the compact wall of one of the long bones after maceration, such as is shown in fig. 31.

Fig. 31.—From a transverse section of the diaphysis of the humerus. Magnified 350 times.

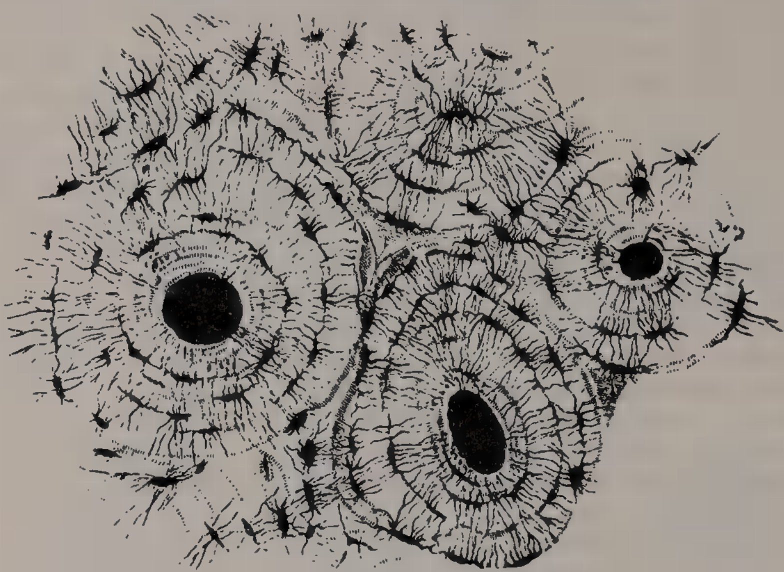


a. Haversian canals. *b.* Lacunæ, with their canaliculi in the lamellæ of these canals. *c.* Lacunæ, of the interstitial lamellæ. *d.* Others at the surface of the Haversian systems, with canaliculi given off from one side.

If this is examined with a rather low power the bone will be seen to be mapped out into a number of circular districts: each one of which consists of a central hole surrounded by a number of concentric rings. These districts are termed *Haversian systems*; the central hole is an *Haversian canal,* and the rings are layers of bone-tissue arranged concentrically around the central canal, and termed *lamellæ.* Moreover, on closer examination, it will be found that between these lamellæ, and therefore also arranged concentrically around the central canal, are a number of little dark specks, the *lacunæ,* and that these lacunæ are connected with each other and with the central Haversian canal by a number of fine dark lines, which radiate like the spokes of a wheel and are called *canaliculi.* All these structures—the concentric lamellæ, the lacunæ, and the canaliculi—may be seen in any single Haversian system, forming a circular district round a central, Haversian, canal. Between these circular systems, filling in the irregular

intervals which are left between them, are other lamellæ, with their lacunæ and canaliculi, running in various directions, but more or less curved (fig. 32). These are termed *interstitial* lamellæ. Again, other lamellæ, for the most part found

FIG. 32.—Transverse section of compact tissue of bone. Magnified about 150 diameters. (Sharpey.)



on the surface of the bone, are arranged concentrically to the circumference of bone, constituting, as it were, a single Haversian system of the whole bone, of which the medullary cavity would represent the Haversian canal. These latter lamellæ are termed *circumferential*, or by some authors *primary* or *fundamental* lamellæ, to distinguish them from those laid down around the axis of the Haversian canals, which are then termed *secondary* or *special* lamellæ.

FIG. 33.—Section parallel to the surface from the shaft of the femur. Magnified 100 times.

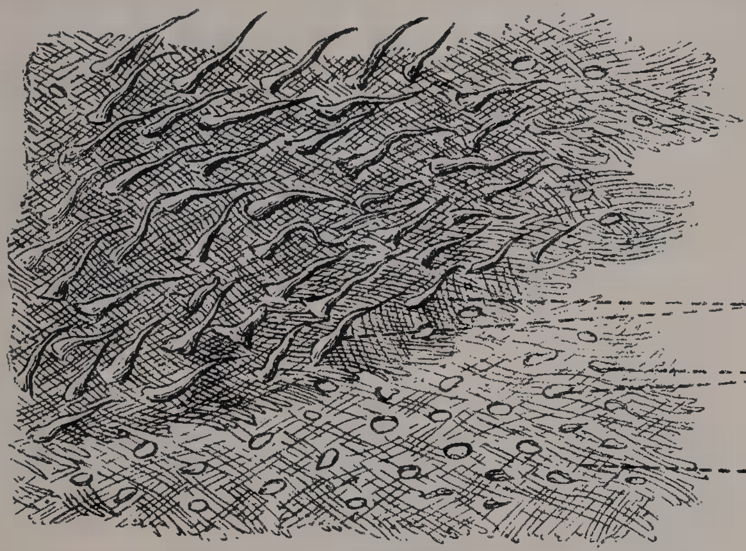
a. Haversian canals. *b.* Lacunæ seen from the side. *c.* Others seen from the surface in lamellæ which are cut horizontally.

The *Haversian canals*, seen as round holes in a transverse section of bone at or about the centre of each Haversian system, may be demonstrated to be true canals, if a longitudinal section is made, as in fig. 33. It will then be seen that these round holes are tubes cut across, which run parallel with the longitudinal axis of the bone for a short distance, and then branch and communicate. They vary considerably in size, some being as large as $\frac{1}{200}$ of an inch in diameter; the average size being, however, about $\frac{1}{500}$ of an inch. Near the medullary cavity the canals are larger than those near the surface of the bone. Each canal contains one or two blood-vessels, with a small quantity of delicate connective tissue and some nerve filaments. In the larger ones there are also lymphatic spaces, and branched cells, the processes of which communicate, through the canaliculi, with the branched processes of certain bone cells in the substance of the bone. Those canals near the surface of the bone open upon it by minute orifices, and those near the medullary cavity open in the same way into this space, so that the whole of the bone is permeated by a system of

blood-vessels running through the bony canals in the centre of the Haversian systems.

The *lamellæ* are thin plates of bone-tissue encircling the central canal, and may be compared, for the sake of illustration, to a number of sheets of paper pasted one over another around a central hollow cylinder. After macerating a piece of bone in dilute mineral acid, these lamellæ may be stripped off in a longitudinal direction as thin films. If one of these is examined with a high

Fig. 34.—Lamellæ torn from a decalcified human parietal bone to show the perforating fibres of Sharpey. (Copied from a drawing by Allen Thomson.)



power under the microscope it will be found to be composed of a finely reticular structure, presenting the appearance of lattice-work made up of very slender, transparent fibres, decussating obliquely, and coalescing at the points of intersection so as to form an exceedingly delicate network. These fibres are composed of fine fibrils, identical with those of white connective tissue. The intercellular matrix between the fibres has been replaced by calcareous deposit which the acid dissolves. In many places the various lamellæ may be seen to be held together by tapering fibres, which run obliquely through them, pinning or bolting them together. These fibres were first described by Sharpey, and were named by him *perforating fibres* (fig. 34).

The *lacunæ* are situated between the lamellæ, and consist of a number of oblong spaces. In an ordinary microscopic section, viewed by transmitted light, they appear as dark, oblong, opaque spots, and were formerly believed to be solid cells. Subsequently, when it was seen that the Haversian canals were channels which lodge the vessels of the part, and the canaliculi minute tubes by which the plasma of the blood circulates through the tissue, the theory was formulated that the lacunæ were hollow spaces filled during life with the same fluid, and only lined (if lined at all) by a delicate membrane. But this view was eventually proved to be erroneous, for examination of the structure of bone, when recent, led Virchow to believe that the lacunæ are occupied during life by a branched cell, termed a bone-cell or bone-corpuscle, the processes from which pass down the canaliculi—a view which is now universally accepted (fig. 35). It is by means of these cells that the fluids necessary for nutrition are brought into contact with the ultimate tissue of bone.

Fig. 35.—Nucleated bone-cells and their processes, contained in the bone-lacunæ and their canaliculi respectively. From a section through the vertebra of an adult mouse. (Klein and Noble Smith.)

The *canaliculi* are exceedingly minute channels, which pass *across* the lamellæ and connect the lacunæ with neighbouring lacunæ and also with the Haversian canal. From this central canal a number of canaliculi are given off, which radiate from it, and open into the first set of lacunæ arranged around the Haversian canal, between the first and second lamellæ. From these lacunæ a second set of canaliculi are given off, which pass outwards to the next series of lacunæ, and so on until they reach the periphery of the Haversian system; here the canaliculi given off from the last series of lacunæ do not communicate with the lacunæ of neighbouring Haversian systems, but after passing outwards for a short distance form loops and return to their own lacuna. Thus every part of an Haversian system is supplied with nutrient fluids derived from the vessels in the Haversian canal and traversing the canaliculi and lacunæ.

The *bone-cells* are contained in the lacunæ, which, however, they do not completely fill. They are flattened nucleated cells, which Virchow has shown are homologous with those of connective tissue. The cells are branched, and the branches, especially in young bones, pass into the canaliculi from the lacunæ.

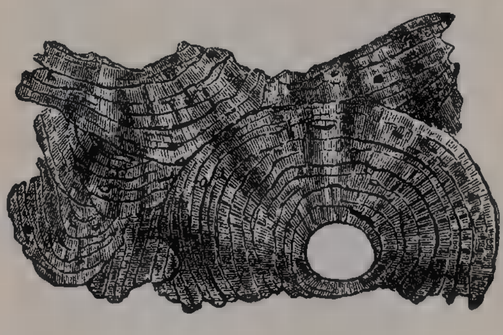
If a longitudinal section is examined, as in fig. 33, the structure is seen to be the same. The appearance of concentric rings is replaced by that of lamellæ or rows of lacunæ, parallel to the course of the Haversian canals, and these canals appear like half-tubes instead of circular spaces. The tubes are seen to branch and communicate, so that each separate Haversian canal runs only a short distance. In other respects the structure has much the same appearance as in transverse sections.

In sections of thin plates of bone (as in the walls of the cells which form the cancellous tissue) the Haversian canals are absent, and the canaliculi open into the spaces of the cancellous tissue (medullary spaces), which thus have the same function as the Haversian canals in the more compact bone.

Chemical Composition.—Bone consists of an animal and an earthy part intimately combined together.

The animal part may be obtained by immersing the bone for a considerable time in dilute mineral acid, after which process the bone comes out exactly the same shape as before, but perfectly flexible, so that a long bone (one of the ribs, for example) can easily be tied in a knot. If now a transverse section is made (fig. 36), the same general arrangement of the Haversian canals, lamellæ, lacunæ, and canaliculi is seen, though not so plainly as in the ordinary section.

Fig. 36.—Section of bone after the removal of the earthy matter by the action of acids.



The earthy part may be separately obtained by calcination, by which the animal matter is completely burnt out. The bone will still retain its original form, but it will be white and brittle, will have lost about one-third of its original weight, and will crumble down with the slightest force. The earthy matter confers on bone its hardness and rigidity, and the animal matter its tenacity.

The animal basis is largely composed of *ossein*, which is identical with the collagen of white fibrous tissue, so that when boiled with water, especially under pressure, it is almost entirely resolved into gelatin.

The organic matter of bone forms about *one-third*, or 33·3 per cent.; the inorganic matter, *two-thirds*, or 66·7 per cent. Of the earthy matter, five-sixths is calcium phosphate, the remainder consisting of calcium carbonate, calcium fluoride, calcium chloride, and magnesium phosphate, with small amounts of sodium chloride and sulphate. Even after the removal of all the marrow, a small percentage of fat is still found in bone.

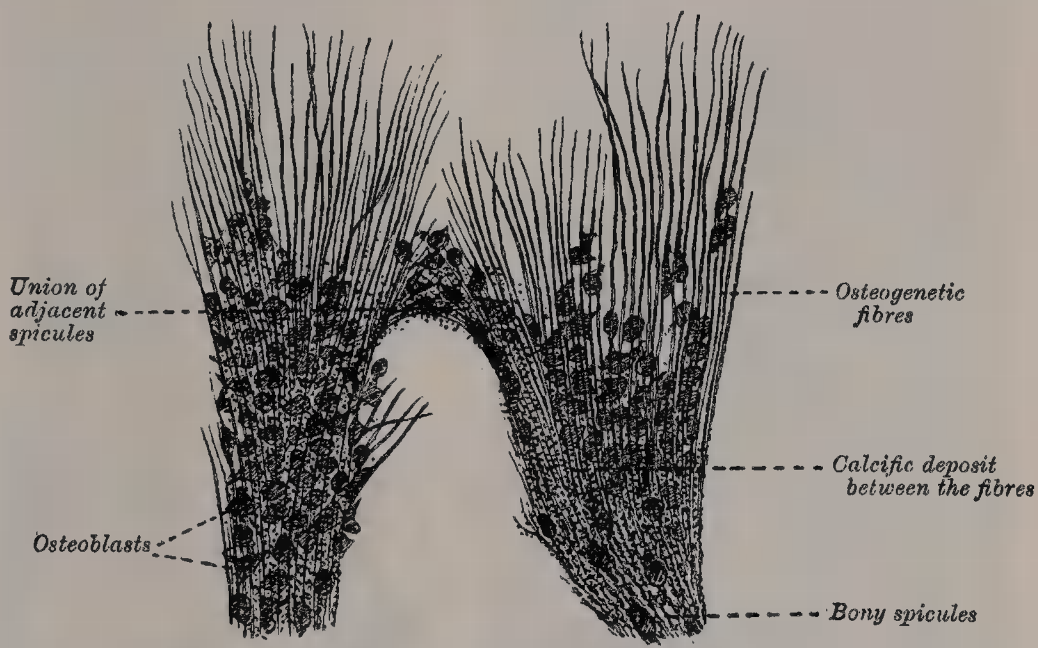
Some of the diseases to which bones are liable mainly depend on the disproportion between the two constituents of bone. Thus in the disease called rickets, so common in the children of the poor, the bones become bent and curved, either from the superincumbent weight of the body, or under the action of certain muscles. This depends upon some defect of nutrition by which bone becomes deprived of its normal proportion of earthy matter, while the animal matter is

of unhealthy quality. In the vertebræ of a rickety subject, Bostock found in 100 parts 79·75 animal and 20·25 earthy matter.

Development of Bone.—In the fœtal skeleton some bones are preceded by membrane, such as those forming the roof and sides of the skull; others, such as the bones of the limbs, are preceded by rods of cartilage. Hence two kinds of ossification are described: the *intramembranous* and the *intracartilaginous*.

Intramembranous Ossification.—In the case of bones which are developed in membrane no cartilaginous mould precedes the appearance of the bone tissue. The membrane, which occupies the place of the future bone, is of the nature of connective tissue, and ultimately forms the periosteum. At this stage it is seen to be composed of fibres and granular cells in a matrix. The outer portion is more fibrous, while, internally, the cells or *osteoblasts* predominate; the whole tissue is richly supplied with blood-vessels. At the outset of the process of bone formation a little network of bony spiculæ is first noticed radiating from the point or centre of ossific tion. When these rays of growing bone are examined by the microscope they are found to consist at their growing point of a network of fine clear fibres and granular corpuscles with an intervening ground substance (fig. 37).

Fig. 37.—Part of the growing edge of the developing parietal bone of a fœtal cat. (After J. Lawrence.)



The fibres are termed *osteogenetic* fibres, and are made up of fine fibrils differing little from those of white fibrous tissue. Like them they are probably deposited in the matrix through the influence of the cells—in this case the osteoblasts. The osteogenetic fibres soon assume a dark and granular appearance from the deposition of calcareous granules in the fibres and in the intervening matrix, and as they calcify they are found to enclose some of the granular corpuscles or osteoblasts. By the fusion of the calcareous granules the bony tissue again assumes a more transparent appearance, but the fibres are no longer so distinctly seen. The involved osteoblasts form the corpuscles of the future bone, the spaces in which they are enclosed constituting the lacunæ. As the osteogenetic fibres grow out to the periphery they continue to calcify, and give rise to fresh bone spicules. Thus a network of bone is formed, the meshes of which contain the blood-vessels and a delicate connective tissue crowded with osteoblasts. The bony trabeculæ thicken by the addition of fresh layers of bone formed by the osteoblasts on their surface, and the meshes are correspondingly encroached upon. Subsequently successive layers of bony tissue are deposited under the periosteum and round the larger vascular channels which become the Haversian canals, so that the bone increases much in thickness.

Intracartilaginous Ossification.—Just before ossification begins the bone is entirely cartilaginous, and in a long bone, which may be taken as an example, the process commences in the centre and proceeds towards the extremities, which

for some time remain cartilaginous. Subsequently a similar process commences in one or more places in those extremities and gradually extends through them. The extremities do not, however, become joined to the shaft by bony tissue until growth has ceased, but are attached to it by a layer of cartilaginous tissue termed the *epiphysial cartilage*.

The first step in the ossification of the cartilage is that the cartilage-cells, at the point where ossification is commencing and which is termed a *centre of ossification*, enlarge and arrange themselves in rows (fig. 38). The matrix in which they are embedded increases in quantity, so that the cells become further separated from each other. A deposit of calcareous material now takes place in this matrix, between the rows of cells, so that they become separated from each

Fig. 39.—Part of a longitudinal section of the developing femur of a rabbit.

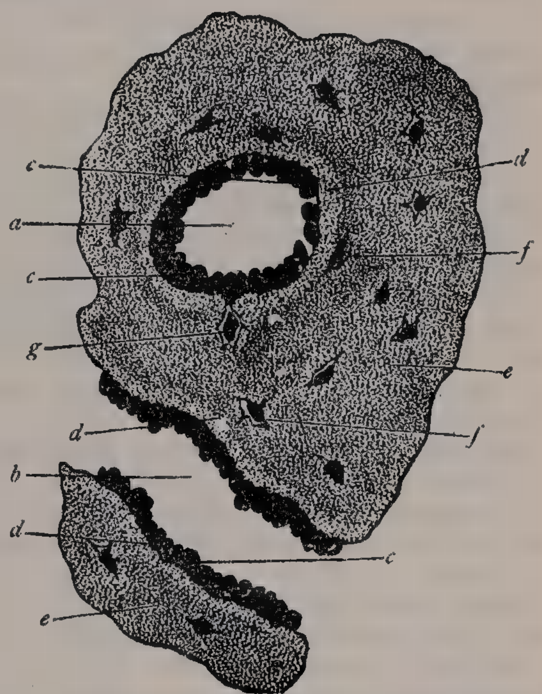
a. Flattened cartilage-cells. *b.* Enlarged cartilage-cells. *c, d.* Newly formed bone. *e.* Osteoblasts. *f.* Giant-cells or osteoclasts. *g, h.* Shrunken cartilage-cells. (From 'Atlas of Histology,' Klein and Noble Smith.)

other by longitudinal columns of calcified matrix, presenting a granular and opaque appearance. Here and there the matrix between two cells of the same row also becomes calcified, and transverse bars of calcified substance stretch across from one calcareous column to another. Thus there are longitudinal groups of the cartilage-cells enclosed in oblong cavities, the walls of which are formed of calcified matrix, which cuts off all nutrition from the cells, and they, in consequence, waste, leaving spaces called the *primary areolæ* (Sharpey).

At the same time that this process is going on in the centre of the solid bar of cartilage of which the fœtal bone consists, certain changes are taking place on its surface. This is covered by a very vascular membrane, the *perichondrium*, entirely similar to the embryonic connective tissue already described as constituting

the basis of membrane bone, on the inner surface of which—that is to say, on the surface in contact with the cartilage—are gathered the formative cells, the *osteoblasts*. By the agency of these cells a thin layer of bony tissue is being formed between the perichondrium and the cartilage, by the *intramembranous* mode of ossification just described. There are then, in this first stage of ossification, two processes going on simultaneously: in the centre of the cartilage the formation of a number of oblong spaces, formed of calcified matrix and containing the withered cartilage-cells, and on the surface of the cartilage the formation of a layer of true membrane-bone. The second stage consists in the prolongation into the cartilage of processes of the deeper or osteogenetic layer of the perichondrium, which has now become periosteum (fig. 38, *ir*). The processes consist of blood-vessels and cells—*osteoblasts*, or bone-formers, and *osteoclasts*, or bone-destroyers. The latter are similar to the giant-cells (myeloplaxes) found in marrow, and they excavate passages through the new-formed bony layer by absorption, and pass through it into the calcified matrix (fig. 38). Wherever these processes come in contact with the calcified walls of the primary areolæ they absorb it, and thus cause a fusion of the original cavities and the formation of larger spaces, which are termed the *secondary areolæ* (Sharpey) or *medullary spaces* (Müller). These secondary spaces, the original cartilage-cells having disappeared, become filled with embryonic marrow, consisting of osteoblasts and vessels, and derived, in the manner described above, from the osteogenetic layer of the periosteum (fig. 39).

Fig. 40.—Transverse section from the femur of a human embryo about eleven weeks old.



a. A medullary sinus cut transversely; and *b.* another longitudinally. *c.* Osteoblasts. *d.* Newly formed osseous substance of a lighter colour. *e.* That of greater age. *f.* Lacunæ with their cells. *g.* A cell still united to an osteoblast.

Thus far there has been traced the formation of enlarged spaces (secondary areolæ), the perforated walls of which are still formed by calcified cartilage-matrix, containing an embryonic marrow, derived from the processes sent in from the osteogenetic layer of the periosteum, and consisting of blood-vessels and round cells, osteoblasts (fig. 39). The walls of these secondary areolæ are at this time of only inconsiderable thickness, but they become thickened by the deposition of layers of new bone on their interior. This process takes place in the following manner. Some of the osteoblasts of the embryonic marrow, after undergoing rapid division, arrange themselves as an epithelioid layer on the surface of the wall of the space (fig. 40). This layer of osteoblasts forms a bony stratum, and thus the wall of the space becomes gradually covered with a layer of true osseous substance. On this a second layer of osteoblasts arrange themselves, and in their turn form an osseous layer. By the repetition of this process the original cavity becomes very much reduced in size, and at last only remains as a small circular hole in the centre, containing the remains of the embryonic marrow—that is, a blood-vessel and a few osteoblasts. This small cavity constitutes the Haversian canal of the perfectly ossified bone. The successive layers of osseous matter which have been laid down, and which encircle this central canal, constitute the lamellæ, of which, as we have seen, each Haversian system is made up. As the successive layers of osteoblasts form osseous tissue, certain of the osteoblastic cells remain included between the various bony layers. These persist as the corpuscles of the future bone, the spaces enclosing them forming the lacunæ (fig. 39). The canaliculi, at first extremely short, are supposed to be extended by absorption, so as to meet those of neighbouring lacunæ.

Such are the changes which may be observed at one particular point, the centre

of ossification. While they have been going on a similar process has been set up in the surrounding parts and has been gradually proceeding towards the end of the shaft, so that in the ossifying bone all the changes described above may be seen in different parts, from the true bone in the centre of the shaft to the hyaline cartilage at the extremities. The bone thus formed differs from the bone of the adult in being more spongy and less regularly lamellated.

In this way the steps of a process have been described by which a solid bony mass is produced, having vessels running into it from the periosteum; Haversian canals in which these vessels run; medullary spaces filled with fœtal marrow; lacunæ with their contained bone-cells; and canaliculi growing out of these lacunæ.

This process of ossification, however, is not the origin of the whole of the skeleton, for even in those bones in which the ossification proceeds in a great measure from a single centre, situated in the cartilaginous shaft of a long bone, a considerable part of the original bone is formed by intramembranous ossification beneath the perichondrium or periosteum; so that the girth of the bone is increased by bony deposit from the deeper layer of this membrane.

The shaft of the bone is at first solid, but a tube is hollowed out in it by absorption around the vessels passing into it, which becomes the medullary canal. This absorption is supposed to be brought about by large giant-cells, the so-called osteoclasts of Kölliker (fig. 39, *f*). They vary in shape and size, and are known by containing a large number of clear nuclei, sometimes as many as twenty. The occurrence of similar cells in some tumours of bones has led to such tumours being denominated 'myeloid.'

As more and more bone is removed by this process of absorption from the interior of the bone to form the medullary canal, so more and more bone is deposited on the exterior from the periosteum, until at length it has attained the shape and size which it is destined to retain during adult life. As the ossification of the cartilaginous shaft extends towards the articular ends it carries with it, as it were, a layer of cartilage, or the cartilage grows as it ossifies, and thus the bone is increased in length. During this period of growth the articular end, or epiphysis, remains for some time entirely cartilaginous, then a bony centre appears in it, and it commences the same process of intracartilaginous ossification; but this process never extends to any great distance. The epiphyses remain separated from the shaft by a narrow cartilaginous layer for a definite time. This layer ultimately ossifies, the distinction between shaft and epiphysis is obliterated, and the bone assumes its completed form and shape. The same remarks also apply to the processes of bone which are separately ossified, such as the trochanters of the femur. The bones, having been formed, continue to grow until the body has acquired its full stature. They increase in length by ossification continuing to extend in the epiphysial cartilage, which goes on growing in advance of the ossifying process. They increase in circumference by deposition of new bone, from the deeper layer of the periosteum, on their external surface, and at the same time an absorption takes place from within, by which the medullary cavity is increased.

The medullary spaces which characterise the cancellous tissue are produced by the absorption of the original fœtal bone in the same way as that by which the original medullary canal is formed. The distinction between the cancellous and the compact tissue appears to depend essentially upon the extent to which this process of absorption has been carried; and we may perhaps remind the reader that in morbid states of the bone inflammatory absorption produces exactly the same change, and converts portions of bone, naturally compact, into cancellous tissue.

The number of ossific centres varies in different bones. In most of the short bones ossification commences by a single point in the centre, and proceeds towards the circumference. In the long bones there is a central point of ossification for the shaft or diaphysis: and one or more for each extremity, the epiphysis. That for the shaft is the first to appear. The union of the epiphyses with the shaft takes place in the reverse order to that in which their ossification began, with the exception of the fibula, and appears to be regulated by the direction of the nutrient artery of the bone. Thus, the nutrient arteries of the bones of the arm and fore-arm are directed towards the elbow, and the epiphyses of the bones forming this joint become united to the shaft before those at the opposite extremity. In the lower limb, on the other hand, the nutrient arteries pass in a direction from the

knee: that is, upwards in the femur, downwards in the tibia and fibula; and in them it is observed that the upper epiphysis of the femur, and the lower epiphysis of the tibia and fibula, become first united to the shaft.

Where there is only one epiphysis, the medullary artery is directed towards that end of the bone where there is no additional centre; as towards the acromial end of the clavicle, towards the distal end of the metacarpal bone of the thumb and great toe, and towards the proximal end of the other metacarpal and metatarsal bones.

Besides these epiphyses for the articular ends, there are others for projecting parts or processes, which are formed separately from the bulk of the bone. For an account of these, the reader must be referred to the description of the individual bones.

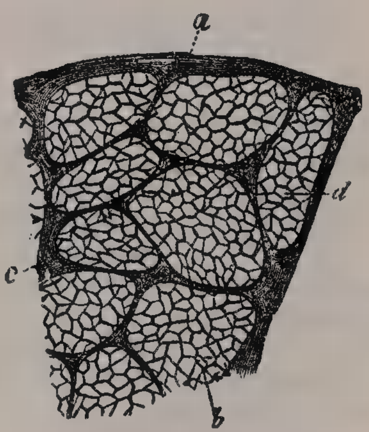
A knowledge of the exact periods when the epiphyses become joined to the shaft is often of great importance in medico-legal inquiries. It also aids the surgeon in the diagnosis of many of the injuries to which the joints are liable; for it not infrequently happens that, on the application of severe force to a joint, the epiphysis becomes separated from the shaft, and such injuries may be mistaken for fracture or dislocation.

MUSCULAR TISSUE

The **muscles** are formed of bundles of reddish fibres, endowed with the property of contractility. The two principal kinds of muscular tissue found in the body are the voluntary and involuntary. The former of these, from the characteristic appearances which its fibres exhibit under the microscope, is known as 'striped' muscle, and from the fact that it is capable of being put into action and controlled by the will, as 'voluntary' muscle. The fibres of the latter do not present any cross-striped appearance, and for the most part are not under the control of the will; hence they are known as the 'unstriped' or 'involuntary' muscles. The muscular fibres of the heart differ in certain particulars from both these groups, and they are therefore separately described as 'cardiac' muscular fibres.

Thus it will be seen that there are three varieties of muscular fibres: (1) transversely striated muscular fibres, which are for the most part voluntary and under the control of the will, but some of which are not so, such as the muscles of the pharynx and upper part of the œsophagus. This variety of muscle is sometimes called *skeletal*; (2) transversely striated muscular fibres, which are not under the control of the will, i.e. the cardiac muscle; (3) plain or unstriped muscular fibres, which are involuntary and controlled by a different part of the nervous system from that which controls the activity of the voluntary muscles. Such are the muscular walls of the stomach and intestine, of the uterus and bladder, of the blood-vessels, &c.

Fig. 41.—Transverse section from the sterno-mastoid in man. Magnified 50 times.

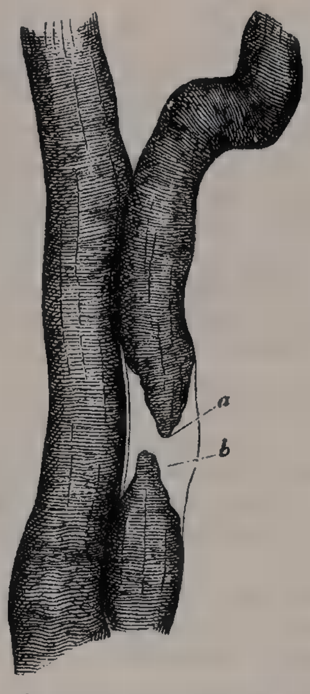


a. Epimysium. *b.* Fasciculus. *c.* Perimysium. *d.* Fibre.

The **striped** or **voluntary muscles** are composed of bundles of fibres enclosed in a delicate web called the 'perimysium,' in contradistinction to the sheath of areolar tissue which invests the entire muscle, the 'epimysium' (fig. 41). The bundles are termed 'fasciculi;' they are prismatic in shape, of different sizes in different muscles, and for the most part placed parallel to one another, though they have a tendency to converge towards their tendinous attachments. Each fasciculus is made up of a strand of *fibres*, which also run parallel with each other, and which are separated from one another by a delicate connective tissue derived from the perimysium and termed *endomysium*. This does not form the sheath of the fibres, but serves to support the blood-vessels and nerves ramifying between them. The fibres are enclosed in a separate and distinct sheath of their own, but it is not areolar tissue and is therefore not derived from the perimysium.

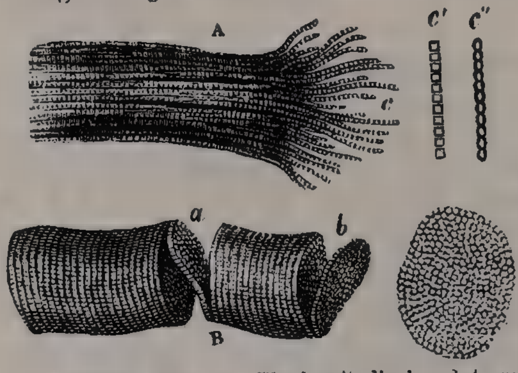
A *muscular fibre* may be said to consist of a soft contractile substance enclosed in a tubular sheath, named by Bowman the *sarcolemma*. The fibres are cylindrical or prismatic in shape, and are of no great length, not exceeding, it is said, an inch and a half. They end either by blending with the tendon or aponeurosis, or else by rounded or tapering extremities which are connected to the neighbouring fibres by means of the sarcolemma. Their breadth varies in man from $\frac{1}{200}$ to $\frac{1}{600}$ of an inch. As a rule, the fibres do not divide or anastomose; but occasionally, especially in the tongue and facial muscles, the fibres may be seen to divide into several branches. The precise mode in which the muscular fibre joins the tendon has been variously described by different observers. It may, perhaps, be sufficient to say that the sarcolemma, or membranous investment of the muscular fibre, appears to become blended with a small bundle of fibres, into which the tendon becomes subdivided, while the muscular substance terminates abruptly and can be readily made to retract from the point of junction. The areolar tissue between the fibres appears to be prolonged more or less into the tendon, so as to form a kind of sheath around the tendon bundles for a longer or

Fig. 42.—Two human muscular fibres. Magnified 350 times.



In the one, the bundle of fibrillæ (*b*) is torn, and the sarcolemma (*a*) is seen as an empty tube.

Fig. 43.—Fragments of striped muscular fibres, showing a cleavage in opposite directions. Magnified 300 diameters.



A. Longitudinal cleavage. The longitudinal and transverse lines are both seen. Some longitudinal lines are darker and wider than the rest, and are not continuous from end to end. This results from partial separation of the fibrillæ. c. Fibrillæ separated from one another by violence at the broken end of the fibre, and marked by transverse lines equal in width to those on the fibre. *c′ c″* represent two appearances commonly presented by the separated single fibrillæ (more highly magnified). At *c′* the borders and transverse lines are all perfectly rectilinear, and the included spaces perfectly rectangular. At *c″* the borders are scalloped and the spaces bead-like. When most distinct and definite the fibrilla presents the former of these appearances.
B. Transverse cleavage. The longitudinal lines are scarcely visible. *a*. Incomplete fracture following the opposite surfaces of a disc, which stretches across the interval, and retains the two fragments in connection. The edge and surfaces of this disc are seen to be minutely granular, the granules corresponding in size to the thickness of the disc, and to the distance between the faint longitudinal lines. *b*. Another disc nearly detached. *b′*. Detached disc, more highly magnified, showing the sarcous elements.

shorter distance. When muscular fibres are attached to the skin or mucous membranes, their fibres are described by Hyde Salter as becoming continuous with those of the areolar tissue.

The *sarcolemma*, or tubular sheath of the fibre, is a transparent, elastic, and apparently homogeneous membrane of considerable toughness, so that it will sometimes remain entire when the included substance is ruptured (see fig. 42), On the internal surface of the sarcolemma in mammalia, and also in the substance of the fibre in the lower animals, elongated nuclei are seen, and in connection with these a row of granules, apparently fatty, is sometimes observed.

Upon examination of a voluntary muscular fibre by transmitted light, it is found to be apparently marked by alternate light and dark bands or striæ, which pass transversely, or somewhat obliquely, round the fibre (fig. 42). The dark and light bands are of nearly equal breadth, and alternate with great regularity. They vary in breadth from about $\frac{1}{1200}$ to $\frac{1}{1700}$ of an inch. If the surface is carefully focussed, rows of granules will be detected at the point of junction of the dark and light bands, and very fine longitudinal lines may be seen running

through the dark bands and joining these granules together. By treating the specimen with certain reagents (e.g. chloride of gold) fine lines may be seen running transversely between the granules uniting them together. This appearance is believed to be due to a reticulum or network of interstitial substance lying between the contractile portions of the muscle. The longitudinal striation gives the fibre the appearance of being made up of a bundle of fibrillæ, which have been termed *sarcostyles* or *muscle columns*, and if the fibre is hardened in alcohol, it can be broken up longitudinally and the sarcostyles separated from each other (fig. 43, A). The reticulum, with its longitudinal and transverse meshes, is called *sarcoplasm*.

If now a transverse section of a muscular fibre is made, it is seen to be divided into a number of areas, called the *areas of Cohnheim*, more or less polyhedral in shape, and consisting of the transversely divided sarcostyles, surrounded by transparent series of sarcoplasm (fig. 43, B, *b'*).

Upon closer examination, and by somewhat altering the focus, the appearances become more complicated, and are susceptible of various interpretations. The

transverse striation, which in figs. 42 and 43 appears as a mere alternation of dark and light bands, is resolved into the appearance seen in fig. 44, which shows a series of broad dark bands, separated by light bands, which are divided into two by a dark dotted line. This line is termed *Krause's membrane* (fig. 46, *k*), because it was believed by Krause to be an actual membrane, continuous with the sarcolemma, and dividing the light band into two compartments. It is now more usually regarded as being due to an optical phenomenon, from the light being reflected between discs of different refrangibility. In addition to the membrane of Krause, fine clear lines may be made out, with a sufficiently high power, crossing the centre of the dark band; these are known as the *lines of Hensen* (fig. 46, H).

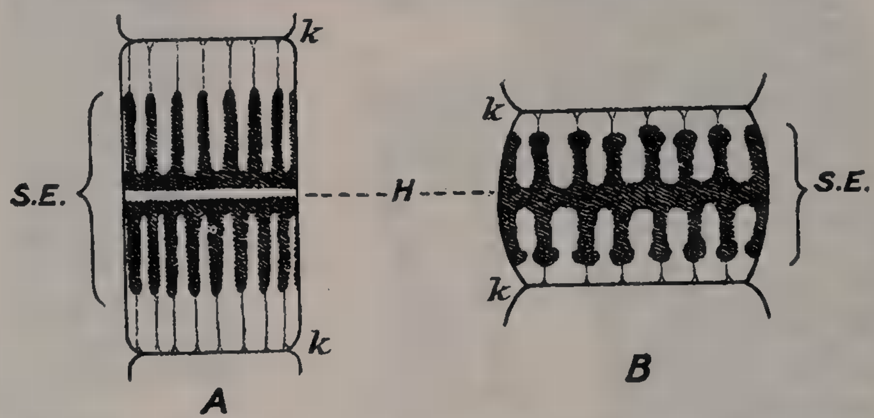
Formerly it was supposed by Bowman that a muscular fibre was made up of a number of quadrangular particles, which he named sarcous elements, joined together like so many bricks forming a column, and he came to this conclusion because he found that under the influence of certain reagents the fibre could be broken up transversely into discs, as well as longitudinally into fibrillæ (fig. 43, B). But it is now believed that this cross cleavage is purely artificial, and that a muscular fibre is built up of fibrillæ and not of small quadrangular particles.

Assuming that this is so, we have now to consider a little more in detail the minute structure of these longitudinal fibrillæ, or sarcostyles, as they are termed. Perhaps there are few subjects in histology which have received more attention, and in which the appearances seen under the microscope have been more differently interpreted, than the minute anatomy of muscular fibre. Schäfer has worked out this subject, particularly in the wing muscles of insects, which are peculiarly adapted for this purpose on account of the large amount for interstitial sarcoplasm which separates the sarcostyles. In the following description that given by Schäfer will be closely followed (fig. 46).

Each sarcostyle may be said to be made up of successive portions, each of which Schäfer terms a *sarcomere*. This is the portion situated between two membranes of Krause, which transversely divides the light band. Each sarcomere consists of a central dark part, which forms a portion of the dark band of the whole fibre, and is named by Schäfer a *sarcous element*.* This sarcous element really consists of two parts, superimposed one on the top of the other, and when the fibre is stretched these two parts become separated from each other at the line of Hensen (fig. 46, A). On either side of this central dark portion is a clear layer, most visible when the fibre is extended; this is situated between the dark centre and the membrane of Krause, and when the sarcomeres are joined together to form the sarcostyle, constitutes the light band of the striated muscular fibre.

When the sarcostyle is extended, the clear intervals are well marked and plainly to be seen; when, on the other hand, the sarcostyle is contracted,

FIG. 46.—Diagram of a sarcomere. (After Schäfer.)
A. In moderately extended condition. B. In a contracted condition.



k. k. Membranes of Krause. H. Line or plane of Hensen. S.E. Poriferous sarcous element.

that is to say, the muscle is in a state of contraction, these clear portions are very small or they may have disappeared altogether (fig. 46, B). When the sarcostyle is stretched to its full extent, not only is the clear portion very well marked, but the dark portion—the sarcous element—will be seen to be separated into its two constituents along the line of Hensen.

The sarcous element does not lie free in the sarcomere, for when the sarcostyle is stretched, so as to render the clear portion visible, very fine lines, which are probably septa, may be seen running through it from the sarcous element to the membrane of Krause.

Schäfer explains these phenomena in the following way. He considers that each sarcous element is made up of a number of longitudinal channels, which open into the clear part towards the membrane of Krause but are closed at the line of Hensen. When the muscular fibre is contracted the *clear* part of the muscular substance finds its way into these channels or tubes and is therefore hidden from sight, but at the same time it swells up the sarcous element and widens and shortens the sarcomere. When, on the other hand, the fibre is extended, this clear substance finds its way out of the tubes and collects between the sarcous element and the membrane of Krause, and gives the appearance of the light part between these two structures; by this means it elongates and narrows the sarcomere.

If this view is true it is a matter of great interest, and, as Schäfer has shown, harmonises the contraction of muscle with the amœboid action of protoplasm.

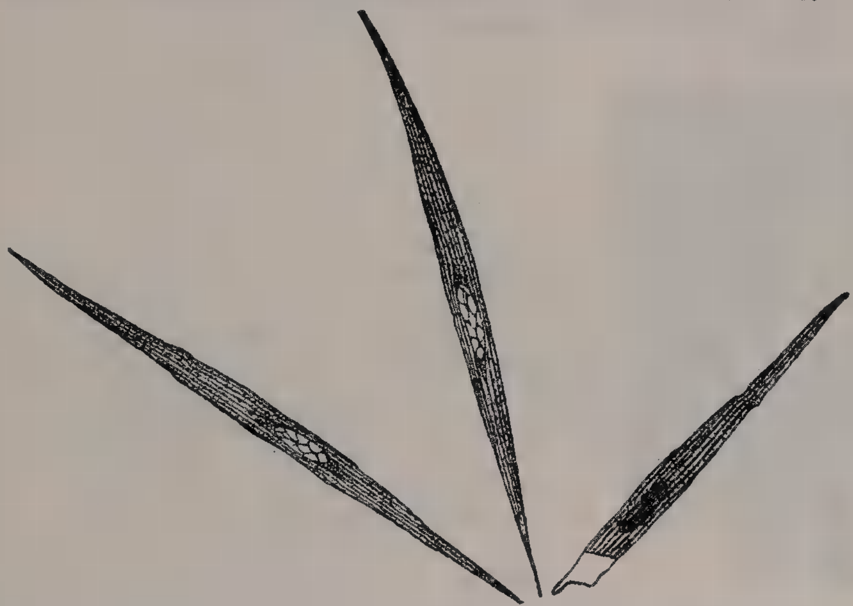
* This must not be confused with the 'sarcous element of Bowman' (see above).

In an amœboid cell there is a framework of spongioplasm, which stains with hæmatoxylin and similar reagents, enclosing in its meshes a clear substance, hyaloplasm, which will not stain with these reagents. Under stimulation the hyaloplasm passes into the pores of the spongioplasm; without stimulation it tends to pass out as in the formation of pseudopodia. In muscle there is the same thing, viz. a framework of spongioplasm staining with hæmatoxylin—the substance of the sarcous element—and this encloses a clear hyaloplasm, the clear substance of the sarcomere, which resists staining with this reagent. During contraction of the muscle—i.e. stimulation—this clear substance passes into the pores of the spongioplasm; while during extension of the muscle—i.e. when there is no stimulation—it tends to pass out of the spongioplasm.

In this way the contraction is brought about: under stimulation the protoplasmic material (the clear substance of the sarcomere) recedes into the sarcous element, causing the sarcomere to widen out and shorten. The contraction of the muscle is merely the sum total of this widening out and shortening of these bodies.

The *capillaries* of striped muscle are very abundant, and form a sort of rectangular network, the branches of which run longitudinally in the endomysium between the muscular fibres, and are joined at short intervals by transverse

FIG. 47.—Non-striated muscular fibre. (From Kirke's 'Physiology.')



anastomosing branches. The larger vascular channels, arteries and veins, are found only in the perimysium, between the muscular fasciculi.

Nerves are profusely distributed to striped muscle. Their mode of termination will be described on a subsequent page.

The existence of *lymphatic* vessels in striped muscle has not been ascertained, though they have been found in tendons and in the sheath of the muscle.

The **unstriped, plain,** or **involuntary muscle** is found in the walls of the hollow viscera—viz. the lower half of the œsophagus and the whole of the remainder of the gastro-intestinal tube; in the trachea and bronchi, and the alveoli and infundibula of the lungs; in the gall-bladder and ductus communis choledochus; in the large ducts of the salivary and pancreatic glands; in the pelvis and calyces of the kidney, the ureter, bladder, and urethra; in the female sexual organs—viz. the ovary, the Fallopian tubes, the uterus (enormously developed in pregnancy), the vagina, the broad ligaments, and the erectile tissue of the clitoris; in the male sexual organs—viz. the dartos of the scrotum, the vas deferens and epididymis, the vesiculæ seminales, the prostate gland, and the corpora cavernosa and corpus spongiosum; in the ducts of certain glands, as in Wharton's duct; in the capsule and trabeculæ of the spleen; in the mucous membranes, forming the muscularis mucosæ; in the skin, forming the arrectores pilorum, and also in the sweat-glands; in the arteries, veins, and lymphatics; in the iris and the ciliary muscle.

Plain or unstriped muscle is made up of spindle-shaped cells, called *contractile fibre-cells*, collected into bundles and held together by a cement substance (fig. 47)

These bundles are further aggregated into larger bundles, or flattened bands, and bound together by ordinary connective tissue.

The *contractile fibre-cells* are elongated, spindle-shaped, nucleated cells of various sizes, averaging from $\frac{1}{600}$ to $\frac{1}{300}$ of an inch in length, and $\frac{1}{4500}$ to $\frac{1}{3500}$ of an inch in breadth. On transverse section they are more or less polyhedral in shape, from mutual pressure. They present a faintly longitudinal striated appearance, and consist of an elastic cell-wall containing a central bundle of fibrillæ, representing the contractile substance, and an oval or rod-like nucleus, which includes, within a membrane, a fine network communicating at the poles of the nucleus with the contractile fibres (Klein). The adhesive interstitial cement substance, which connects the fibre-cells together, represents the endomysium, or delicate connective tissue which binds the fibres of striped muscular tissue into fasciculi; while the tissue connecting the individual bundles together represents the perimysium. The unstriped muscle, as a rule, is not under the control of the will, neither is the contraction rapid nor does it involve the whole muscle, as is the case with the voluntary muscles. The membranes which are composed of the unstriped muscle slowly contract in a part of their extent, generally under the influence of a mechanical stimulus, as that of distension or of cold; and then the contracted part slowly relaxes while another portion of the membrane takes up the contraction. This peculiarity of action is most strongly marked in the intestines, constituting their *vermicular motion.*

Fig. 48.—Anastomosing muscular fibres of the heart seen in a longitudinal section. On the right the limits of the separate cells with their nuclei are exhibited somewhat diagrammatically.

Cardiac Muscular Tissue.—The fibres of the heart differ very remarkably from those of other striped muscles. They are smaller by one-third, and their transverse striæ are by no means so well marked. The fibres are made up of distinct quadrangular cells joined end to end (fig. 48). Each cell contains a clear oval nucleus, situated near the centre of the cell. The extremities of the cells have a tendency to branch or divide, the subdivisions uniting with offsets from other cells, and thus producing an anastomosis of the fibres. The connective tissue between the bundles of fibres is much less than in ordinary striped muscle, and no sarcolemma has been proved to exist.

Development of Muscle Fibres.—Voluntary muscular fibres are developed from the mesoblast, the embryonic cells of which elongate, show multiplication of nuclei, and eventually become striated; the striation is first obvious at the side of the fibre, spreads around the circumference, and ultimately extends to the centre. The nuclei, at first situated centrally, gradually pass out to assume their final position immediately beneath the sarcolemma. In the case of plain muscle the mesoblastic cells assume a pointed shape at the extremities and become flattened, the nucleus also lengthening out to its permanent rod-like form.

Chemical Composition of Muscle.—In chemical composition the muscular fibres may be said, in round numbers, to consist of 75 per cent. of water, about 20 per cent. of proteids, 2 per cent. of fat, 1 per cent. of nitrogenous extractives and carbohydrates, and 2 per cent. of salts, which are mainly potassium phosphate and carbonate.

NERVOUS TISSUE

The **nervous tissues** of the body are comprised in two great systems—the *cerebro-spinal* and the *sympathetic.*

The *cerebro-spinal* system comprises the brain (including the medulla oblongata), the spinal cord, the cranial nerves, the spinal nerves, and the ganglia connected with these nerves. The *sympathetic* system consists of a double chain of ganglia, with the nerves which go to and come from them. It is not directly connected with the brain or spinal cord, though it is so

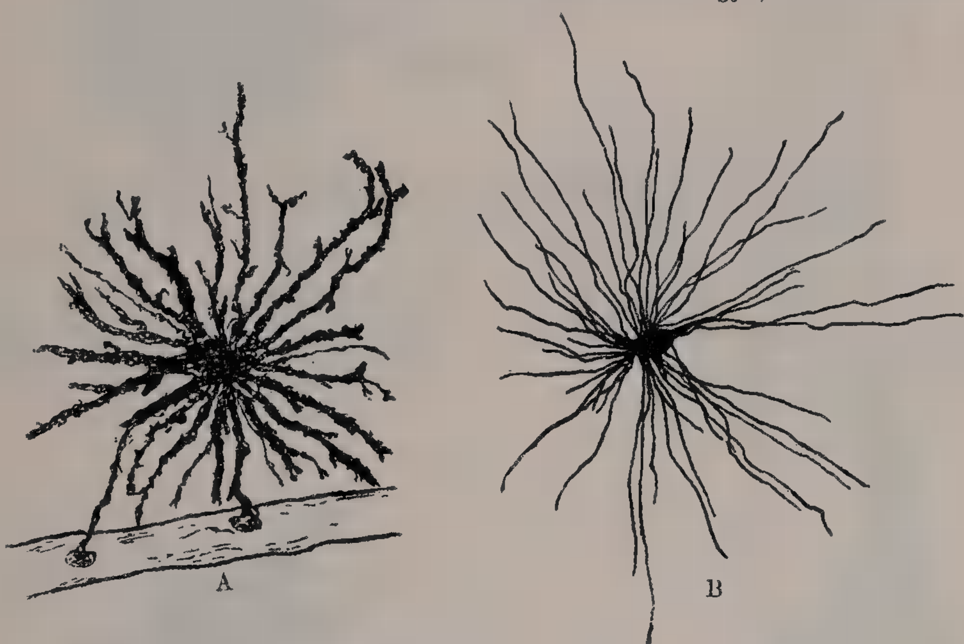
indirectly by means of its numerous communications with the cranial and spinal nerves.

The nervous tissues are found microscopically to be composed of *nerve-cells* and their various processes, together with a supporting tissue called *neuroglia*, which, however, is found only in the brain and spinal cord. Certain long processes of the nerve-cells are of special importance, and it is convenient to consider them apart from the cells; they are known as *nerve-fibres*.

To the naked eye a difference is obvious between certain portions of the brain and spinal cord, viz. the *grey matter* and the *white matter*. This is found to be due to the fact that the grey matter is largely composed of nerve-cells, while the white matter contains only their long processes, the nerve-fibres. It is in the former, as is generally supposed, that nervous impressions and impulses originate, and by the latter that they are conducted. Hence the grey matter forms the essential constituent of all the ganglionic centres, both those in the isolated ganglia and those aggregated in the cerebro-spinal axis; while the white matter is found in all the commissural portions of the nerve-centres and in all the cerebro-spinal nerves.

Neuroglia, the peculiar ground substance in which are embedded the true nervous constituents of the brain and spinal cord, consists of fibres and cells.

FIG. 49.—Neuroglia cells of brain shown by Golgi's method. (After Andriezen.) (Copied from Schäfer's 'Essentials of Histology.')



A. Cell with branched processes. B. Spider cell with unbranched processes.

Some of the cells are stellate in shape, and their fine processes become neuroglia fibres, which extend radially and unbranched (fig. 49, B) among the nerve-cells and fibres which they aid in supporting. Other cells give off fibres which branch repeatedly (fig. 49, A). In addition to these fibres there are others which do not appear to be connected with the neuroglia cells. They start from the epithelial cells lining the ventricles of the brain and central canal of the spinal cord, and pass through the nervous tissue, branching repeatedly to terminate in slight enlargements on the pia mater. Thus, neuroglia is evidently a connective tissue in function but is not so in development; it is epiblastic in origin, whereas all connective tissues are mesoblastic.

Nerve-cells or **ganglion-cells** are largely aggregated in the grey substance of the brain and spinal cord, but smaller collections of these cells also form the swellings seen on many nerves, which are called *ganglia*. These are found chiefly upon the spinal and cranial nerve-roots and in connection with the sympathetic nerves. Each nerve-cell consists of a finely fibrillated protoplasmic material, of a reddish or yellowish-brown colour, which occasionally presents patches of a deeper tint, caused by the aggregation of pigment-granules at one side of the nucleus, as in the substantia nigra and locus cœruleus. The protoplasm also sometimes contains peculiar angular granules, which stain deeply with basic dyes, such

as methylene blue; these are known as *Nissl's granules* (fig. 52). The nucleus is, as a rule, a large, well-defined, round, vesicular body, often presenting an

FIG. 51.—Bipolar nerve-cell from the spinal ganglion of the pike. (After Kölliker.)

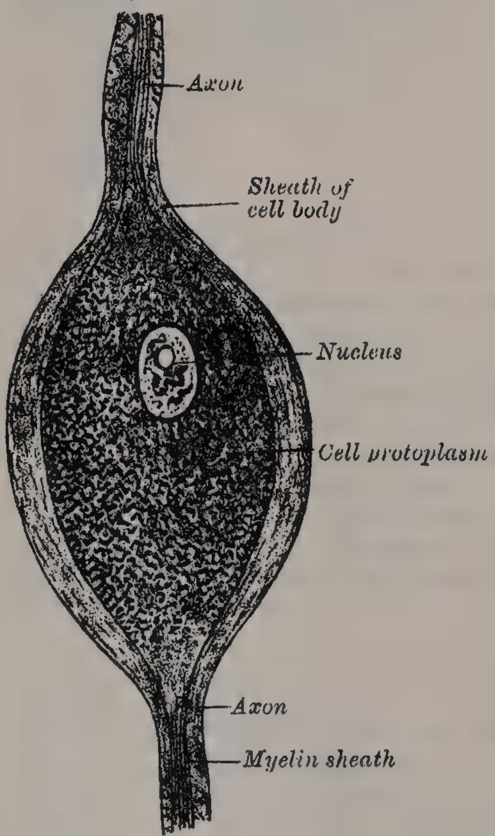

FIG. 52.—Motor nerve-cell from ventral horn of spinal cord of rabbit. (After Nissl.) The angular and spindle-shaped Nissl bodies are well shown.

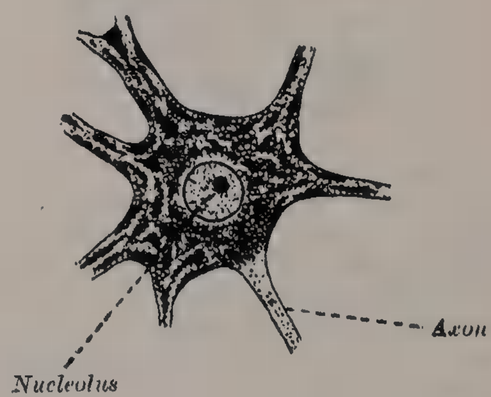

intranuclear network, and containing a nucleolus which is peculiarly clear and brilliant. The nerve-cells vary in shape and size, and have one or more processes. They may be divided for purposes of description into three groups, according to the number of processes which they possess: (1) Unipolar cells, which are found in the spinal ganglia; their single process, after a short course, divides in a T-shaped manner. (2) Bipolar cells, also found in the spinal ganglia (fig. 51), when the cells are in an embryonic condition. They are best demonstrated in the sympathetic ganglion-cells of a frog. Sometimes the processes com-

off from opposite poles of the cell, and the cell then assumes a spindle shape; at others they both emerge at the same point. In some cases where two fibres are apparently connected with a cell, one of the fibres is really derived from an adjoining nerve-cell and is passing to end in a ramification around the ganglion-cell, or, again, it may be coiled spirally round the nerve process which is issuing from the cell. (3) Multipolar cells, which are caudate or stellate in shape, and characterised by their large size and by the tail-like processes which issue from them. The processes are of two kinds: one of them is termed the *axis-cylinder process* or *axon* because it becomes the axis cylinder of a nerve-fibre (figs. 52, 53, 54). The others are termed the *protoplasmic processes* or *dendrons*; they begin to divide and subdivide as soon as they emerge from the cell, and finally end in minute twigs and become lost among the other elements of the nervous tissue.

Fig. 53.—Pyramidal cell from the cerebral cortex of a mouse. (After Ramón y Cajal.)

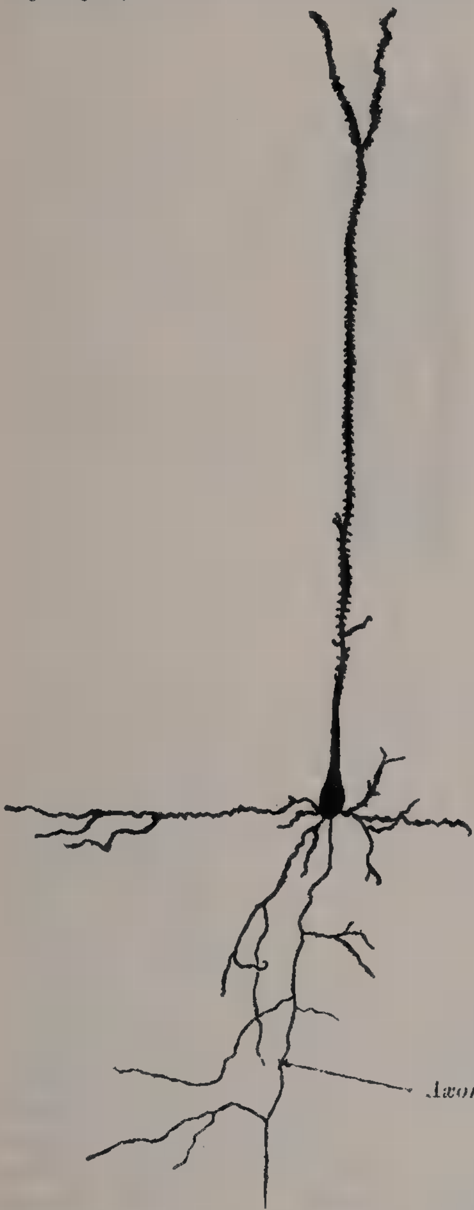

Fig. 54.—Cell of Purkinje from the cerebellum of a cat. (After Ramón y Cajal.)

Nerve-fibres are found universally in the peripheral nerves, and in the white substance of the brain and spinal cord. The fibres are of two kinds, the *medullated* or *white* fibres, and the *non-medullated* or *grey* fibres.

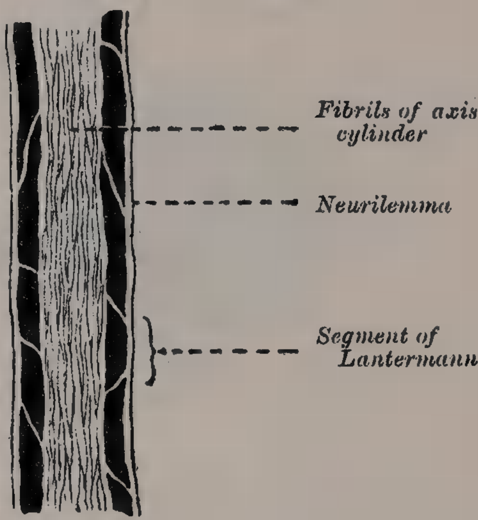
The *medullated* fibres form the white part of the brain and spinal cord, and also the greater part of the cerebro-spinal nerves, and give to these structures their opaque, white aspect. When perfectly fresh they appear to be homogeneous; but soon after removal from the body they present, when examined by transmitted light, a double outline or contour, as if consisting of two parts (fig. 55). The central portion is named the *axis cylinder of Purkinje*; around this is a sort of sheath of fatty material, staining black with osmic acid, named the *white substance of Schwann*, which gives to the fibre its double contour, and the whole is enclosed in a delicate membrane, the *neurilemma*, *primitive sheath*, or *nucleated sheath of Schwann* (fig. 55).

The *axis cylinder* is the essential part of the nerve-fibre, and is always present; the other parts, the medullary sheath and the neurilemma, being

occasionally absent, especially at the origin and termination of the nerve-fibre. It undergoes no interruption from its origin in the nerve-centre to its peripheral termination, and must be regarded as a direct prolongation of a nerve-cell. It constitutes about one-half or one-third of the nerve-tube, the white substance being greater in proportion in the nerves than in the central organs. It is quite transparent, and is therefore indistinguishable in a perfectly fresh and natural state of the nerve. It is made up of exceedingly fine fibrils, which stain darkly with gold chloride (fig. 56). At its termination the axis cylinder of a nerve-fibre may be seen to break up into fibrillæ, confirming the view of its structure. These

Fig. 55.—White or medullated nerve-fibres, showing the sinuous outline and double contours. (After Schäfer.)

Fig. 56.—Longitudinal section through a nerve-fibre from the sciatic nerve of a frog. × 830. (After Böhm and Davidoff.)



fibrillæ have been termed the *primitive fibrillæ* of Schultze. The axis cylinder is said by some to be enveloped in a special, reticular sheath, which separates it from the white matter of Schwann, and is composed of a substance called *neurokeratin*. The more common opinion is that this network or reticulum is contained in the white matter of Schwann, and by some it is believed to be produced by the action of the reagents employed to show it. The *medullary sheath* or *white matter of Schwann* (fig. 56) is regarded as being a fatty matter in a fluid state, which insulates and protects the essential part of the nerve—the axis cylinder. The white matter varies in thickness to a very considerable extent, in some forming a layer of extreme thinness, so as to be scarcely distinguishable, in others forming about one-half the nerve-tube. The size of the nerve-fibres, which varies from $\frac{1}{1200}$ to $\frac{1}{2000}$ of an inch, depends mainly upon the amount of the white substance, though the axis cylinder also varies in size within certain limits. The white matter of Schwann does not always form a continuous sheath to the axis cylinder, but undergoes interruptions in its continuity at regular intervals, giving to the fibre the appearance of constriction at these points. These were first described by Ranvier, and are known as the *nodes of Ranvier* (fig. 57). The portion of nerve-fibre between two nodes is called an *internodal segment*. The neurilemma or primitive sheath is not interrupted at the nodes, but passes over them as a continuous membrane. In addition to these interruptions oblique clefts

Fig. 57.—A node of Ranvier of a medullated nerve-fibre, viewed from above, magnified about 750 diameters. The medullary sheath is discontinuous at the node, whereas the axis cylinder passes from one segment into the other. At the node the sheath of Schwann appears thickened. (Klein and Noble Smith.)

may be seen in the medullary sheath, subdividing it into irregular portions, which are termed *medullary segments*, or *segments of Lantermann* (fig. 56). There is reason to believe that these clefts are artificially produced in the preparation of the specimens. Medullated nerve-fibres, when examined, frequently present a beaded or varicose appearance: this is due to manipulation and pressure causing the oily matter to collect into drops, and in consequence of the extreme delicacy of the primitive sheath, even slight pressure will cause the transudation of the fatty matter, which collects as drops of oil outside the membrane. This is, of course, promoted by the action of certain reagents.

The *neurilemma* or *primitive sheath* (sometimes called the *tubular membrane* or *sheath of Schwann*) presents the appearance of a delicate, structureless membrane. Here and there beneath it, and situated in depressions in the white matter of Schwann, are nuclei surrounded by a small amount of protoplasm. The nuclei are oval and somewhat flattened, and bear a definite relation to the nodes of Ranvier; one nucleus generally lying in the centre of each internode. The primitive sheath is not present in all medullated nerve-fibres, being absent in those fibres which are found in the brain and spinal cord.

Non-medullated Fibres.—Most of the nerves of the sympathetic system, and some of the cerebro-spinal, consist of another variety of nervous fibres, which are called the *grey* or *gelatinous* nerve-fibres—*fibres of Remak* (fig. 58). These consist of a central core or axis cylinder enclosed in a nucleated sheath, which tends to split into fibrillæ, and is probably of the nature of neurokeratin. In external appearance the gelatinous nerves are semi-transparent and grey or yellowish-grey. The individual fibres vary in size, generally averaging about half the size of the medullated fibres.

Fig. 58.—A small nervous branch from the sympathetic of a mammal.

a. Two medullated nerve-fibres among a number of grey nerve-fibres, *b.*

Development of Nerve-cells and Fibres.—The nerve-cells are developed from certain of the cells which line the neural canal or form the neural crest of the embryo (see section on development). Some of these cells assume a rounded form and are termed *neuroblasts*, and from each neuroblast there grows out a process, the axis-cylinder process or axon, and subsequently the branching processes or dendrons. The axis cylinders, at first naked, acquire their medullary sheath, possibly by some metamorphosis of their outer layer. The neurilemma is thought to be derived from mesoblastic cells which become flattened and wrapped round the fibre, the cement substance at their apposed ends forming the material which stains with silver nitrate at the nodes of Ranvier. Nerve-cells in the sympathetic and peripheral ganglia take their origin from small collections of neuroblasts, which are split off from the rudimentary spinal ganglia. Cells which are, originally, similar to neuroblasts seem to give rise to neuroglia cells, numerous processes sprouting from the cell to form the neuroglial fibres.

Chemical Composition.—The amount of water in nervous tissue varies with the situation. Thus in the grey matter of the cerebrum it constitutes about 83 per cent., in the white matter from the same region about 70 per cent., while in the peripheral nerves, such as the sciatic, it may fall to 60 per cent. The solids consist of proteids (in the grey matter they form half the total solids), neurokeratin, nuclein, protagon, lecithin, cerebrosides, cholesterin, nitrogenous extractives, and salts with some gelatin and fat from the adherent connective tissue.

The nervous structures are divided, as before mentioned, into two great systems—viz. the *cerebro-spinal*, comprising the brain and spinal cord, the nerves connected with these structures, and the ganglia situated on them; and the *sympathetic*, consisting of a double chain of ganglia and the nerves connected with them. All these structures require separate consideration; they are composed of the two kinds of nervous tissue above described, intermingled in various proportions, and having, in some parts, a very intricate arrangement.

The **brain** or **encephalon** is that part of the cerebro-spinal system which is contained in the cavity of the skull. It is divided into several parts, which

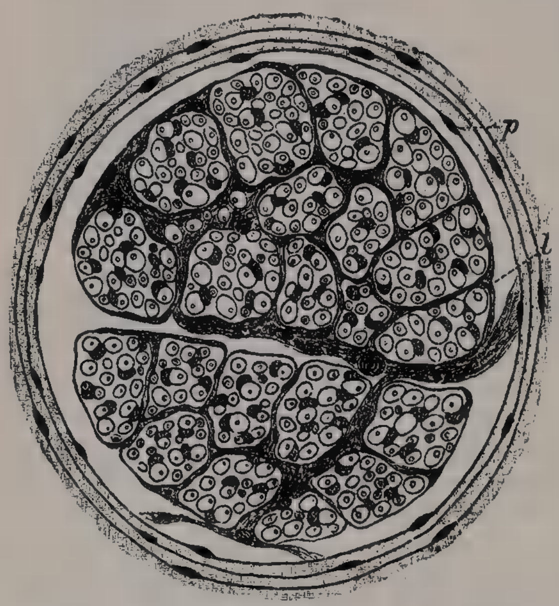
will be described subsequently. In these parts the grey or vesicular nervous matter is found on the surface of the brain, forming the convolutions of the cerebrum, and the laminæ of the cerebellum. Again, grey matter is found in the interior of the brain, collected into large and distinct masses or ganglionic bodies, such as the corpus striatum, optic thalamus, and corpora quadrigemina. Finally, grey matter is found intermingled intimately with the white, but without definite arrangement, as in the grey matter in the pons Varolii and the floor of the fourth ventricle.

The white matter of the brain is divisible into three distinct classes of fibres: (1) Diverging or peduncular fibres, which connect the hemispheres with the medulla oblongata and the spinal cord. (2) Commissural fibres, which connect together the two hemispheres. (3) Association fibres, which connect different parts of the same hemisphere.

The manner in which these fibres are intermingled with each other and with the grey matter in the brain and spinal cord is very intricate, and can only be fully understood by a careful study of the details of its descriptive anatomy. The further consideration of this subject will therefore be deferred until after the description of the various divisions of which the cerebro-spinal system is made up.

Fig. 59.—Transverse section through a microscopic nerve, representing a compound nerve-bundle, surrounded by perineurium. Magnified 120 diameters.

The medullated fibres are seen as circles with a central dot, viz. medullary sheath and axis cylinder, in transverse section. They are embedded in endoneurium, containing numerous nuclei, which belong to the connective-tissue cells of the latter. (Klein and Noble Smith.)



Perineurium, consisting of laminæ of fibrous connective-tissue, alternating with flattened nucleated connective-tissue cells. *l*. Lymph-space between perineurium and surface of nerve-bundle.

The **nerves** are round or flattened cords, formed of the nerve-fibres already described. They are connected at one end with the cerebro-spinal centre or with the ganglia, and are distributed at the other end to the various textures of the body; they are subdivided into two great classes—the *cerebro-spinal* nerves, which proceed from the cerebro-spinal axis, and the *sympathetic* or *ganglionic* nerves, which proceed from the ganglia of the sympathetic.

The **cerebro-spinal nerves** consist of numerous nerve-fibres collected together and enclosed in a membranous sheath (fig. 59). A small bundle of primitive fibres, enclosed in a tubular sheath, is called a *funiculus*; if the nerve is of small size, it may consist only of a single funiculus; but if large, the funiculi are collected together into larger bundles or fasciculi, which are bound together in a common membranous investment, and constitute the nerve.

In structure, the common membranous investment, or sheath of the whole nerve, which is called the *epineurium*, as well as the septa given off from it, and which separate the fasciculi, consists of connective tissue, composed of white and yellow elastic fibres, the latter existing in great abundance. The tubular sheath of the funiculi, called the *perineurium*, is a fine, smooth, transparent membrane, which may be easily separated, in the form of a tube, from the fibres it encloses; in structure it is made up of connective tissue, which has a distinctly lamellar arrangement, consisting of several lamellæ, separated from each other by spaces containing lymph. The nerve-fibres are held together and supported within the funiculus by delicate connective tissue, called the *endoneurium*. It is continuous with septa which pass inwards from the innermost layer of the perineurium, and shows a ground substance in which are embedded fine bundles of fibrous connective tissue which run for the most part longitudinally.

It serves to support capillary vessels, which are arranged so as to form a network with elongated meshes. The cerebro-spinal nerves consist almost exclusively of the medullated nerve-fibres, the non-medullated existing in very small proportions.

The blood-vessels supplying a nerve terminate in a minute capillary plexus, the vessels composing which pierce the perineurium, and run, for the most part, parallel with the fibres; they are connected together by short, transverse vessels, forming narrow, oblong meshes, similar to the capillary system of muscle. Fine non-medullated nerve-fibres accompany these capillary vessels, *vaso-motor fibres*, and break up into elementary fibrils, which form a network around the vessel. Horsley has also demonstrated certain medullated fibres as running in the epineurium and terminating in small spheroidal tactile corpuscles or end-bulbs of Krause. These nerve-fibres, which Marshall believes to be sensory, and which he has termed *nervi nervorum*, are considered by him to have an important bearing upon certain neuralgic pains.

The nerve-fibres, as far as is at present known, do not coalesce, but pursue an uninterrupted course from the centre to the periphery. In separating a nerve, however, into its component funiculi, it may be seen that these do not pursue a perfectly insulated course, but occasionally join at a very acute angle with other funiculi proceeding in the same direction; from this, branches are given off, to join again in like manner with other funiculi. It must be distinctly understood, however, that in these communications the nerve-fibres do not coalesce, but merely pass into the sheath of the adjacent nerve, become intermixed with its nerve-fibres, and again pass on, to become blended with the nerve-fibres in some adjoining funiculus.

Nerves, in their course, subdivide into branches, and these frequently communicate with branches of a neighbouring nerve. The communications which thus take place form what is called a *plexus*. Sometimes a plexus is formed by the primary branches of the trunks of the nerves—as the cervical, brachial, lumbar, and sacral plexuses—and occasionally by the terminal funiculi, as in the plexuses formed at the periphery of the body. In the formation of a plexus, the component nerves divide, then join, and again subdivide in such a complex manner that the individual funiculi become interlaced most intricately; so that each branch leaving a plexus may contain filaments from each of the primary nervous trunks which form it. In the formation also of smaller plexuses at the periphery of the body there is a free interchange of the funiculi and primitive fibres. In each case, however, the individual filaments remain separate and distinct, and do not inosculate with one another.

It is probable that through this interchange of fibres the different branches passing off from a plexus have a more extensive connection with the spinal cord than if they each had proceeded to be distributed without such connection with other nerves. Consequently the parts supplied by these nerves have more extended relations with the nervous centres; by this means, also, groups of muscles may be associated for combined action.

The **sympathetic** nerves are constructed in the same manner as the cerebro-spinal nerves, but consist mainly of non-medullated fibres, collected in funiculi, and enclosed in a sheath of connective tissue. There is, however, in these nerves, a certain admixture of medullated fibres, and the amount varies in different nerves, and may be known by their colour. Those branches of the sympathetic which present a well-marked grey colour are composed more especially of gelatinous nerve-fibres, intermixed with a few medullated fibres; while those of a white colour contain more of the latter fibres, and a few of the former. Occasionally, the grey and white cords run together in a single nerve, without any intermixture, as in the branches of communication between the sympathetic ganglia and the spinal nerves, or in the communicating cords between the ganglia.

The nerve-fibres, both of the cerebro-spinal and sympathetic system, convey impressions of a twofold kind. The *sensory* nerves, called also *centripetal* or *afferent* nerves, transmit to the nervous centres impressions made upon the peripheral extremities of the nerves, and in this way the mind, through the medium of the brain, becomes conscious of external objects. The *motor* nerves, called also *centrifugal* or *efferent* nerves, transmit impressions from the nervous centres to the parts to which the nerves are distributed, these impressions either

exciting muscular contraction, or influencing the processes of nutrition, growth, and secretion.

Origin and Termination of Nerves.—By the expression 'the termination of nerve-fibres' is signified their connections with the nerve-centres, and with the parts they supply. The former are sometimes called their *origin*, or *central* termination; the latter their *peripheral* termination. The origin in some cases is single—that is to say, the whole nerve emerges from the nervous centre by a single root; in other instances the nerve arises by two or more roots, which come off from different parts of the nerve-centre, sometimes widely apart from each other, and it often happens, when a nerve arises in this way by two roots, that the functions of these two roots are different; as, for example, in the spinal nerves, each of which arises by two roots, the anterior of which is motor, and the posterior sensory. The point where the nerve root or roots emerge from the nervous centre is named the *superficial* or *apparent* origin, but the fibres of which the nerve consists can be traced for a certain distance into the nervous centre to some portion of the grey substance, which constitutes the *deep* or *real* origin of the nerve. The manner in which these fibres arise at their deep origin varies with their functions. The centrifugal or efferent nerve-fibres originate in the nerve-cells of the grey substance, the axis-cylinder processes of these cells being prolonged to form the fibres. In the case of the centripetal or afferent nerves the fibres grow inwards either from nerve-cells in the organs of special sense (e.g. the retina) or from nerve-cells in the ganglia. Having entered the nerve-centre they branch and send their ultimate twigs among the cells, without, however, uniting with them.

Peripheral Terminations of Nerves.—Nerve-fibres terminate peripherally in various ways, and these may be conveniently studied in the sensory and motor nerves respectively. **Sensory** nerves would appear to terminate either in *minute primitive fibrillæ* or networks of these; or else in special terminal organs, which have been termed *peripheral end-organs*, and of which there are several principal varieties, viz. the end-bulbs of Krause, the tactile corpuscles of Wagner, the Pacinian corpuscles, and the neuro-tendinous and neuro-muscular spindles.

Termination in Fibrillæ.—When a medullated nerve-fibre approaches its termination, the white matter of Schwann suddenly disappears, leaving only the axis cylinder, surrounded by the neurilemma, and forming a non-medullated fibre. This, after a time, loses its neurilemma, and consists only of an axis cylinder, which can be seen, in preparations stained with chloride of gold, to be made up of fine varicose fibrils. Finally, the axis cylinder breaks up into its constituent primitive nerve-fibrillæ, which often present regular varicosities and anastomose with one another, thus forming a network. This network passes between the elements of the tissue to which the nerves are distributed, which is always epithelial, the nerve-fibrils lying in the interstitial substance between the epithelial cells, and there terminating, though some observers maintain that the actual terminations are within the cells. In this way nerve-fibres have been found to terminate in the epithelium of the skin and mucous membranes, and in the anterior epithelium of the cornea.

FIG. 60.—End-bulb of Krause.

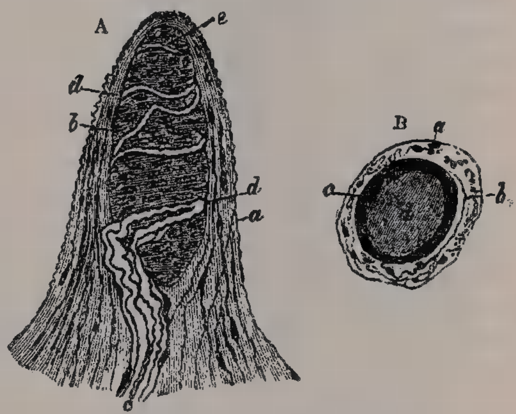
a. Medullated nerve-fibre. *b.* Capsule of corpuscle. (From Klein's 'Elements of Histology.')

The **end-bulbs of Krause** (fig. 60) are minute cylindrical or oval bodies, consisting of a capsule formed by the expansion of the connective-tissue sheath of a medullated fibre, and containing a soft semi-fluid core in which the termination of the axis cylinder is situated, ending either as a bulbous extremity, or in a coiled-up plexiform mass. End-bulbs are found in the conjunctiva of the eye, where they are spheroidal in shape in man, but cylindrical in most other animals, in the mucous membrane of the lips and tongue, and in the epineurium of nerve-trunks. They are also found in the genital organs of both sexes, the penis in the male and the clitoris in the female. In this situation they have a mulberry-like appearance, from being constricted by connective-tissue septa into from two to

six knob-like masses, and have received the name of *genital corpuscles.* Very similar corpuscles are found in the epineurium of nerve-trunks. In the synovial membrane of certain joints (e.g. those of the fingers), rounded or oval end-bulbs have been found ; these are designated *articular end-bulbs.*

Tactile corpuscles have been described by Grandry as occurring in the papillæ of the beak and tongue of birds, and by Merkel as occurring in the papillæ and epithelium of the skin of man and animals, especially in those parts of the skin devoid of hair. They consist of a capsule composed of a very delicate, nucleated membrane, and contain two or more granular, somewhat flattened cells, between which the medullated nerve-fibre, which enters the capsule by piercing its investing membrane, is supposed to terminate.

Fig. 61.—Papilla of the hand, treated with acetic acid. Magnified 350 times.

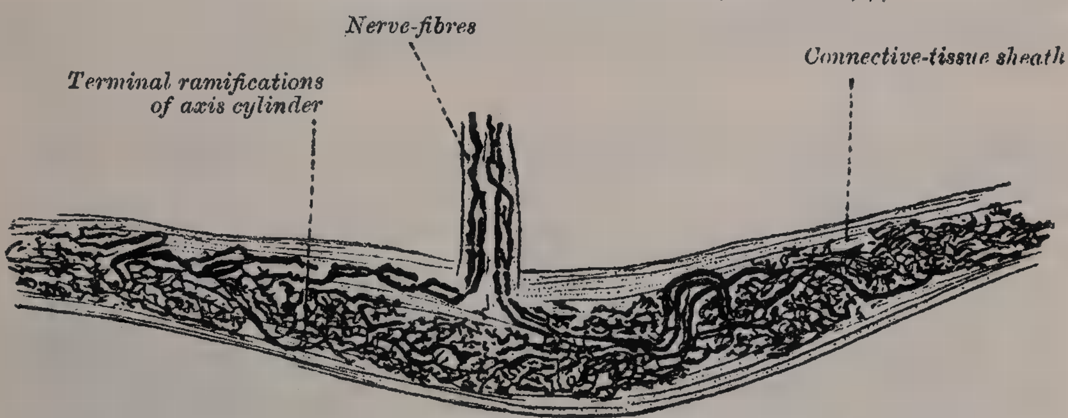


A. Side view of a papilla of the hand. *a.* Cortical layer. *b.* Tactile corpuscle, with transverse nuclei. *c.* Small nerve of the papilla, with neurilemma. *d.* Its two nervous fibres running with spiral coils around the tactile corpuscle. *e.* Apparent termination of one of these fibres. B. A tactile papilla seen from above so as to show its transverse section. *a.* Cortical layer. *b.* Nerve-fibre. *c.* Outer layer of the tactile body, with nuclei. *d.* Clear interior substance.

The **tactile corpuscles** (fig. 61), described by Wagner and Meissner, are oval-shaped bodies, made up of connective tissue, and consisting of a capsule, and imperfect membranous septa, derived from it, which penetrate its interior. The axis cylinder of the medullated fibres passes through the capsule, and having entered the corpuscle terminates in a small globular or pyriform enlargement, near the inner surface of the capsule. These tactile corpuscles have been described as occurring in the papillæ of the corium of the hand and foot, the front of the forearm, the skin of the lips, and the mucous membrane of the tip of the tongue, the palpebral conjunctiva, and the skin of the nipple. They are not found in all the papillæ ; but from their existence in those parts in which the skin is highly sensitive, it is probable that they are specially concerned in the sense of touch, though their absence from the papillæ of other tactile parts shows that they are not essential to this sense.

Ruffini has described a special variety of nerve-ending in the subcutaneous tissue of the human finger (fig. 62). These are usually known as *Ruffini's endings.*

Fig. 62.—Nerve-ending of Ruffini.
(After A. Ruffini, 'Arch. ital. de Biol. Turin,' t. xxi. 1894.)



They are principally situated at the junction of the corium with the subcutaneous tissue ; they are oval in shape, and consist of a strong connective-tissue sheath, inside which the nerve-fibre divides into numerous branches, which show varicosities and end in small free knobs. They resemble the organs of Golgi.

The **Pacinian corpuscles** * (fig. 63) are found in the human subject chiefly on the nerves of the palm of the hand and sole of the foot and in the genital organs

* Often called in German anatomical works 'corpuscles of Vater.'

of both sexes lying in the subcutaneous tissue; but they have also been described as connected with the nerves of the joints, and in some other situations, as the mesentery of the cat and along the tibia of the rabbit. Each of these corpuscles is attached to and encloses the termination of a single nerve-fibre. The corpuscle, which is perfectly visible to the naked eye (and which can be most easily demonstrated in the mesentery of a cat), consists of a number of lamellæ or capsules arranged more or less concentrically around a central clear space, in which the nerve-fibre is contained. Each lamella is composed of bundles of fine connective-tissue fibres, and is lined on its inner surface by a single layer of flattened epithelioid cells. The central clear space, which is elongated or cylindrical in shape, is filled with a transparent material, in the middle of which is the single medullated fibre, which traverses the space to near its distal extremity. Here it terminates in a rounded knob or end, sometimes bifurcating previously, in which case each branch has a similar arrangement. Todd and Bowman have described minute arteries as entering by the sides of the nerves and forming capillary loops in the intercapsular spaces, and even penetrating into the central space. Other authors describe the artery as entering the corpuscle at the pole opposite to the nerve-fibre.

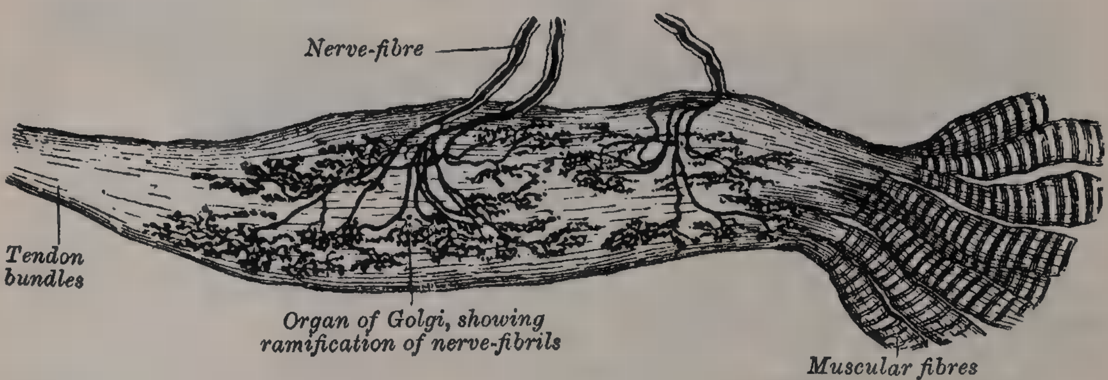
Fig. 63.—Pacinian corpuscle, with its system of capsules and central cavity.

a. Arterial twig, ending in capillaries, which form loops in some of the intercapsular spaces, and one penetrates to the central capsule. *b.* The fibrous tissue of the stalk prolonged from the neurilemma. *n.* Nerve-tube advancing to the central capsule, there losing its white matter, and stretching along the axis to the opposite end, where it is fixed by a tubercular enlargement.

Herbst has described a somewhat similar 'nerve-ending' to the Pacinian corpuscle, as being found in the mucous membrane of the tongue of the duck, and in some other situations. It differs, however, from the Pacinian corpuscles, in being smaller, its capsule thinner and more closely approximated, and especially in the fact that the axis cylinder in the central clear space is coated with a continuous row of nuclei. These bodies are known as the *corpuscles of Herbst.*

Neuro-tendinous spindles.—The nerves supplying tendons have a special modification of the terminal fibres, especially numerous at the point where the tendon is becoming muscular. The tendon bundles become enlarged, and the nerve-fibres—one, two, or more in number—penetrate between the fasciculi of

Fig. 64.—Organ of Golgi (neuro-tendinous spindle) from the human tendo Achillis. (After Ciaccio.)



the tendon and spread out between the fibres to end in irregular discs or varicosities. A spindle-shaped body is thus formed, composed of tendon bundles and nerve-fibres, which is known as the *organ of Golgi* (fig. 64).

Neuro-muscular spindles.—In the majority of voluntary muscles there have been found special end-organs consisting of a small bundle of peculiar muscular fibres (intrafusal fibres), embryonic in type, invested by a capsule, within which nerve-fibres, experimentally shown to be sensory in origin, terminate. These neuro-muscular spindles vary in length from $\frac{1}{30}$ to $\frac{1}{5}$ of an inch and have a distinctly fusiform appearance. The large medullated nerve-fibres passing to the end-organ are from one to three or four in number; entering the fibrous capsule, they divide several times, and, losing their medulla, ultimately end in naked axis cylinders encircling the intrafusal fibres by flattened expansions, or irregular ovoid or rounded discs (fig. 65). Neuro-muscular spindles have not yet been demonstrated in the tongue or eye muscles.

In the organs of **special sense** the nerves appear to terminate in cells, which belong to the epithelial class, and have received the name of *sensory* or *nerve-epithelium* cells. This is not, however, the real state of the case; the nerve-fibre is in reality a process from the epithelial cell, and terminates by branching around a ganglion-cell. The stimulus carried by it is continued onwards by an axis cylinder, derived from the ganglion, to the brain. These nerve-

FIG. 65.—Middle third of a terminal plaque in the muscle spindle of an adult cat. (After Ruffini.)

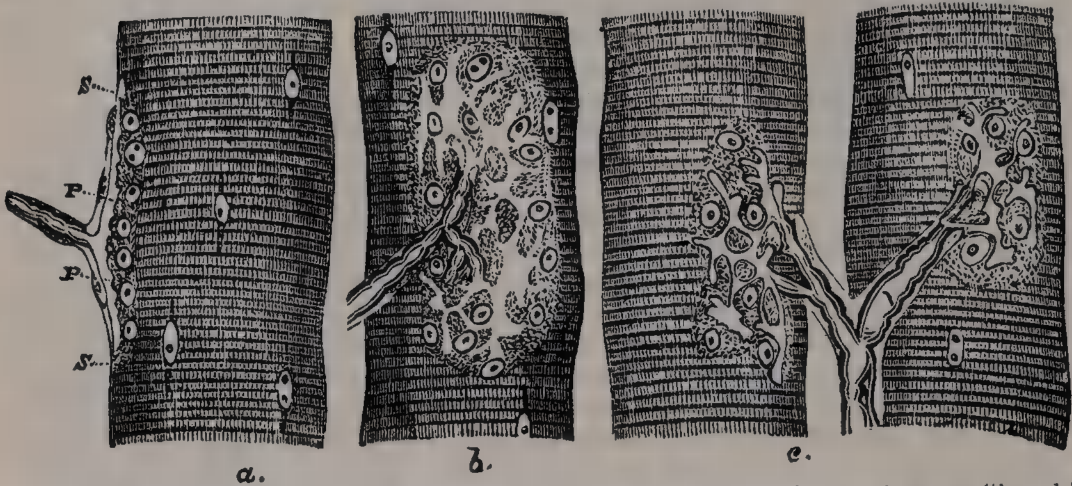
epithelium cells must therefore be regarded as modified forms of nerve-cells. They will be more particularly described in the chapter on the organs of special sense.

Motor nerves are to be traced either into unstriped or striped muscular fibres. In the **unstriped** or **involuntary** muscles the nerves are derived from the sympathetic, and are composed mainly of the non-medullated fibres. Near their termination they divide into a number of branches, which communicate and form an intimate plexus. At the junction of the branches small triangular nuclear bodies (ganglion-cells) are situated. From these plexuses minute branches are given off, which divide and break up into the ultimate fibrillæ of which the nerve is composed. These fibrillæ course between the involuntary muscle-cells, and, according to Elischer, terminate on the surface of the cell, opposite the nucleus, in a minute swelling. Arnold and Frankenhäuser believed that these ultimate fibrillæ penetrated the muscular cell, and ended in the nucleus. More recent observation has, however, tended to disprove this.

In the **striped** or **voluntary** muscle, the nerves supplying the muscular fibres are derived from the cerebro-spinal nerves, and are composed mainly of medullated fibres. The nerve, after entering the sheath of the muscle, breaks up into fibres, or bundles of fibres, which form plexuses, and gradually divide until, as a rule, a single nerve-fibre enters a single muscular fibre. Sometimes, however, if the muscular fibre is long, more than one nerve-fibre enters it. Within the muscular fibre the nerve terminates in a special expansion, called by Kühne,

who first accurately described them, *motorial end-plates* (fig. 66).* The nerve-fibre, on approaching the muscular fibre, suddenly loses its white matter of Schwann, which abruptly terminates; the neurilemma becomes continuous with

Fig. 66.—Muscular fibres of *Lacerta viridis* with the terminations of nerves.



a. Seen in profile. P P. The nerve end-plates. S S. The base of the plate, consisting of a granular mass with nuclei. *b.* The same as seen in looking at a perfectly fresh fibre, the nervous ends being probably still excitable. (The forms of the variously divided plate can hardly be represented in a woodcut by sufficiently delicate and pale contours to reproduce correctly what is seen in nature.) *c.* The same as seen two hours after death from poisoning by curare.

the sarcolemma of the muscle, and only the axis cylinder enters the muscular fibre, where it at once spreads out, ramifying like the roots of a tree, immediately beneath the sarcolemma, and is embedded in a layer of granular matter, containing a number of clear, oblong nuclei, the whole constituting an end-plate from which the contractile wave of the muscular fibre is said to start.

Fig. 67.—Section through a microscopic ganglion. Magnified 300 diameters. (Klein and Noble Smith.)

c. Capsule of the ganglion. *n.* Nerve-fibres passing out of the ganglion. The nerve-fibres which entered the ganglion are not represented. The nerve-fibres are ordinary medullated fibres, but the details of their structure are not shown, owing to the low magnifying power. The ganglion-cells are invested by a special capsule, lined by a few nuclei, which are here represented as if contained *in* the capsule.

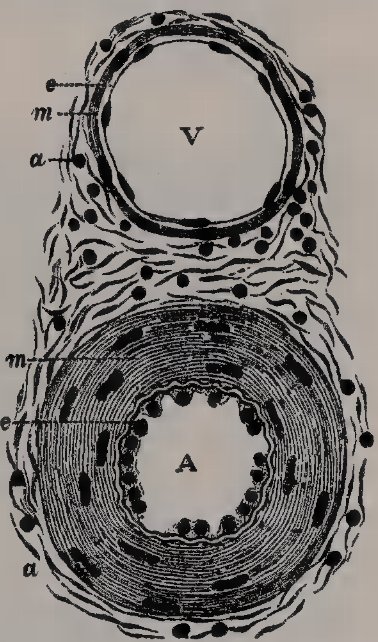
The **Ganglia** may be regarded as separate small aggregations of nerve-cells, connected with each other, with the cerebro-spinal axis, and with the nerves in various situations. They are found on the posterior root of each of the spinal nerves; on the posterior or sensory root of the fifth cranial nerve; on the facial and auditory nerves; on the glosso-pharyngeal and pneumogastric nerves. They are also found in a connected series along each side of the vertebral column, forming the trunk of the sympathetic; and on the branches of that nerve, generally in the plexuses or at the point of junction of two or more nerves with each other, or with branches of the cerebro-spinal system. On section they are seen to consist of a reddish-grey substance, traversed by numerous white nerve-fibres; they vary considerably in form and size; the largest are found in the cavity of the abdomen; the smallest, not visible to the naked eye, exist in considerable numbers upon the nerves distributed to the different viscera. The ganglia are invested by a smooth and firm, closely

* They had, however, previously been noticed, though not accurately described, by Doyère, who named them 'nerve-hillocks.'

adhering, membranous envelope, consisting of dense areolar tissue; this sheath is continuous with the perineurium of the nerves, and sends numerous processes into the interior of the ganglion, which support the blood-vessels supplying its substance.

In structure all ganglia are essentially similar (fig. 67), consisting of the same structural elements—viz. a collection of nerve-cells and nerve-fibres. Each nerve-cell has a nucleated sheath, which is continuous with the sheath of the nerve-fibre with which the cell is connected. The nerve-cells in the ganglia of the spinal nerves are pyriform in shape, and have only one process, the axis cylinder or axon. A short distance from the cell and while still within the ganglion this process divides in a T-shaped manner, one limb of the cross-bar passing centrally and forming the central portion of a sensory nerve-fibre; the other limb passing peripherally to form the axis-cylinder process of the peripheral nerve-fibre. In the sympathetic ganglia the nerve-cells are multipolar and have one axis-cylinder process or axon and several protoplasmic processes or dendrons. The former of these emerges from the ganglion as a non-medullated nerve-fibre. Similar cells are found in the ganglia connected with the fifth cranial nerve, and these ganglia are therefore regarded by some as the cranial portions of the sympathetic system. The nerve-cells are disposed in the ganglia in groups of varying size, and these groups are separated from each other by bundles of nerve-fibres, some of which traverse the ganglia without being connected with the cells.

Fig. 68.—Transverse section through a small artery and vein of the mucous membrane of the epiglottis of a child. Magnified about 350 diameters. (Klein and Noble Smith.)



A. Artery, showing the nucleated endothelium, *e*, which lines it: the vessel being contracted, the endothelial cells appear very thick. Underneath the endothelium is the wavy elastic intima. The chief part of the wall of the vessel is occupied by the circular muscle-coat *m*: the staff-shaped nuclei of the muscle-cells are well seen. Outside this is *a*, part of the adventitia. This is composed of bundles of connective-tissue fibres, shown in section, with the nuclei of the connective-tissue corpuscles. The adventitia gradually merges into the surrounding connective tissue. V. Vein showing a thin endothelial membrane, *e*, raised accidentally from the intima, which on account of its delicacy is seen as a mere line on the media *m*. This latter is composed of a few circular unstriped muscle-cells. *a*. The adventitia, similar in structure to that of an artery.

THE VASCULAR SYSTEM

The **Vascular System**, exclusive of its central organ, the heart, is divided into four classes of vessels: the arteries, capillaries, veins, and lymphatics. The minute structure of these vessels will be briefly described here, the reader being referred to the body of the work for the details of their ordinary anatomy.

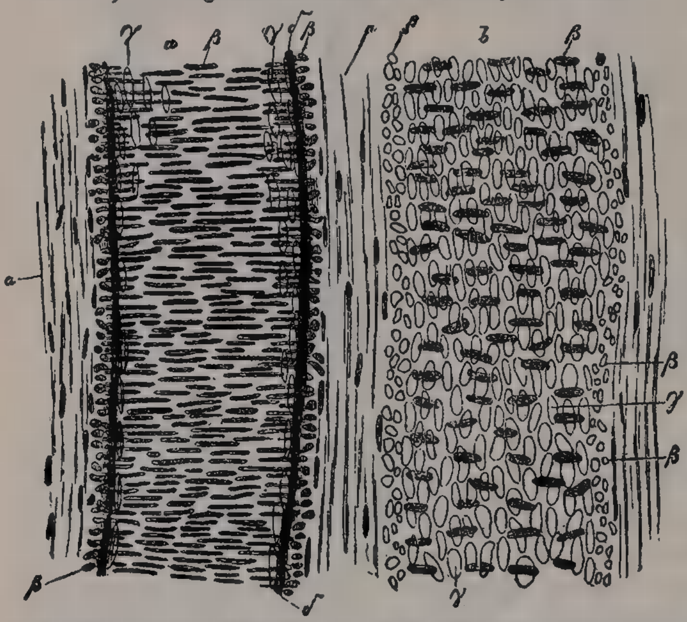
Structure of Arteries (fig. 68).—The arteries are composed of three coats: internal or endothelial coat (*tunica intima* of Kölliker); middle muscular coat (*tunica media*); and external connective-tissue coat (*tunica adventitia*).

The two inner coats together are very easily separated from the external, as by the ordinary operation of tying a ligature on an artery. If a fine string be tied forcibly upon an artery and then taken off, the external coat will be found undivided, but the internal coats are divided in the track of the ligature and can easily be further dissected from the outer coat. The *inner coat* can be separated from the middle by a little maceration, or it may be stripped off in small pieces; but, on account of its friability, it cannot be separated as a complete membrane. It is a fine, transparent, colourless structure which is highly elastic, and is commonly corrugated into longitudinal wrinkles. The inner coat consists of: (1) A layer of pavement-endothelium, the cells of which are polygonal, oval, or fusiform, and have very distinct round or oval nuclei. This endothelium is brought into view most distinctly by staining with nitrate of silver. (2) A sub-endothelial layer, consisting of delicate connective tissue with branched cells

lying in the interspaces of the tissue. In arteries of less than a line in diameter the subendothelial layer consists of a single stratum of stellate cells, and the connective tissue is only largely developed in vessels of a considerable size. (3) An elastic or fenestrated layer, which consists of a membrane containing a network of elastic fibres, having principally a longitudinal direction, and in which, under the microscope, small elongated apertures or perforations may be seen, giving it a fenestrated appearance. It was therefore called by Henle the *fenestrated membrane*. This membrane forms the chief thickness of the inner coat, and can be separated into several layers, some of which present the appearance of a network of longitudinal elastic fibres, and others present a more membranous character, marked by pale lines having a longitudinal direction. The fenestrated membrane in microscopic arteries is a very thin layer; but in the larger arteries, and especially in the aorta, it has a very considerable thickness.

The *middle coat* (*tunica media*) is distinguished from the inner by its colour and by the transverse arrangement of its fibres, in contradistinction to the longitudinal direction of those of the inner coat. In the smaller arteries it consists principally of muscular tissue, being made up of plain muscle-fibres in fine bundles, arranged in lamellæ and disposed circularly around the vessel. These lamellæ vary in number according to the size of the vessel; the very small arteries having only a single layer, and those not larger than one-tenth of a line in diameter three or four layers. It is to this coat that the great thickness of the walls of the artery is mainly due (fig. 68, A, *m*). In the larger vessels, as the iliac, femoral, and carotid, elastic fibres unite to form lamellæ, which alternate with the layers of muscular fibre and are united by elastic fibres, which pass between the muscular bundles, and are connected with the fenestrated membrane of the inner coat (fig. 70). In the largest arteries, as the aorta and innominate, the amount of elastic tissue is very considerable. In these vessels also bundles of white connective tissue have been found in small quantities in the middle coat. The muscle-fibre cells of which the middle coat is made up are about $\frac{1}{500}$ of an inch in length and contain well-marked, rod-shaped nuclei, which are often slightly curved.

Fig. 69.—Longitudinal section of artery and vein.



a. An artery from the mesentery of a child, ·062''', and *b*, vein ·067''' in diameter, treated with acetic acid and magnified 350 times. *a.* Tunica adventitia, with elongated nuclei. *β.* Nuclei of the contractile fibre-cells of the tunica media, seen partly from the surface, partly apparent in transverse section. *γ.* Nuclei of the endothelial cells. *δ.* Elastic longitudinal fibrous coat.

The *external coat* (*tunica adventitia*) consists mainly of fine and closely felted bundles of white connective tissue, but also contains elastic fibres in all but the smallest arteries. The elastic tissue is much more abundant next the tunica media, and it is sometimes described as forming here, between the adventitia and media, a special layer, the *tunica elastica externa* of Henle. This layer is most marked in arteries of medium size. In the largest vessels the external coat is relatively thin; but in small arteries it is of greater proportionate thickness. In the smaller arteries it consists of a single layer of white connective tissue and elastic fibres; while in the smallest arteries, just above the capillaries, the elastic fibres are wanting, and the connective tissue, of which the coat is composed, becomes more homogeneous the nearer it approaches the capillaries, and is gradually reduced to a thin membranous envelope, which finally disappears.

Some arteries have extremely thin coats in proportion to their size; this is

especially the case in those situated in the cavity of the cranium and spinal canal, the difference depending on the greater thinness of the external and middle coats.

The arteries, in their distribution throughout the body, are included in a thin fibro-areolar investment, which forms what is called their *sheath*. In the limbs this is usually formed by a prolongation of the deep fascia; in the upper part of the thigh it consists of a continuation downwards of the transversalis and iliac fasciæ of the abdomen; in the neck, of a prolongation of the deep cervical fascia. The included vessel is loosely connected with its sheath by delicate areolar tissue; and the sheath usually encloses the accompanying veins, and sometimes a nerve. Some arteries, as those in the cranium, are not included in sheaths.

All the larger arteries are supplied with blood-vessels like the other organs of the body; they are called the *vasa vasorum*. These nutrient vessels arise from a branch of the artery or from a neighbouring vessel, at some considerable distance from the point at which they are distributed; they ramify in the loose areolar tissue connecting the artery with its sheath, and are distributed to the external coat, but do not, in man, penetrate the other coats; though in some of the larger mammals some few vessels have been traced into the middle coat. Minute veins serve to return the blood from these vessels; they empty themselves into the vein or veins accompanying the artery. Lymphatic vessels and lymphatic spaces are also present in the outer coat.

Fig. 70.—Section of a medium-sized artery. (After Grünstein.)

Arteries are also supplied with nerves, which are derived chiefly from the sympathetic, but partly from the cerebro-spinal system. They form intricate plexuses upon the surfaces of the larger trunks, and run along the smaller arteries as single filaments or bundles of filaments, which twist around the vessel and unite with each other in a plexiform manner. The branches derived from these plexuses penetrate the external coat and are principally distributed to the muscular tissue of the middle coat, and thus regulate, by causing the contraction and relaxation of this tissue, the amount of blood sent to any part.

The Capillaries.—The smaller arterial branches (excepting those of the cavernous structure of the sexual organs, of the spleen, and in the uterine placenta) terminate in a network of vessels which pervade nearly every tissue of the body. These vessels, from their minute size, are termed capillaries (*capillus*, a 'hair'). They are interposed between the smallest branches of the arteries and the commencing veins, constituting a network, the branches of which maintain the same diameter throughout; the meshes of the network being more uniform in shape and size than those formed by the anastomoses of the small arteries and veins.

The *diameter* of the capillaries varies in the different tissues of the body, their

usual size being about $\frac{1}{3000}$ of an inch. The smallest are those of the brain, and the mucous membrane of the intestines; and the largest those of the skin and the marrow of bone, where they are stated to be as large as $\frac{1}{1200}$ of an inch. The *form* of the capillary net varies in the different tissues, the meshes being generally rounded or elongated.

The *rounded form of mesh* is most common, and prevails where there is a dense network, as in the lungs, in most glands and mucous membranes, and in the cutis; here the meshes are more or less angular, sometimes nearly quadrangular, or polygonal, or more often irregular and not of an absolutely circular outline.

Elongated meshes are observed in the muscles and nerves, the meshes being usually of a parallelogram form, the long axis of the mesh running parallel with the long axis of the nerve and fibre. Sometimes the capillaries have a *looped* arrangement; a single vessel projecting from the common network and returning after forming one or more loops, as in the papillæ of the tongue and skin.

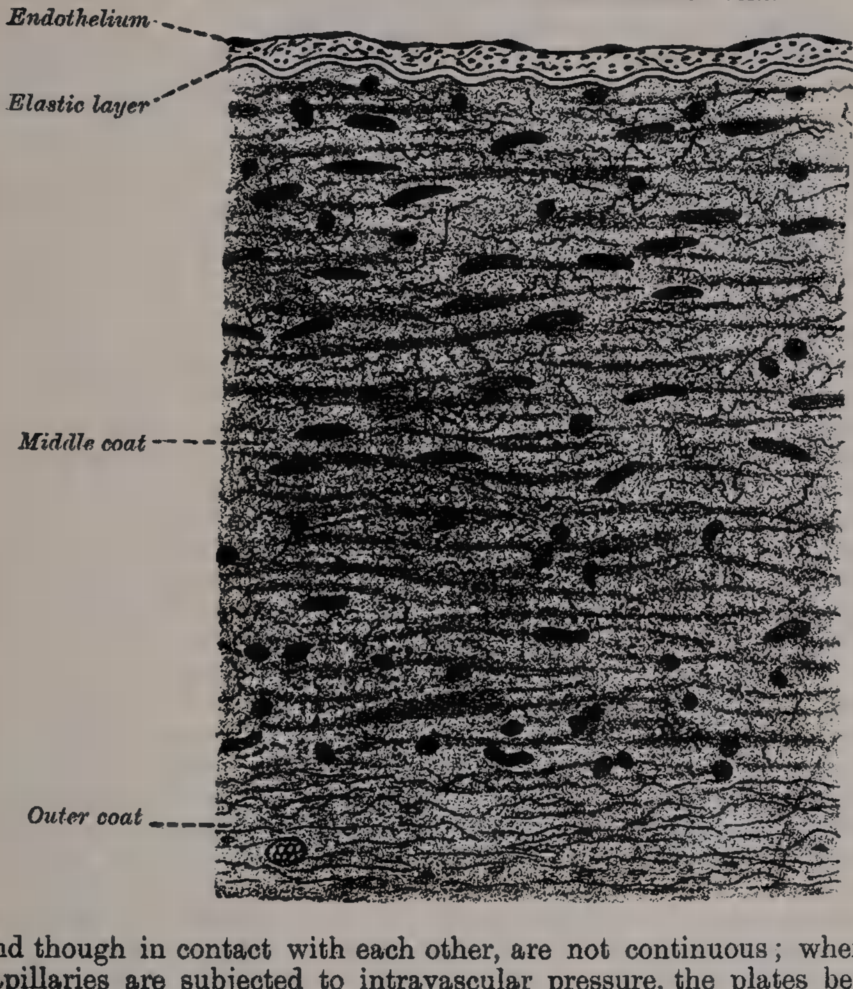
The number of the capillaries, and the size of the meshes, determine the degree of vascularity of a part. The closest network and the smallest interspaces are found in the lungs and in the choroid coat of the eye. In these situations the interspaces are smaller than the capillary vessels themselves. In the kidney, in the conjunctiva, and in the cutis the interspaces are from three to four times as large as the capillaries which form them; and in the brain from eight to ten times as large as the capillaries in their long diameter, and from four to six times as large in their transverse diameter. In the adventitia of arteries the width of the meshes is ten times that of the capillary vessels. As a general rule, the more active the function of the organ, the closer is its capillary net and the larger its supply of blood; the meshes of the network are very narrow in all growing parts, in the glands and in the mucous membranes; wider in bones and ligaments, which are comparatively inactive; and nearly altogether absent in tendons, in which very little organic change occurs after their formation.

Structure.—The walls of the capillaries consist of a fine transparent endothelial layer, composed of cells joined edge to edge by an interstitial cement substance,

and continuous with the endothelial cells which line the arteries and veins. When stained with nitrate of silver the edges which bound the epithelial cells are brought into view (fig. 71). These cells are of large size and of an irregular polygonal or lanceolate shape, each containing an oval nucleus which may be brought into view by carmine or hæmatoxylin. Between their edges, at various points of their meeting, roundish dark spots are sometimes seen, which have been described as stomata, though they are closed by intercellular substance. They have been believed to be the situation through which the white corpuscles of the blood, when migrating from the blood-vessels, emerge; but this view, though probable, is not universally accepted.

Kolossow, a Russian observer, describes these cells as having a rather more complex structure. He states that they consist of two parts: of hyaline ground-plates, and of a protoplasmic granular part, in which is embedded the nucleus, on the outside of the ground-plates. The hyaline internal coat of the capillaries does not form a complete membrane, but consists of 'plates' which are inelastic,

FIG. 73.—Section of a medium-sized vein.



and though in contact with each other, are not continuous; when therefore the capillaries are subjected to intravascular pressure, the plates become separated from each other; the protoplasmic portions of the cells, on the other hand, are united together.

In many situations a delicate sheath or envelope of branched nucleated connective-tissue cells is found around the simple capillary tube, particularly in the larger ones; and in other places, especially in the glands, the capillaries are invested with retiform connective tissue.

In the largest capillaries (which ought, perhaps, to be described rather as the smallest arteries or pre-capillaries) there is, outside the epithelial layer, a muscular layer, consisting of contractile fibre-cells, arranged tranversely, as in the tunica media of the arteries (fig. 72).

The **veins**, like the arteries, are composed of three coats—internal, middle, and external; and these coats are, with the necessary modifications, analogous to the coats of the arteries; the internal being the endothelial, the middle the muscular, and the external the connective or areolar (fig. 73). The main difference between

the veins and the arteries is in the comparative weakness of the middle coat of the former, and to this is due the fact that the veins do not stand open when divided, as the arteries do, and that they are passive rather than active organs of the circulation.

In the veins immediately above the capillaries the three coats are hardly to be distinguished. The endothelium is supported on an outer membrane separable into two layers, the outer of which is the thicker, and consists of a delicate, nucleated membrane (adventitia), while the inner is composed of a network of longitudinal elastic fibres (media). In the veins next above these in size (one-fifth of a line according to Kölliker) a connective-tissue layer containing numerous muscle-fibres circularly disposed can be traced, forming the middle coat, while the elastic and connective-tissue elements of the outer coat become more distinctly perceptible. In the middle-sized veins the typical structure of these vessels becomes clear. The endothelium is of the same character as in the arteries, but its cells are more oval and less fusiform. It is supported by a connective-tissue layer, consisting of a delicate network of branched cells, and external to this is a layer of elastic fibres disposed in the form of a network in place of the definite fenestrated membrane seen in arteries. This constitutes the *internal* coat. The *middle* coat is composed of a thick layer of connective tissue with elastic fibres, intermixed, in some veins, with a transverse layer of muscular tissue. The white fibrous element is in considerable excess, and the elastic fibres are in much smaller proportion in the veins than in the arteries. The *outer* coat consists of areolar tissue, as in the arteries, with longitudinal elastic fibres. In the largest veins the outer coat is from two to five times thicker than the middle coat, and contains a large number of longitudinal muscular fibres. This is most distinct in the inferior vena cava, especially at the termination of this vein in the heart, in the trunks of the hepatic veins, in all the large trunks of the vena portæ, in the splenic, superior mesenteric, external iliac, renal and azygos veins. In the renal and portal veins it extends through the whole thickness of the outer coat, but in the other veins mentioned a layer of connective and elastic tissue is found external to the muscular fibres. All the large veins which open into the heart are covered for a short distance with a layer of striped muscular tissue continued on to them from the heart. Muscular tissue is wanting—(1) in the veins of the maternal part of the placenta; (2) in the venous sinuses of the dura mater and the veins of the pia mater of the brain and spinal cord; (3) in the veins of the retina; (4) in the veins of the cancellous tissue of bones; (5) in the venous spaces of the corpora cavernosa. The veins of the above-mentioned parts consist of an internal endothelial lining supported on one or more layers of areolar tissue.

Most veins are provided with valves, which serve to prevent the reflux of the blood. They are formed by a reduplication of the inner coat, strengthened by connective tissue and elastic fibres, and are covered on both surfaces with endothelium, the arrangement of which differs on the two surfaces. On the surface of the valve next the wall of the vein, the cells are arranged transversely; while on the other surface, over which the current of blood flows, the cells are arranged vertically in the direction of the current. The valves are semilunar. They are attached by their convex edge to the wall of the vein; the concave margin is free, directed in the course of the venous current, and lies in close apposition with the wall of the vein as long as the current of blood takes its natural course; if, however, any regurgitation takes place, the valves become distended, their opposed edges are brought into contact, and the current is interrupted. Most commonly two such valves are found placed opposite one another, more especially in the smaller veins or in the larger trunks at the point where they are joined by smaller branches; occasionally there are three and sometimes only one. The wall of the vein on the cardiac side of the point of attachment of each segment of the valve is expanded into a pouch or sinus, which gives to the vessel, when injected or distended with blood, a knotted appearance. The valves are very numerous in the veins of the extremities, especially of the lower extremities; these vessels having to conduct the blood against the force of gravity. They are absent in the very small veins, i.e. those less than $\frac{1}{12}$ of an inch in diameter, also in the venæ cavæ, the hepatic veins, portal vein and most of its branches, the renal, uterine, and ovarian veins. A few valves are found in the spermatic veins, and one also at their point of junction with the renal vein and inferior vena cava

respectively. The cerebral and spinal veins, the veins of the cancellated tissue of bone, the pulmonary veins, and the umbilical vein and its branches, are also destitute of valves. They are occasionally found, few in number, in the venæ azygos and intercostal veins.

The veins are supplied with nutrient vessels, *vasa vasorum*, like the arteries. Nerves also are distributed to them in the same manner as to the arteries, but in much less abundance.

The **lymphatic** vessels, including in this term the lacteal vessels, which are identical in structure with them, are composed of three coats. The *internal* is an endothelial and elastic coat. It is thin, transparent, slightly elastic, and ruptures sooner than the other coats. It is composed of a layer of elongated endothelial cells with serrated margins, by which the adjacent cells are dovetailed into one another. These are supported on an elastic membrane. The *middle* coat is composed of smooth muscular and fine elastic fibres, disposed in a transverse direction. The *external* coat consists of connective tissue, intermixed with smooth muscular fibres, longitudinally or obliquely disposed. It forms a protective covering to the other coats, and serves to connect the vessel with the neighbouring structures. The above description applies only to the larger lymphatics; in the smaller vessels there is no muscular or elastic coat, and their structure consists only of a connective-tissue coat, lined by endothelium. The thoracic duct is a somewhat more complex structure than the other lymphatics; it presents a distinct subendothelial layer of branched corpuscles, similar to that found in the arteries, and in the middle coat is a layer of connective tissue with its fibres arranged longitudinally. The lymphatics are supplied by nutrient vessels, which are distributed to their outer and middle coats; and here also have been traced many non-medullated nerve-fibres in the form of a fine plexus of fibrils.

The lymphatics are very generally provided with valves, which assist materially in effecting the circulation of the fluid they contain. These valves are formed of a thin layer of fibrous tissue, lined on both surfaces by endothelium, which presents the same arrangement upon the two surfaces as was described in connection with the valves of veins. Their form is semilunar; they are attached by their convex edge to the sides of the vessel, the concave edge being free and directed along the course of the contained current. Usually two such valves, of equal size, are found opposite one another; but occasionally exceptions occur, especially at or near the anastomoses of lymphatic vessels. Thus, one valve may be of very rudimentary size and the other increased in proportion.

The valves in the lymphatic vessels are placed at much shorter intervals than in the veins. They are most numerous near the lymphatic glands, and they are found more frequently in the lymphatics of the neck and upper extremity than in the lower. The wall of the lymphatics immediately above the point of attachment of each segment of a valve is expanded into a pouch or sinus, which gives to these vessels, when distended, the knotted or beaded appearance which they present. Valves are wanting in the vessels composing the plexiform network in which the lymphatics usually originate on the surface of the body.

Origin of Lymphatics.—The finest visible lymphatic vessels (lymphatic capillaries) form a plexiform network in the tissues and organs, and they consist of a single layer of endothelial plates, with more or less sinuous margins. These vessels commence in an intercommunicating system of clefts or spaces, which have no complete endothelial lining, in the connective tissue of the different organs. They have been named the *rootlets* of the lymphatics, and are identical with the spaces in which the connective-tissue corpuscles are contained. This then is properly regarded as one method of their commencement, where the lymphatic vessels are apparently continuous with spaces in the connective tissue, and Klein has described and figured a direct communication between these spaces and the lymphatic vessel.* But the lymphatics have also other modes of origin, for the intestinal lacteals commence by closed extremities, though some observers believe that the closed extremity is continuous with a minute network contained in the substance of the villus, through which the lacteal is connected with the endothelial cells covering it. Again, it seems now to be conclusively proved that the serous membranes present stomata or openings between the endothelial cells

* *Atlas of Histology*, pl. viii. fig. xiv.

(fig. 74), by which there is an open communication with the lymphatic system and through which the lymph is thought to be pumped by the alternate dilatation and contraction of the serous surface, due to the movements of respiration and circulation, so that the serous and synovial sacs may be regarded, in a certain sense, as large lymph cavities or sinuses.* Von Recklinghausen was the first to observe the passage of milk and other coloured fluids through these stomata on the peritoneal surface of the central tendon of the diaphragm. Again, in most glandular structures the lymphatic capillaries have a lacunar origin. Here they begin in irregular clefts or spaces in the tissue of the part; occupying the penetrating connective tissue and surrounding the lacunæ or tubules of the gland, and in many places separating the capillary network from the alveolus or tubule, so that the interchange between the blood and the secreting cells of the part must be carried on through these lymph-spaces or lacunæ. Closely allied to this is the mode of origin of lymphatics in perivascular and perineural spaces. Sometimes a minute artery may be seen to be ensheathed for a certain distance by a lymphatic capillary vessel, which is often many times wider than a blood capillary. These are known as perivascular lymphatics.

Section through the pleura of the same animal. *b.* Free orifices of short lateral passages of the lymph-canals. (Copied from Ludwig, Schweigger-Seidel and Dybkowsky.)

Terminations of Lymphatics.—The lymphatics, including the lacteals, discharge their contents into the veins at two points: namely, at the angles of junction of the subclavian and internal jugular veins: on the left side by means of the thoracic duct, and on the right side by the right lymphatic duct. (See description of lymphatics.)

Lymphatic Glands (*lymph glands*) are small oval or bean-shaped bodies, situated in the course of lymphatic and lacteal vessels so that the lymph and chyle pass through them on their way to the blood. They generally present on one side a slight depression—the *hilum*—through which the blood-vessels enter and leave the interior. The efferent lymphatic vessel also emerges from the gland at this spot, while the afferent vessels enter the organ at different parts of the periphery. On section (fig. 75), a lymphatic gland displays two different structures: an external, of lighter colour—the *cortical*; and an internal, darker—the *medullary*. The cortical structure does not form a complete investment, but is deficient at the hilum, where the medullary portion reaches the surface of the gland; so that the efferent vessel is derived directly from the medullary structure, while the afferent vessels empty themselves into the cortical substance.

Lymphatic glands consist of (1) a fibrous envelope, or *capsule*, from which a framework of processes (*trabeculæ*) proceeds inwards, imperfectly dividing the gland into open spaces freely communicating with each other; (2) a quantity of lymphoid tissue occupying these spaces without completely filling them; (3) a free supply of blood-vessels, which are supported on the trabeculæ; and (4) the *afferent* and *efferent* vessels. The nerves passing into the hilum are few in number and are chiefly distributed to the blood-vessels supplying the gland.

The *capsule* is composed of connective tissue with some plain muscle-fibres, and from its internal surface are given off a number of membranous processes or trabeculæ, consisting, in man, of connective tissue, with a small admixture of plain muscle-fibres; but in many of the lower animals composed almost entirely of involuntary muscle. They pass inwards, radiating towards the centre of the

* The resemblance between lymph and serum led Hewson long ago to regard the serous cavities as sacs into which the lymphatics open. Recent microscopic discoveries confirm this opinion in a very interesting manner.

gland, for a certain distance—that is to say, for about one-third or one-fourth of the space between the circumference and the centre of the gland. In some animals

they are sufficiently well marked as to apparently divide the peripheral or cortical portion of the gland into a number of compartments (so-called follicles), but in

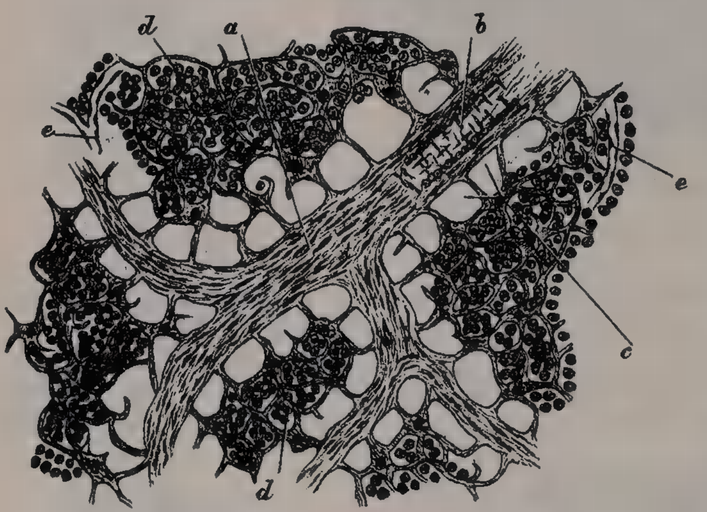
man this arrangement is not apparent. The larger trabeculæ springing from the capsule break up into finer bands, and these interlace to form a meshwork in the central or medullary portion of the gland. In these spaces formed by the interlacing trabeculæ (fig. 76) is contained the proper gland-substance or lymphoid tissue. The gland-pulp does not, however, completely

fill the spaces, but leaves, between its outer margin and the enclosing trabeculæ, a channel or space of uniform width throughout. This is termed the *lymph-path* or *lymph-sinus* (fig. 78). Running across it are a number of finer trabeculæ of retiform connective tissue, the fibres of which are, for the most part, covered by ramified cells.

On account of the peculiar arrangement of the framework of the organ, the gland-pulp in the cortical portion is disposed in the form of nodules, and in the medullary part in the form of rounded cords. It consists of ordinary lymphoid tissue, being made up of a delicate reticulum of retiform tissue, which is continuous with that in the lymph-paths, but marked off from it by a closer reticulation; in its meshes are closely packed lymph-corpuscles, traversed by a dense plexus of capillary blood-vessels. It is probable, moreover, that the reticular tissue of the gland-pulp and the lymph-paths is continuous with that of the trabeculæ, and ultimately with that of the capsule of the gland. The nodules or follicles in the cortical portion of the gland frequently show, in their centres, areas where karyokinetic figures indicate the division of the lymph-corpuscles. These areas are termed *germ-centres* (fig. 75).

Fig. 78.—Section of lymphatic-gland tissue.



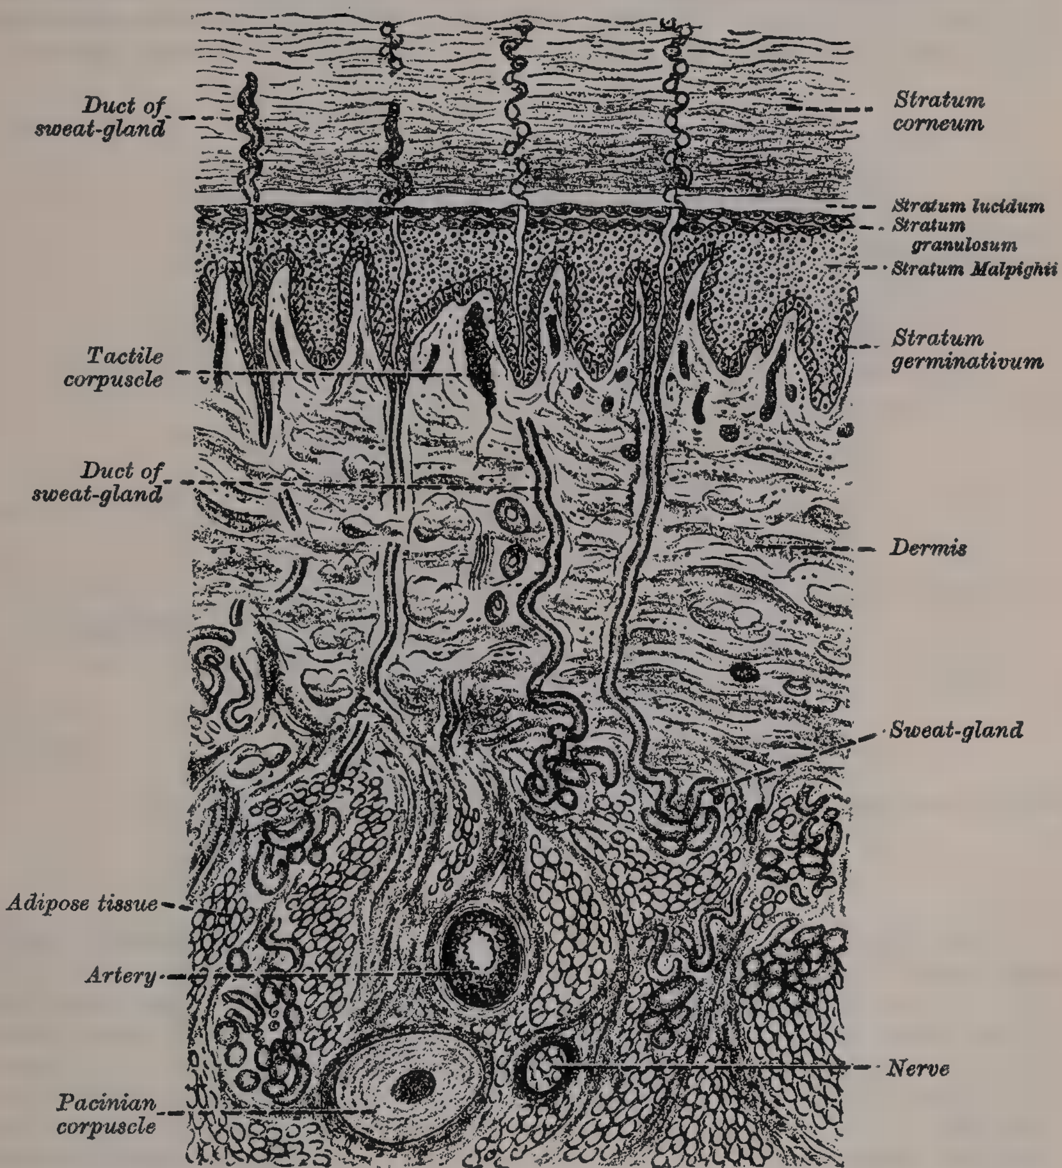
a. Trabeculæ. b. Small artery in substance of same. c. Lymph-paths. d. Lymph-corpuscles. e. Capillary plexus.

The *afferent vessels*, as above stated, enter at all parts of the periphery of the gland, and after branching and forming a dense plexus in the substance of the capsule open into the lymph-sinuses of the cortical part. In doing this, they lose all their coats except their endothelial lining, which is continuous with a layer of similar cells lining the lymph-paths. In like manner the *efferent* vessel commences from the lymph-sinuses of the medullary portion. The stream of lymph carried to the gland by the afferent vessel thus passes through the plexus in the capsule to the lymph-paths of the cortical portion, where it is exposed to the action of the gland-pulp; flowing through these it enters the paths or sinuses of the medullary portion, and finally emerges from the hilum by means of the efferent vessel. The stream of lymph in its passage through the lymph-sinuses is much retarded by the presence of the reticulum. Hence morphological elements, either normal or morbid, are easily arrested and deposited in the sinuses. This is a matter of considerable importance in connection with the subject of poisoned wounds and the absorption of the poison by the lymphatic system, since by this means septic organisms carried along the lymphatic vessels may be arrested in the lymph-sinuses of the gland-tissue, and thus be prevented from entering the general circulation. Many lymph-corpuscles pass with the efferent lymph-stream to join the general blood-stream. The arteries of the gland enter at the hilum, and either pass at once to the gland-pulp, to break up into a capillary plexus, or else run along the trabeculæ, partly to supply them and partly running across the lymph-paths to assist in forming the capillary plexus of the gland-pulp. This plexus traverses the lymphoid tissue, but does not pass into the lymph-sinuses. From it the veins commence and emerge from the organ at the same place as that at which the artery enters.

THE SKIN AND ITS APPENDAGES

The **skin** (fig. 79) is the principal seat of the sense of touch, and may be regarded as a covering for the protection of the deeper tissues; it plays an important part in the regulation of the body temperature, and is also an excretory and absorbing organ. It consists principally of a layer of vascular connective tissue, named the *dermis, corium,* or *cutis vera,* and an external covering of epithelium, termed the *epidermis* or *cuticle.* On the surface of the former layer are the sensitive *papillæ*; and within, or embedded beneath it, are certain organs with special functions: namely, the *sweat-glands, hair-follicles,* and *sebaceous glands.*

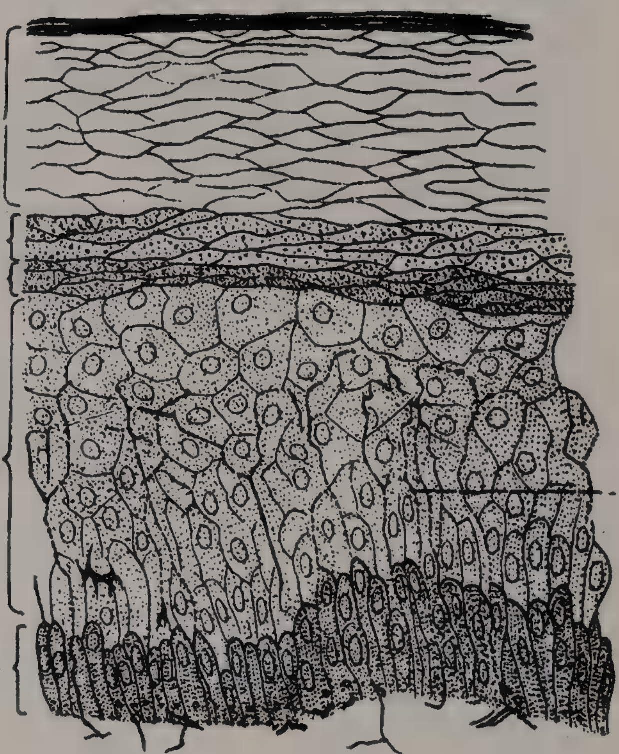
FIG. 79.—A diagrammatic sectional view of the skin (magnified).



The **epidermis** or **cuticle** (*scarf-skin*) is non-vascular, and consists of stratified epithelium (fig. 80). It is accurately moulded on the papillary layer of the dermis. It forms a defensive covering to the surface of the true skin, and limits the evaporation of watery vapour from its free surface. It varies in thickness in different parts. In some situations, as in the palms of the hands and soles of the feet, it is thick, hard, and horny in texture. This may be in a measure due to the fact that these parts are exposed to intermittent pressure, but that this is not the only cause is proved by the fact that the condition exists to a very considerable extent at birth. The more superficial layers of cells, called the *horny* layer (*stratum corneum*), may be separated by maceration from the deeper layers, which are

called the *rete mucosum* or *stratum Malpighii*, and which consist of several layers of differently shaped cells. The free surface of the epidermis is marked by a network of linear furrows of variable size, marking out the surface into a number of spaces of polygonal or lozenge-shaped form. Some of these furrows are large, as opposite the flexures of the joints, and correspond to the folds in the dermis produced by their movements. In other situations, as upon the back of the hand, they are exceedingly fine, and intersect one another at various angles. Upon the palmar surface of the hand and fingers, and upon the sole of the foot, these lines are very distinct, and are disposed in curves; they depend upon the large size and peculiar arrangement of the papillæ upon which the epidermis is placed. The deep surface of the epidermis is accurately moulded upon the papillary layer of the dermis, each papilla being invested by its epidermic sheath; so that when this layer is removed by maceration, it presents on its under surface a number of pits or depressions corresponding to the elevations in the papillæ, as well as the ridges left in the intervals between them. Fine tubular prolongations are continued from this layer into the ducts of the sudoriferous and sebaceous glands.

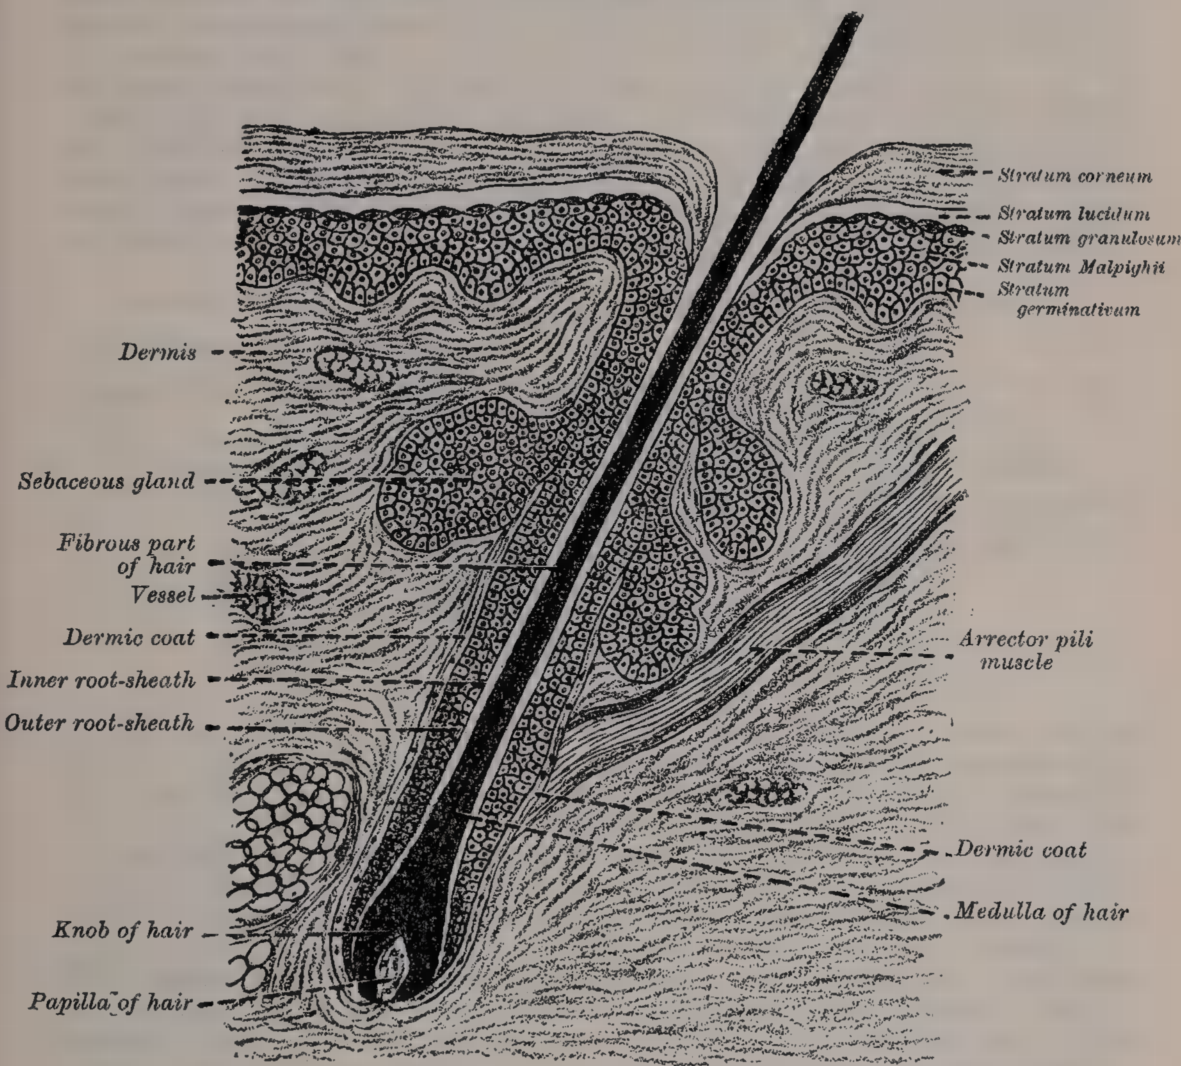
FIG. 80.—Section of epidermis. (Ranvier.)



In structure, the epidermis consists of several layers of epithelial cells, agglutinated together and having a laminated arrangement. These several layers may be described as composed of four different strata from within outwards: (1) the *stratum Malpighii*, composed of several layers of epithelial cells, of which the deepest layer is columnar in shape and placed perpendicularly on the surface of the corium, their lower ends being denticulate, to fit into corresponding denticulations of the true skin; this deepest layer is sometimes termed the basilar layer or *stratum germinativum*; the succeeding laminæ consist of cells of a more rounded or polyhedral form, the contents of which are soft, opaque, granular, and soluble in acetic acid. They are often marked on their surfaces with ridges and furrows, and are covered with numerous fibrils, which connect the surfaces of the cells: these are known as *prickle* cells (see page 13). They contain numerous epidermic fibrils, which are stained violet with hæmatoxylin and red by carmine, and form threads of union connecting adjacent cells. Between the cells are fine intercellular clefts which serve for the passage of lymph and in which lymph-corpuscles or pigment-granules may be found. (2) Immediately superficial to these are two or three layers of flattened, spindle-shaped cells, the *stratum granulosum*, which contain granules that become deeply stained in hæmatoxylin; the granules consist of a material named *eleidin*, an intermediate substance in the formation of

keratin. They are supposed to be cells in a transitional stage between the protoplasmic cells of the stratum Malpighii and the horny cells of the superficial layers. (3) Above this layer, the cells become indistinct, and appear, in sections, to form a homogeneous or dimly striated membrane, composed of closely packed scales, in which traces of a flattened nucleus may be found. It is called the *stratum lucidum*. (4) As these cells successively approach the surface by the development of fresh layers from beneath, they assume a flattened form, from the evaporation of their fluid contents, and consist of many layers of horny epithelial scales in which no nucleus is discernible, forming the *stratum corneum*. These cells are unaffected by acetic acid, the protoplasm having become changed into horny material or *keratin*. According to Ranvier they contain granules of a material

FIG. 81.—Section of skin, showing the epidermis and dermis: a hair in its follicle: the arrector pili muscle; sebaceous glands.



which has the characters of beeswax. The deepest layer of the stratum Malpighii is separated from the papillæ by an apparently homogeneous basement-membrane, which is most distinctly brought into view in specimens prepared with chloride of gold. This, according to Klein, is merely the deepest portion of the epithelium, and is 'made up of the basis of the individual cells, which have undergone a chemical and morphological alteration.' The black colour of the skin in the negro, and the tawny colour among some of the white races, is due to the presence of pigment in the cells of the cuticle. This pigment is more especially distinct in the cells of the deeper layer, or stratum Malpighii, and is similar to that found in the cells of the pigmentary layer of the retina. As the cells approach the surface and desiccate, the colour becomes partially lost; the disappearance of the pigment from the superficial layers of the epidermis is, however, difficult to explain.

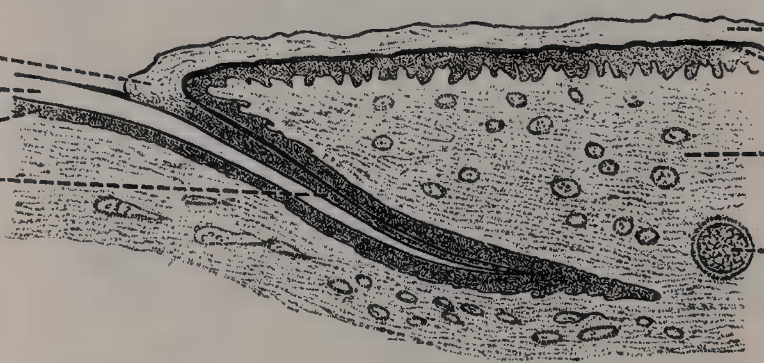
The **dermis, corium,** or **cutis vera** is tough, flexible, and highly elastic, in order to defend the parts beneath from violence.

It varies in thickness, from a quarter of a line to a line and a half, in different parts of the body. Thus it is very thick in the palms of the hands and soles of the feet; thicker on the posterior aspect of the body than the front, and on the outer than the inner side of the limbs. In the eyelids, scrotum, and penis it is exceedingly thin and delicate. The skin generally is thicker in the male than in the female, and in the adult than in the child.

The corium consists of felted connective tissue, with a varying amount of elastic fibres and numerous blood-vessels, lymphatics, and nerves. The fibro-areolar tissue forms the framework of the cutis, and is differently arranged in different parts, so that it is usual to describe it as consisting of two layers: the deeper or *reticular* layer, and the superficial or *papillary* layer. Unstriped muscular fibres are found in the superficial layers of the corium, wherever hairs are present; and in the subcutaneous areolar tissue of the scrotum, penis, labia majora of the female, and the nipples. In the last situation the fibres are disposed in bands, closely reticulated and arranged in superimposed laminæ.

The *reticular* layer consists of strong interlacing fibrous bands, composed chiefly of the white variety of fibrous tissue, but containing, also, some fibres of the yellow elastic tissue, which vary in number in different parts; and connective-tissue corpuscles, which are often to be found flattened against the white fibrous tissue bundles. Towards the attached surface the fasciculi are large and coarse, and the areolæ which are left by their interlacement are large, and occupied by

FIG. 82.—Longitudinal section through human nail and its nail groove (sulcus).



adipose tissue and sweat-glands. Below this the elements of the skin become gradually blended with the subcutaneous areolar tissue, which, except in a few situations, contains fat. Towards the free surface the fasciculi are much finer, and their mode of interlacing close and intricate.

The *papillary layer* is situated upon the free surface of the *reticular layer*; it consists of numerous small, highly sensitive, and vascular eminences, the *papillæ*, which rise perpendicularly from its surface. The papillæ are conical-shaped eminences, having a round or blunted extremity, occasionally divided into two or more parts, and are received into corresponding pits on the under surface of the cuticle. Their average length is about $\frac{1}{100}$ of an inch, and they measure at their base $\frac{1}{250}$ of an inch in diameter. On the general surface of the body, more especially in those parts which are endowed with slight sensibility, they are few in number, short, exceedingly minute, and irregularly scattered over the surface; but in some situations, as upon the palmar surface of the hands and fingers, upon the plantar surface of the feet and toes, and around the nipple, they are long, of large size, closely-aggregated together, and arranged in parallel curved lines, forming the elevated ridges seen on the free surface of the epidermis. Each ridge contains two rows of papillæ, and between the two rows the ducts of the sweat-glands pass outwards to open on the summit of the ridges. In structure the papillæ consist of very small and closely interlacing bundles of finely fibrillated tissue, with a few elastic fibres; within this tissue is a capillary loop, and in some papillæ, especially in the palms of the hands and the fingers, there are tactile corpuscles.

The *arteries* supplying the skin form a network in the subcutaneous tissue, from which branches are given off to supply the sweat-glands, the hair-follicles,

and the fat. Other branches are given off which constitute a plexus immediately beneath the corium; from this, fine capillary vessels pass into the papillæ, forming, in the smaller ones, a single capillary loop, but in the larger, a more or less convoluted vessel. There are numerous *lymphatics* supplied to the skin, which form two networks, superficial and deep, communicating with each other and with those of the subcutaneous tissue by oblique branches. They originate in the cell-spaces of the tissue.

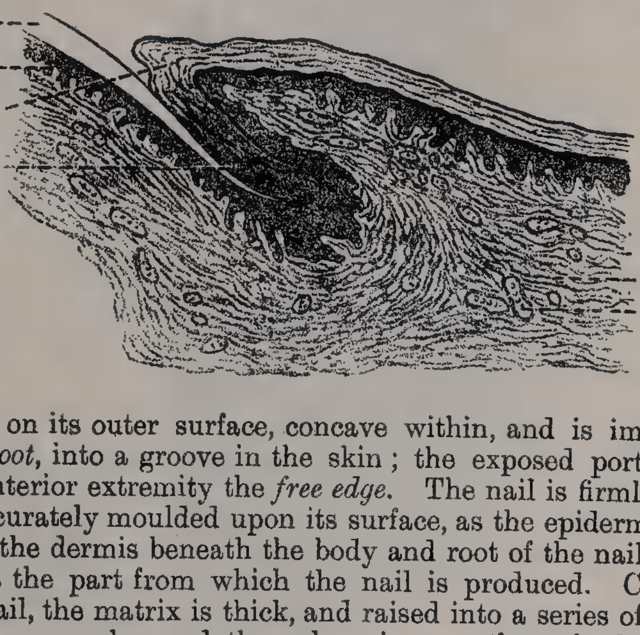
The *nerves* of the skin terminate partly in the epidermis and partly in the cutis vera. The former are prolonged into the epidermis from a dense plexus in the superficial layer of the corium and terminate between the cells in bulbous extremities; or, according to some observers, in the deep epithelial cells themselves. The latter terminate in end-bulbs, touch-corpuscles, or Pacinian bodies, in the manner already described; and, in addition to these, a considerable number of fibrils are distributed to the hair-follicles, which are said to entwine the follicle in a circular manner. Other nerve-fibres are supplied to the plain muscular fibres of the hair-follicles (arrectores pili) and to the muscular coat of the blood-vessels. These are probably non-medullated fibres.

The **appendages of the skin** are the nails, the hairs, the sudoriferous and sebaceous glands, and their ducts.

The nails and hairs are peculiar modifications of the epidermis, consisting essentially of the same cellular structure as that tissue.

The **nails** (figs. 82 and 83) are flattened, elastic structures of a horny texture, placed upon the dorsal surface of the terminal phalanges of the fingers and toes.

FIG. 83.—Transverse section through human nail and its sulcus.



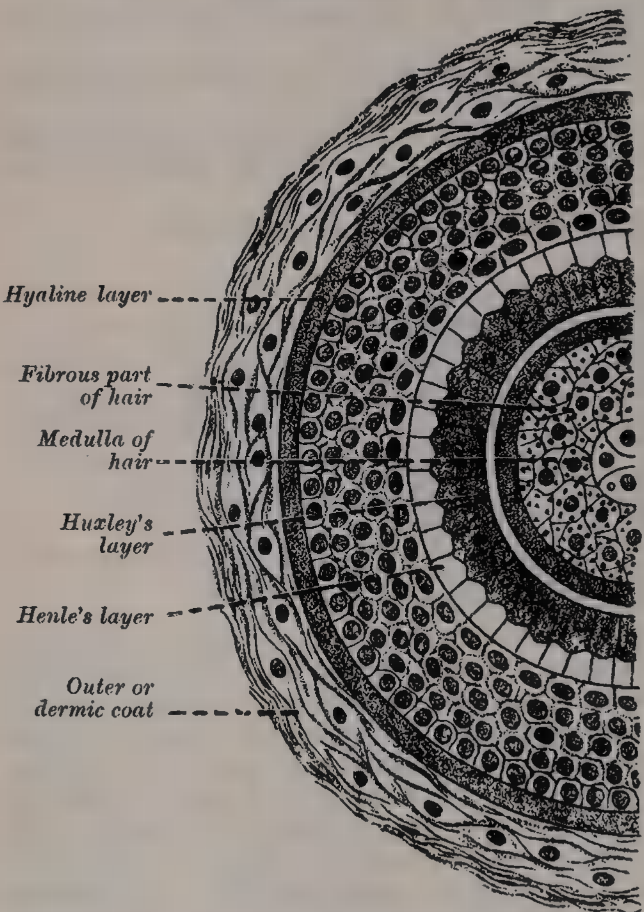
Each nail is convex on its outer surface, concave within, and is implanted by a portion, called the *root*, into a groove in the skin; the exposed portion is called the *body*, and the anterior extremity the *free edge*. The nail is firmly adherent to the dermis, being accurately moulded upon its surface, as the epidermis is in other parts. The part of the dermis beneath the body and root of the nail is called the *matrix*, because it is the part from which the nail is produced. Corresponding to the body of the nail, the matrix is thick, and raised into a series of longitudinal ridges which are very vascular, and the colour is seen through the transparent tissue. Behind this, near the root of the nail, there are papillæ which are small, less vascular, and have no regular arrangement, and here the tissue of the nail is somewhat more opaque; hence this portion is of a whiter colour, and is called the *lunula* on account of its shape.

The cuticle, as it passes forwards on the dorsal surface of the finger or toe, is attached to the surface of the nail, a little in advance of its root; at the extremity of the finger it is connected with the under surface of the nail a little behind its free edge. The cuticle and horny substance of the nail (both epidermic structures) are thus directly continuous with each other. The nails consist of a greatly thickened stratum lucidum, the stratum corneum forming merely the thin cuticular fold (*eponychium*) which overlaps the lunula. The cells have a laminated arrangement, and are essentially similar to those composing the epidermis. The cells of the deepest layer, which lie in contact with the papillæ of the matrix, are columnar in form and arranged perpendicularly to the surface; those which succeed them are of a rounded or polygonal form, the more superficial ones becoming broad, thin, and flattened, and so closely packed as to make the limits of each cell very

indistinct. It is by the successive growth of new cells at the root and under surface of the body of the nail that it advances forwards and maintains a due thickness, while, at the same time, the growth of the nail in the proper direction is secured. As these cells in their turn become displaced by the growth of new ones, they assume a flattened form, and finally become compacted together into a firm, dense, horny texture. In *chemical composition* the nails resemble the upper layers of the epidermis. According to Mulder, they contain a somewhat larger proportion of carbon and sulphur.

The **hairs** are peculiar modifications of the epidermis, and consist essentially of the same structure as that membrane. They are found on nearly every part of the surface of the body, excepting the palms of the hands, soles of the feet, and the glans penis. They vary much in length, thickness, and colour in different parts of the body and in different races of mankind. In some parts, as in the skin of the eyelids, they are so short as not to project beyond the follicles containing them; in others, as upon the scalp, they are of considerable length; again, in other parts, as the eyelashes, the hairs of the pubic region, and the whiskers and beard, they are remarkable for their thickness. Straight hairs are stronger than curly hairs, and present on transverse section a cylindrical or oval outline; curly hairs, on the other hand, are flattened.

Fig. 84.—Transverse section of hair-follicle.



A hair consists of a *root*, the part implanted in the skin; the *shaft* or *stem*, the portion projecting from its surface; and the *point*.

The *root of the hair* presents at its extremity a bulbous enlargement, which is whiter in colour and softer in texture than the shaft, and is lodged in a follicular involution of the epidermis called the *hair-follicle* (fig. 81). When the hair is of considerable length the follicle extends into the subcutaneous cellular tissue. The hair-follicle commences on the surface of the skin with a funnel-shaped opening, and passes inwards in an oblique or curved direction—the latter in curly hairs—to become dilated at its deep extremity, where it corresponds with the bulbous condition of the hair which it contains. It has opening into it, near its free extremity, the orifices of the ducts of one or more sebaceous glands. At the bottom of each hair-follicle is a small conical, vascular eminence or papilla, similar in every respect to those found upon the surface of the skin; it is continuous with the dermic layer of the follicle, is highly vascular, and probably supplied with nervous fibrils. In structure the hair-follicle consists of two coats—an outer or *dermic*, and an inner or *epidermic*.

The *outer* or *dermic* coat is formed mainly of fibrous tissue; it is continuous with the corium, is highly vascular, and supplied by numerous minute nervous filaments. It consists of three layers (fig. 84). The most internal, next the cuticular lining of the follicle, consists of a hyaline basement-membrane having a glassy, transparent appearance, which is well marked in the larger hair-follicles, but is not very distinct in the follicles of minute hairs. It is continuous with the basement-membrane of the surface of the corium. External to this is a compact

layer of fibres and spindle-shaped cells arranged circularly around the follicle. This layer extends from the bottom of the follicle as high as the entrance of the ducts of the sebaceous glands. Externally is a thick layer of connective tissue, arranged in longitudinal bundles, forming a more open texture and corresponding to the reticular part of the corium. In this are contained the blood-vessels and nerves.

The *inner* or *epidermic* layer is closely adherent to the root of the hair, so that when the hair is plucked from its follicle this layer most commonly adheres to it and forms what is called the *root-sheath*. It consists of two strata named respectively the *outer* and *inner root-sheaths*; the former of these corresponds with the Malpighian layer of the epidermis, and resembles it in the rounded form and soft character of its cells; at the bottom of the hair-follicle these cells become continuous with those of the root of the hair. The *inner* root-sheath consists of a delicate cuticle next the hair, composed of a thin layer of imbricated scales having a downward direction, so that they fit accurately over the upwardly directed imbricated scales of the hair itself; then of one or two layers of horny, flattened, nucleated cells, known as *Huxley's layer*; and finally of a single layer of horny oblong cells without visible nuclei, called *Henle's layer*.

The hair-follicle contains the root of the hair, which terminates in a bulbous extremity, and is excavated so as to exactly fit the papilla from which it grows. The bulb is composed of polyhedral epithelial cells, which as they pass upwards into the root of the hair become elongated and spindle-shaped, except some in the centre which remain polyhedral. Some of these latter cells contain pigment-granules, which give rise to the colour of the hair. It occasionally happens that these pigment-granules completely fill the cells in the centre of the bulb; this gives rise to the dark tract of pigment often found, of greater or less length, in the axis of the hair.

The *shaft of the hair* consists of a central pith or medulla, the fibrous part of the hair, and the cuticle externally. The *medulla* occupies the centre of the shaft and ceases towards the point of the hair. It is usually wanting in the fine hairs covering the surface of the body, and commonly in those of the head. It is more opaque and deeper coloured when viewed by transmitted light than the fibrous part; but when viewed by reflected light it is white. It is composed of rows of polyhedral cells, which contain granules of eleidin and frequently air-bubbles. The *fibrous* portion of the hair constitutes the chief part of the shaft; its cells are elongated and unite to form flattened fusiform fibres. Between the fibres are found minute spaces which contain either pigment-granules in dark hair, or minute air-bubbles in white hair. In addition to this there is also a diffused pigment contained in the fibres. The cells which form the *hair-cuticle* consist of a single layer which surrounds those of the fibrous part; they are converted into thin, flat scales, having an imbricated arrangement.

Connected with the hair-follicles are minute bundles of involuntary muscular fibres, termed the *arrectores pili*. They arise from the superficial layer of the corium, and are inserted into a thickened portion of the outer surface of the hair-follicle, below the entrance of the duct of the sebaceous gland. They are placed on the side towards which the hair slopes, and by their action elevate the hair (fig. 81).* The sebaceous gland is situated in the angle which the arrector muscle forms with the superficial portion of the hair-follicle, and contraction of the muscle thus tends to squeeze the sebaceous secretion out from the duct of the gland.

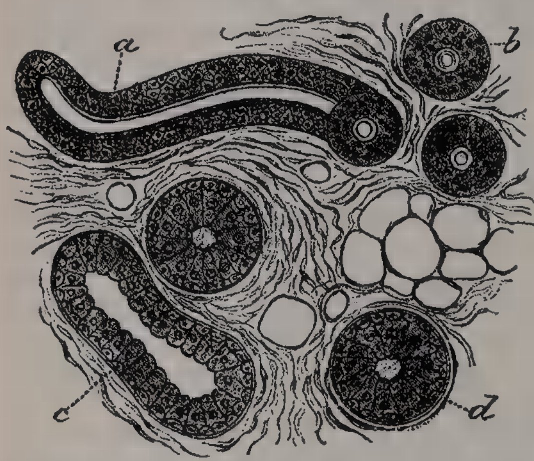
The **sebaceous glands** are small, sacculated, glandular organs, lodged in the substance of the corium. They are found in most parts of the skin, but are especially abundant in the scalp and face: they are also very numerous around the apertures of the anus, nose, mouth, and external ear, but are wanting in the palms of the hands and soles of the feet. Each gland consists of a single duct, more or less capacious, which terminates in a cluster of small secreting pouches or saccules. The sacculi connected with each duct vary, as a rule, in number from two to five, but, in some instances, may be as many as twenty. They are

* Arthur Thomson suggests that the contraction of these muscles on follicles which contain weak, flat hairs will tend to produce a permanent curve in the follicle, and this curve will be impressed on the hair which is moulded within it, so that the hair, on emerging through the skin, will be curled. Curved hair-follicles are characteristic of the scalp of the Bushman.

composed of a transparent, colourless membrane, enclosing a number of epithelial cells. Those of the outer or marginal layer are small and polyhedral, and are continuous with the lining cells of the duct. The remainder of the sac is filled with larger cells, containing fat, except in the centre, where the cells have become broken up, leaving a cavity filled with their débris and a mass of fatty matter, which constitutes the sebaceous secretion. The orifices of the ducts open most frequently into the hair-follicles, but occasionally upon the general surface, as in the labia minora and the free margin of the lips. On the nose and face the glands are of large size, distinctly lobulated, and often become much enlarged from the accumulation of pent-up secretion. The largest sebaceous glands are those found in the eyelids—the Meibomian glands.

The **sudoriferous** or **sweat glands** are the organs by which a large portion of the aqueous and gaseous materials are excreted by the skin. They are found in almost every part of this structure, and are situated in small pits on the under surface of the corium, or, more frequently, in the subcutaneous areolar tissue, surrounded by a quantity of adipose tissue. They are small, lobular, reddish bodies, consisting of a single convoluted tube, from which the efferent duct proceeds upwards through the corium and cuticle, becomes somewhat dilated at its extremity, and opens on the surface of the cuticle by an oblique valve-like aperture. The duct, as it passes through the epidermis, presents a spiral arrangement, being twisted like a corkscrew, in those parts where the epidermis is thick; where, however, it is thin, the spiral arrangement does not exist. In the superficial layers of the corium the duct is straight, but in the deeper layers it is convoluted or even twisted. The spiral course of these ducts is particularly distinct in the thick cuticle of the palm of the hand and sole of the foot. The size of the glands varies. They are especially large in those regions where the amount of perspiration is great, as in the axillæ, where they form a thin, mammillated layer of a reddish colour, which corresponds exactly to the situation of the hair in this region; they are large also in the groin. Their number varies. They are most numerous on the palm of the hand, presenting, according to Krause, 2,800 orifices on a square inch of the integument, and are rather less numerous on the sole of the foot. In both of these situations the orifices of the ducts are exceedingly regular, and open on the curved ridges. In other situations they are more irregularly scattered, but the number in a given extent of surface presents a fairly uniform average. In the neck and back they are least numerous, their number amounting to 417 on the square inch (Krause). Their total number is estimated by the same writer at 2,381,248, and, supposing the aperture of each gland to represent a surface of $\frac{1}{56}$ of a line in diameter, he calculates that the whole of these glands would present an evaporating surface of about eight square inches. Each gland consists of a single tube intricately convoluted, terminating at one end by a blind extremity, and opening at the other end upon the surface of the skin. In the larger glands this single duct usually divides and subdivides dichotomously; the smaller ducts ultimately terminating in short cæcal pouches, rarely anastomosing. The wall of the duct is thick, the width of the canal seldom exceeding one-third of its diameter. The tube, both in the gland and where it forms the excretory duct, consists of two layers—an outer, formed by fine areolar tissue, and an inner layer of epithelium (fig. 85). The external or fibro-cellular coat is thin, continuous with the superficial layer of the corium, and extends only as high as the surface of the true skin. The epithelial lining in the distal part of the coiled tube of the gland proper consists of a single layer of cubical epithelium, supported on a

Fig. 85.—Coiled tube of a sweat-gland cut in various directions.



a. Longitudinal section of the proximal part of the coiled tube. *b.* Transverse section of the same. *c.* Longitudinal section of the distal part of the coiled tube. *d.* Transverse section of the same. (From Klein and Noble Smith's 'Atlas of Histology.')

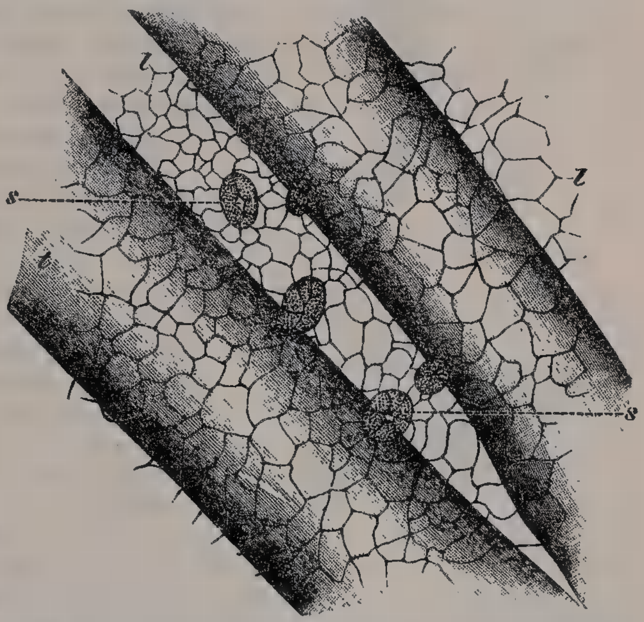
basement-membrane, and beneath it, between the epithelium and the fibro-cellular coat, a layer of longitudinally or obliquely arranged fibres, which are usually regarded as muscular, though the evidence that this is so is not conclusive. In the duct and the proximal part of the coiled tube of the gland proper there are two or more layers of polyhedral cells, lined on their internal surface, i.e. next the lumen of the tube, by a delicate membrane or cuticle, and on their outer surface by a limiting membrana propria, but there are no muscular fibres. The epithelium is continuous with the epidermis and with the delicate internal cuticle of the epidermic portion of the tube. When the cuticle is carefully removed from the surface of the cutis, these convoluted tubes of epithelium may be drawn out and form short, thread-like processes on its under surface.

The contents of the smaller sweat-glands are quite fluid; but in the larger glands the contents are semi-fluid and opaque, and contain a number of coloured granules and cells which appear analogous to epithelial cells.

SEROUS MEMBRANES

The **serous membranes** form shut sacs and may be regarded as lymph-sacs, from which lymphatic vessels arise by stomata or openings between the endothelial cells (see page 57). The sac consists of one portion which is applied to the walls of the cavity which it lines—the *parietal* portion; and another reflected over the surface of the organ or organs contained in the cavity—the *visceral* portion. Sometimes the sac is arranged quite simply, as the tunica vaginalis testis; at others with numerous involutions or recesses, as the peritoneum, in which, nevertheless, the membrane can always be traced continuously around the whole circumference. The sac is completely closed, so that no communication exists between the serous cavity and the parts in its neighbourhood. An apparent exception exists in the peritoneum of the female; for the Fallopian tube opens freely into the peritoneal cavity in the dead subject so that a bristle can be passed from the one into the other. But this communication is closed during life, except at the moment of the passage of the ovum out of the ovary into the tube, as is proved by the fact that no interchange of fluids ever takes place between the two cavities in dropsy of the peritoneum, or in accumulation of fluid in the Fallopian tubes.* The serous membrane is sometimes supported by a firm, fibrous layer, as is the case with the pericardium, and such membranes may be spoken of as 'fibro-serous.'

Fig. 86.—Part of peritoneal surface of the central tendon of diaphragm of rabbit, prepared with nitrate of silver.



s. Stomata. *l.* Lymph-channels. *t.* Tendon-bundles. The stomata are surrounded by germinating epithelial cells. (From 'Handbook for the Physiological Laboratory.' Klein.)

The various serous membranes are the peritoneum, lining the cavity of the abdomen; the two pleuræ and the pericardium, covering the lungs and heart respectively; and the tunicæ vaginales, surrounding the testicles in the scrotum.†

* The communication between the uterine cavity and the peritoneal sac is not only apparent in the dead subject, but is an anatomical fact, which is established by the continuity of its epithelium with that covering the uterus, Fallopian tubes, and fimbriæ.

† The arachnoid membrane covering the brain and spinal cord was formerly regarded as a serous membrane, but is now no longer classed with them, as it differs from them in structure, and does not form a shut sac as do the other serous membranes.

Serous membranes are thin, transparent, glistening structures, consisting of homogeneous basement-membranes lined on their inner surface by a single layer of polygonal or pavement endothelial cells, supported on a matrix of fibrous connective tissue, with networks of fine elastic fibres, in which are contained numerous capillaries and lymphatics. On the surface of the endothelium between the cells numerous apertures or interruptions are to be seen. Some of these are stomata, surrounded by a ring of cubical endothelium (see fig. 86), and communicate with a lymphatic capillary; others (*pseudostomata*) are mere interruptions in the endothelial layer, and are occupied by processes of the branched connective-tissue corpuscle of the subjacent tissue or by accumulations of the intercellular cement substance.

The amount of fluid contained in these closed sacs is, in most cases, only sufficient to moisten the surface, but not to furnish any appreciable quantity of fluid. When a small quantity can be collected, it is found to resemble lymph, and like that fluid coagulates spontaneously; but when secreted in large quantities, as in dropsy, it is a more watery fluid, yet still contains a considerable amount of proteid which is coagulated on boiling.

Fig. 87.—Villus of synovial membrane. (After Hammar.)

SYNOVIAL MEMBRANES

Synovial membranes, like serous membranes, are connective-tissue membranes placed between two movable tissues, so as to diminish friction, as in movable joints; or between a tendon and a bone, where the former glides over the latter; and between the skin and various subcutaneous bony prominences.

The synovial membranes are composed essentially of connective tissue, with the cells and fibres of that structure, containing numerous vessels and nerves. It was formerly supposed that these membranes were analogous in structure to the serous membranes, and consisted of a layer of flattened cells on a basement-membrane. No such continuous layer, however, exists, although here and there are patches of cells probably epithelial in nature. They are surrounded and held together by an albuminous ground-substance. Long villus-like processes (fig. 87) are often found projecting from the surface of synovial membranes; they are covered by small rounded cells, and are supposed to extend the surface for the secretion of the fluid which moistens the membranes and which is named *synovia*. It is a rich lymph, plus a mucin-like substance, and to the latter constituent it owes its viscidity. A further description of the synovial membranes will be given with the anatomy of the joints.

MUCOUS MEMBRANES

Mucous membranes line all those passages by which the internal parts communicate with the exterior, and are continuous with the skin at the various orifices of the surface of the body. They are soft and velvety, and very vascular, and their surface is coated over by their secretion, *mucus*, which is of a tenacious consistence, and serves to protect them from the foreign substances introduced into the body with which they are brought in contact.

They are described as lining the two tracts—the gastro-pulmonary and the genito-urinary; and all, or almost all, mucous membranes may be classed as belonging to and continuous with the one or the other of these tracts.

The deep surfaces of these membranes are attached to the parts which they line by means of connective tissue, which is sometimes very abundant,

forming a loose and lax bed, so as to allow considerable movement of the opposed surfaces on each other. It is then termed the *submucous tissue.* At other times it is exceedingly scanty, and the membrane is closely connected to the tissue beneath; sometimes, for example, to muscle, as in the tongue; sometimes to cartilage, as in the larynx; and sometimes to bone, as in the nasal fossæ and sinuses of the skull.

In structure a mucous membrane is composed of *corium* and *epithelium.* The epithelium is of various forms, including the squamous, columnar, and ciliated, and is often arranged in several layers. This epithelial layer is supported by the corium, which is analogous to the dermis of the skin, and consists of connective tissue, either simply areolar, or containing a greater or less quantity of lymphoid tissue. This tissue is usually covered on its external surface by a transparent basement-membrane generally composed of clear flattened cells, placed edge to edge; on this the epithelium rests. It is only in some situations that the basement-membrane can be demonstrated. The corium is an exceedingly vascular membrane, containing a dense network of capillaries, which lie immediately beneath the epithelium and are derived from small arteries in the submucous tissue.

The fibro-vascular layer of the corium contains, besides the areolar tissue and vessels, unstriped muscle-cells, which form in many situations a definite layer called the *muscularis mucosæ.* These are situated in the deepest part of the membrane, and are plentifully supplied with nerves. Other nerves pass to the epithelium and terminate between the cells. Lymphatic vessels are found in great abundance, commencing either by blind extremities or in networks, and communicating with plexuses in the submucous tissue.

Embedded in the mucous membrane are found numerous glands, and projecting from it are processes (villi and papillæ) analogous to the papillæ of the skin. These glands and processes, however, exist only at certain parts, and it will be more convenient to defer their description so that they may be described as they occur.

SECRETING GLANDS

The **secreting glands** are organs whose cells produce, by the metabolism of their protoplasm, certain substances, called 'secretions,' of a more or less definite composition; the material for the secretion being primarily selected from the blood. The essential parts therefore of a secreting gland are *cells,* which have the power of extracting from the blood certain matters, and in some cases converting them into new chemical compounds; and *blood-vessels,* by which the blood is brought into close relationship with these cells. The general arrangement in all secreting structures—that is to say, not only in secreting glands, but also in secreting membranes—is that the cells are arranged on one surface of an extra-vascular basement-membrane, which supports them, and a minute plexus of capillary vessels ramifies on the other surface of the membrane. The cells then extract from the blood certain constituents which pass through the membrane into the cells, where they are prepared and elaborated. The basement-membrane does not, however, always exist, and any free surface would appear to answer the same purpose in some cases.

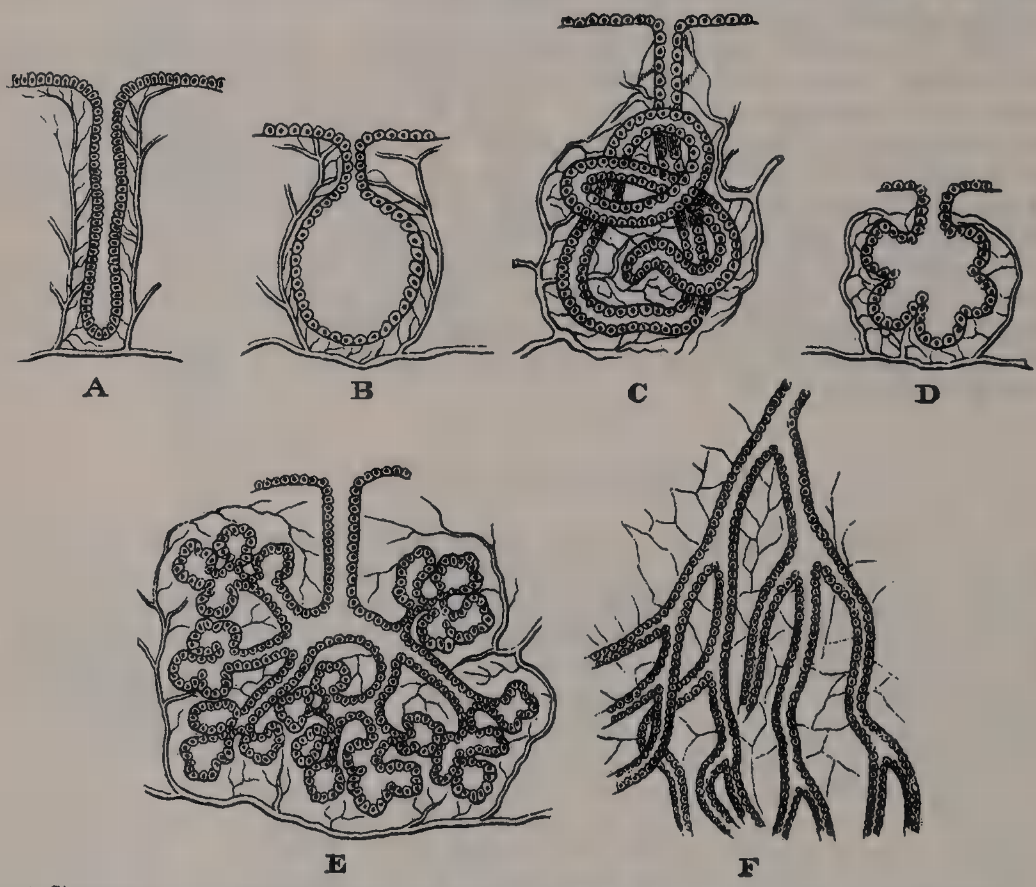
By the various modifications of this secreting surface the different glands are formed. This is generally effected by an invagination of the membrane in different ways, the object being to increase the extent of secreting surface within a given bulk.

In the simplest form a single invagination takes place, constituting a *simple* gland; this may be either in the form of an open tube (fig. 88, A), or the walls of the tube may be dilated so as to form a saccule (fig. 88, B). These are named the *simple tubular* or *saccular* glands. Or, instead of a short tube, the invagination may be lengthened to a considerable extent, and then coiled up to occupy less space. This constitutes the *simple convoluted tubular* gland, an example of which may be seen in the sweat-glands of the skin (fig. 88, C).

If, instead of a single invagination, secondary invaginations take place from the primary one, as in fig. 88, D and E, the gland is then termed a compound one. These secondary invaginations may assume either a saccular or tubular form, and

so constitute the two subdivisions—the *compound saccular* or *racemose* gland, and the *compound tubular*. The racemose gland in its simplest form consists of a primary invagination which forms a sort of duct, upon the extremity of which are found a number of secondary invaginations, called saccules or alveoli, as in Brunner's glands (fig. 88, D). But, again, in other instances, the duct, instead of being simple, may divide into branches, and these again into other branches, and so on; each ultimate ramification terminating in a dilated cluster of saccules, and thus we may have the secreting surface almost indefinitely extended, as in the salivary glands (fig. 88, E). In the *compound tubular* glands the division of the primary duct takes place in the same way as in the racemose glands, but the branches retain their tubular form, and do not terminate in saccular recesses, but become greatly lengthened out (fig. 88, F). The best example of this form of gland is to be found in the kidney. All these varieties of glands are produced by a more or less complicated invagination of a secreting membrane, and they are

Fig. 88.—Diagrammatic plan of the varieties of secreting glands.



A. Simple gland. B. Sacculated simple gland. C. Simple convoluted tubular gland. D, E. Racemose gland. F. Compound tubular gland.

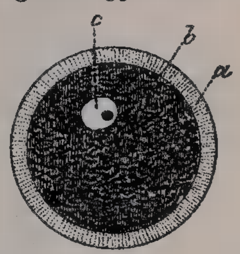
all identical in structure: that is to say, the saccules or tubes, as the case may be, are lined with cells, generally spheroidal or columnar in figure, and on their outer surface is an intimate plexus of capillary vessels. The secretion, whatever it may be, is eliminated by the cells from the blood, and is poured into the saccule or tube, and so finds its way out through the primary invagination on to the free surface of the secreting membrane. In addition, however, to these glands, which are formed by an *invagination* of the secreting membrane, there are some few others which are formed by a *protrusion* of the same structure, as in the vascular fringes of synovial membranes. This form of secreting structure is not nearly so frequently met with.

There are also certain glands which are described as capable of *internal secretion*, wherein are no ducts leading to any free surface, the secretion being carried either directly into the blood stream, or indirectly through the medium of lymphatics. Such are the thyroid and suprarenal glands.

EMBRYOLOGY

THE whole body is developed out of the female germ-cell or **ovum** after it has been fertilised by the male germ-cell or **spermatozoon.** The ovum is a simple nucleated cell, and all the complicated changes by which the various tissues and organs of the body are formed from it, after fertilisation, are the result of two general processes, viz. the *segmentation* or *cleavage* of cells, and their *differentiation.* The former consists of the division of the nucleus and surrounding cell-substance, whereby the original cell is represented by two, a process which is again and again repeated. The differentiation of cells is a term used to describe that unknown power or tendency impressed upon cells, apparently identical in structure, whereby they assume different shapes and become associated, it may be, with the formation of widely differing tissues.

Fig. 89.—Human ovum from a middle-sized follicle. Magnified 350 times.



a. Zona pellucida or zona striata. *b.* Yolk or vitellus. *c.* Germinal vesicle and germinal spot.

The earliest stages of the development of the human embryo have not yet been observed, and therefore many of the statements which are accepted in human embryology regarding these early stages are made on the strength of what has been observed to occur in the lower animals.

Having regard to the main purpose of this work, it is impossible, in the space available in this chapter, to describe fully, or illustrate adequately, all the phenomena which occur in the different stages of the development of the human body. The principal facts only will be given—the student being referred for further details to one or other of the text-books on embryology.

STRUCTURE OF THE OVUM

The human ovum is extremely minute, measuring only from $\frac{1}{150}$ to $\frac{1}{125}$ of an inch in diameter, and is situated within a Graafian follicle of the ovary.* By the rupture of the Graafian follicle on to the surface of the ovary the ovum is liberated, and is then conveyed by the Fallopian tube or oviduct to the cavity of the uterus. Unless it be fertilised by the spermatozoon, it undergoes no further development, and is discharged from the uterus. If, on the other hand, fertilisation occurs, the fertilised ovum is retained within the uterus, and is developed into a new being.

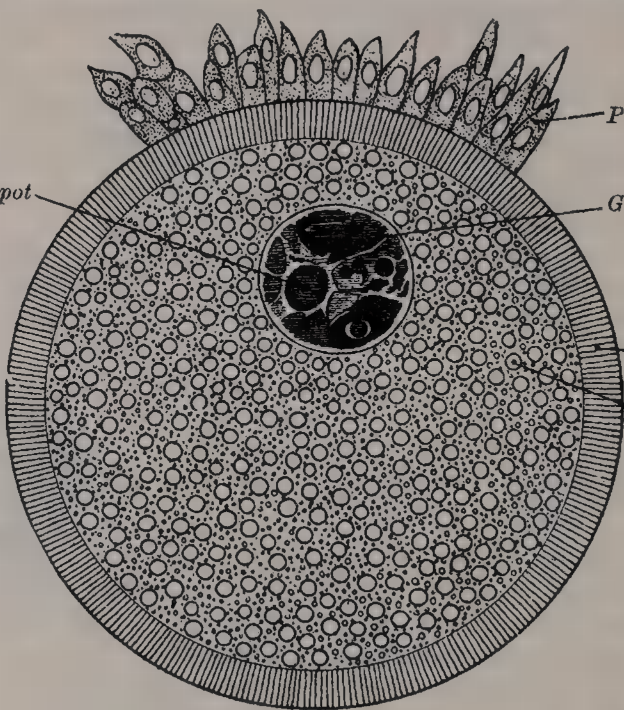
In appearance and structure the ovum (figs. 89, 90) differs little from an ordinary cell, but distinctive names have been applied to its several parts; thus, the body of the cell is known as the *vitellus* or *yolk*, the nucleus as the *germinal vesicle,* and the nucleolus as the *germinal spot.* The ovum is enclosed within a thick, transparent envelope, the *zona pellucida* or *zona striata,* adhering to the outer surface of which there are several layers of cells, derived from those of the Graafian follicle, which collectively constitute the *corona radiata.*

The **vitellus** or **yolk** comprises (1) the *cytoplasm* of the ordinary animal cell, with its network or cyto-reticulum filled with cell-sap or cytolymph. The

* See description of the ovary on a future page.

cytoplasm of the ovum is frequently termed the *formative yolk*, in order to distinguish it from (2) the *nutritive yolk* or *deutoplasm*, which consists of numerous rounded granules of fatty and albuminoid substances embedded in the cytoplasm. In the mammalian ovum the nutritive yolk is extremely small in amount, and is only of service in nourishing the ovum in the earliest stages of its development, whereas in the egg of the bird there is sufficient to supply the chick with nutriment throughout the whole period of incubation. The nutritive yolk not only varies in amount, but in its mode of distribution within the egg: thus, in some animals it is nearly uniformly distributed throughout the cytoplasm; in others it is centrally placed and is surrounded by the cytoplasm; in still others it is accumulated at the lower pole of the ovum, while the cytoplasm, being lighter, occupies the upper pole. An *attraction sphere* with its *centrosome* is present in the ova of the lower animals, and is probably represented in the ova of mammals by the body of Balbiani. This body is not visible during all the stages

Fig. 90.—Ovum of rabbit. Highly magnified. (After Waldeyer.)



of the development of the ovum, and is 'most readily seen before the space appears in the Graafian follicle. Then the body in question lies in the immediate neighbourhood of the nucleus. It consists of a lighter central sphere enclosing one or two smaller spheres, and surrounded by a more darkly staining protoplasm.' *

The **germinal vesicle** or nucleus is a large spherical body which at first occupies a nearly central position, but becomes eccentric as the growth of the ovum proceeds. Its structure is that of an ordinary cell-nucleus, and consists of an intranuclear network of achromatin filled with nuclear sap or karyoplasm; while connected with, or embedded in, the achromatic reticulum are a number of chromatin masses or chromosomes, which may present the appearance of a skein or may assume the form of rods or loops. It is now very generally admitted that in every species of animal the nucleus contains a fixed and definite number of chromosomes, a number which varies from two in certain threadworms to as many as a hundred and sixty-eight in the crustacea; in man, as well as in the ox and guinea pig, the number is said to be sixteen. The nucleus is enclosed by a delicate nuclear membrane, and contains in its interior a well-defined nucleolus or germinal spot.

* Robinson, 'Hunterian Lectures on the Mammalian Ovum and Placenta.' *Journal of Anatomy and Physiology*, vol. xxxviii.

COVERINGS OF THE OVUM

The **zona pellucida** or **zona striata** (fig. 90) is probably secreted by the cells of the corona radiata. It consists of a thick, clear membrane, which, under the higher powers of the microscope, is seen to be perforated by numerous fine radially arranged channels. These give to it a striated appearance, and may suffice for the passage of nutritive materials to the ovum; they may also provide an entrance for the spermatozoa at the time of fertilisation. In some animals (e.g. insects) the zona pellucida presents one, sometimes several small perforations or *micropyles*, by which the spermatozoa are believed to enter. The zona pellucida persists for some time after fertilisation has occurred, and may act as a source of protection during the earlier stages of segmentation.*

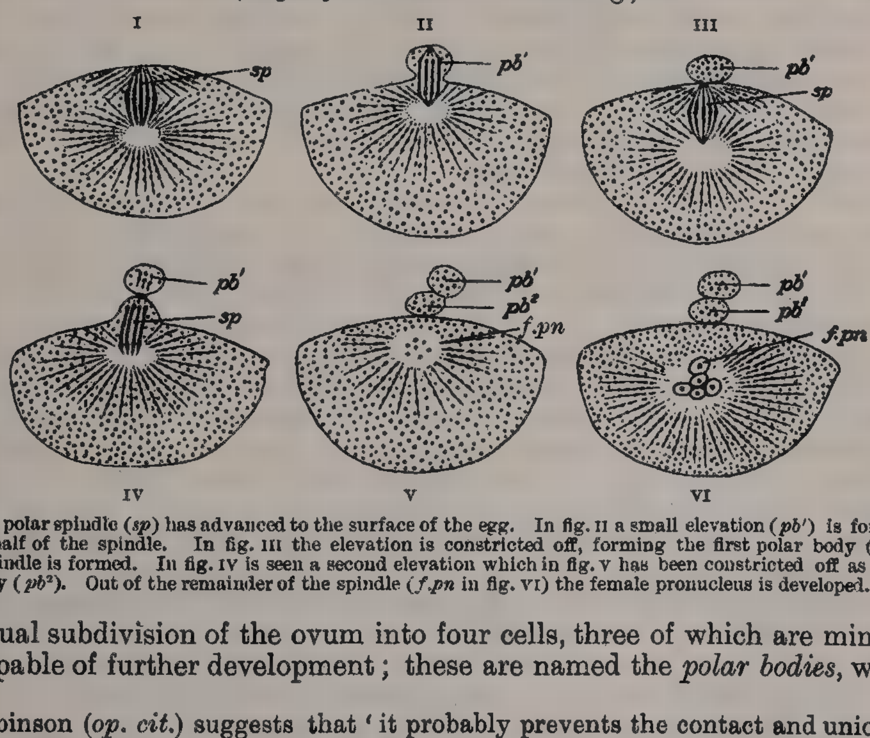
The **corona radiata** (fig. 90) consists of two or three strata of cells; they are derived from the cells of the Graafian follicle, and adhere to the outer surface of the zona pellucida when the ovum is set free from the follicle. Its cells are radially arranged around the zona, those of the innermost layer being columnar in shape, and sending, according to some observers, delicate processes from their deep ends into the channels of the zona. The cells of the corona radiata soon disappear; though in some animals they secrete, or are replaced by, a layer of adhesive albumen, which may not only assist in protecting and nourishing the ovum, but may help to fix it temporarily to the uterine mucous membrane.

The phenomena attending the discharge of the ova from the Graafian follicles belong more to the ordinary functions of the ovary than to the general subject of the development of the body, and are therefore described with the anatomy of the ovaries on a subsequent page.

MATURATION OF THE OVUM

The ovum is incapable of being fertilised by the spermatozoon until after it has undergone a process of maturation. This takes place either before or immediately after its escape from the Graafian follicle, and consists essentially of

FIG. 91.—Formation of polar bodies in asterias glacialis. (Slightly modified from Hertwig.)



In fig. I the polar spindle (*sp*) has advanced to the surface of the egg. In fig. II a small elevation (*pb'*) is formed which receives half of the spindle. In fig. III the elevation is constricted off, forming the first polar body (*pb'*), and a second spindle is formed. In fig. IV is seen a second elevation which in fig. V has been constricted off as the second polar body (*pb²*). Out of the remainder of the spindle (*f.pn* in fig. VI) the female pronucleus is developed.

an unequal subdivision of the ovum into four cells, three of which are minute and are incapable of further development; these are named the *polar bodies*, while the

* Robinson (*op. cit.*) suggests that 'it probably prevents the contact and union of the chorionic cells on the outer surface of the developing ovum with the decidua until the ovum has attained a sufficient size. It also probably serves to prevent contact of the embryonic ectoderm with the uterine wall until the differentiation of the embryonic ectoderm cells has taken place to such an extent that they are no longer disposed to fuse with the decidua.'

fourth and much larger cell constitutes the *mature ovum*. The phenomena of maturation (fig. 91) may be shortly described as follows: the germinal vesicle approaches the surface of the ovum, and, having undergone the usual mitotic changes, divides; one-half of its contained chromatin, surrounded by a small amount of cytoplasm, is then separated from the main mass of the ovum to form the first polar body. The process is repeated, and a second polar body, containing one-half of the remaining chromatin, is separated, while the first, in many cases, becomes divided into two, thus forming three in all. The remainder of the germinal vesicle recedes towards the centre of the ovum, and is now known as the *female pronucleus*; from what has been said, it will be seen that it contains only one-fourth of the chromatin originally present in the germinal vesicle.

The number of polar bodies varies in the ova of different animals; in some only one is formed, in others two—the latter condition being probably explained by the fact that the first polar body has not undergone subdivision by the time the second is separated from the ovum. Coincident with the extrusion of the polar bodies a shrinking of the yolk or vitellus takes place, and a fluid, the *perivitelline fluid*, collects between it and the zona pellucida. In this the polar bodies are situated, and in it also spermatozoa may be subsequently seen (e.g. in the ovum of the rabbit).

THE SPERMATOZOON

The spermatozoa or male germ-cells are developed within the tubuli seminiferi of the testicles. They are present in enormous numbers in the seminal fluid, and consist of small but greatly modified cells. The human spermatozoon possesses a head, a neck, a connecting piece or body, and a tail (fig. 92).

The **head** is oval or elliptical, but flattened, so that when viewed in profile it is pear-shaped. Its anterior two-thirds are covered by a layer of modified protoplasm, which is named the *head-cap*. This, in some animals (e.g. the salamander), is prolonged into a barbed spearlike process or *perforator*, which probably facilitates the entrance of the spermatozoon into the ovum. Bardeleben and E. Nelson have described spearlike perforators as being present in the human spermatozoa, but other observers deny their presence. Waldeyer inclines to the view that in man the perforator consists of the anterior sharp margin of the head-cap, and acts as a cutting rather than a boring apparatus. The posterior part of the head exhibits an affinity for certain reagents, and presents a transversely striated appearance, being crossed by three or four dark bands. In some animals a central rodlike filament extends forwards for about two-thirds of the length of the head, while in others a rounded body is seen near its centre. The head contains a mass of chromatin, and is generally regarded as the nucleus of the cell surrounded by a thin envelope.

The **neck** immediately succeeds the head, and in some animals appears as a marked constriction, which, however, is not very clearly differentiated in the human spermatozoon. At the junction of the head and neck two or three rounded nodules, the *anterior centrosome bodies*, are seen; behind these is a band of homogeneous substance.

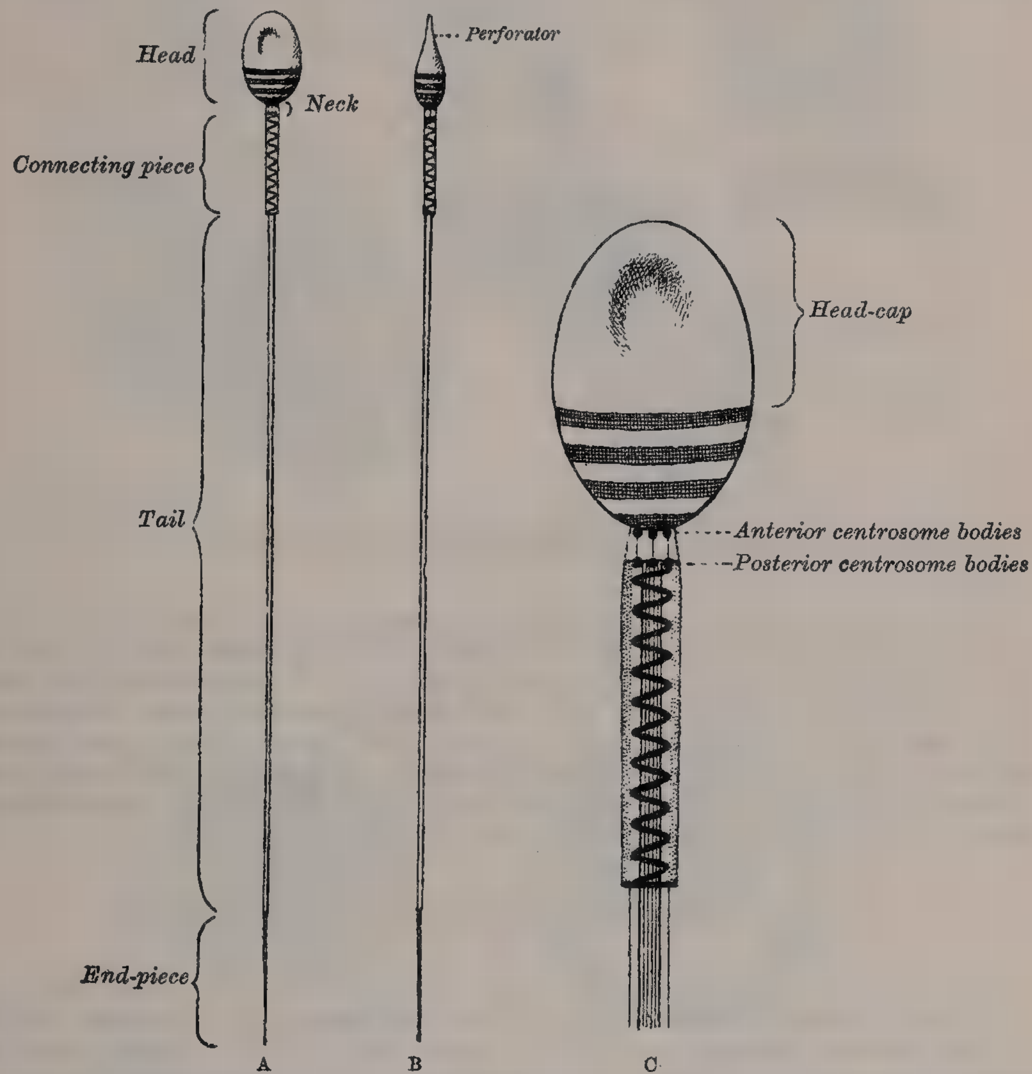
The **connecting piece** or **body** is rodlike and about the same length as the head. At its anterior end are two or three rounded nodules, the *posterior centrosome bodies*: fine threads connect these with the anterior centrosome bodies. An axial filament runs through the connecting piece, and is continued backwards into the tail. It is probably a derivative of the centrosome bodies. Outside the axial filament is a layer of protoplasm which contains a spirally arranged fibril.

The **tail** is of great length, and contains an axial thread or filament which is composed of delicate fibrillæ. It is surrounded by a protoplasmic envelope, which may contain a spiral thread or may present a striated appearance. Further, in some animals there is attached to the connecting piece and tail a thin undulatory membrane, along the free edge of which there is a marginal filament. The terminal portion of the tail is named the *end-piece*, and consists of the axial filament only.

It is interesting to note that in the development of the spermatozoa a nuclear reduction occurs similar to that seen during the maturation of the ovum. In the testicle are certain cells identical with primitive ova. These are termed *spermatogonia*, and each divides into a couple of *spermatocytes*, which again

undergo subdivision, giving rise to four *spermatids* or young spermatozoa. From this it will be seen that the spermatozoon contains only one-fourth of the chromatin which originally existed in the nucleus of the spermatogone. The matured ovum and the spermatozoon may therefore be looked upon as of the same morphological value. It must, however, be kept in mind that all four

Fig. 92.—Human spermatozoon. (Diagrammatic.)



A. Surface view. B. Profile view. In C the head, neck, and connecting piece are highly magnified to show the centrosome bodies and their uniting threads, the spirally arranged fibril, and the axial filament.

spermatozoa are functionally active, whereas the polar bodies given off during the maturation of the ovum are apparently of no functional value.

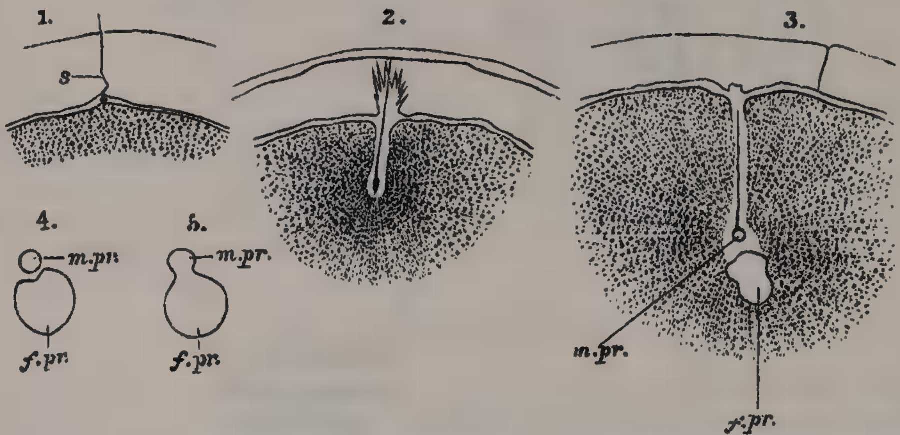
In virtue of their tails, which act as propellers, the spermatozoa, in the fresh condition, are capable of free movement, and if placed in favourable surroundings (e.g. in the female passages) may retain their vitality for several days.

FERTILISATION OF THE OVUM

Fertilisation consists in the union of the spermatozoon with the mature ovum (fig. 93). This usually takes place in the upper part of the Fallopian tube, and the ovum is then conveyed to the cavity of the uterus—a journey which probably occupies two or three days. Should the passage of the fertilised ovum along the tube be arrested, a tubal pregnancy is the result. Numerous spermatozoa may pierce the zona pellucida (e.g. in the rabbit as many as sixty have been seen in its interior), but only one, under normal conditions, enters the vitellus and takes part in the process of fertilisation. At the point where the spermatozoon is about to pierce the vitellus the latter is drawn out into a conical elevation, termed the

cone of attraction. As soon as the spermatozoon has entered at this point, a membrane appears to be secreted over the aperture of its entrance to prevent the passage of additional spermatozoa. Occasionally a second spermatozoon may enter the vitellus, thus giving rise to a condition of *polyspermy*: when this occurs the ovum usually develops in an abnormal manner and gives rise to a monstrosity. Having pierced the vitellus, the tail of the spermatozoon disappears, while its head assumes the form of a nucleus containing a cluster of chromosomes.

FIG. 93.—Fertilisation of the ovum of an echinoderm.



s. Spermatozoon. *m.pr.* Male pronucleus. *f.pr.* Female pronucleus. 1. Accession of a spermatozoon to the periphery of the vitellus. 2. Its penetration. 3. Transformation of the head of the spermatozoon into the male pronucleus. 4, 5. Blending of the male and female pronuclei. (From Quain's 'Anatomy,' Selenka.)

This constitutes the *male pronucleus*, and associated with it there is seen a centrosome and attraction sphere. The male pronucleus passes more deeply into the vitellus, and coincident with this the granules of the surrounding cytoplasm become radially arranged. The male and female pronuclei migrate towards each other, and, meeting near the centre of the vitellus, fuse to form a new nucleus, the *first segmentation nucleus*, which therefore contains both male and female nuclear substance; the former transmits the individualities of the father, the latter those of the mother, to the future embryo.

SEGMENTATION OF THE FERTILISED OVUM

After it has been fertilised the ovum undergoes repeated subdivision into a number of small cells (figs. 94, 95). The first segmentation nucleus exhibits the usual mitotic changes, and these are succeeded by a division of the ovum into two cells of equal or unequal size. Whether the two cells may differ in quality as well as in quantity is as yet a matter of some doubt. (Consult Hertwig's 'Handbuch der vergleichenden und experimentellen Entwickelungslehre der Wirbeltiere.') The process is repeated again and again, so that the two cells are succeeded by four, eight, sixteen, thirty-two, and so on, with the result that a mass of cells is found within the zona pellucida (which itself takes no share in the process, but ultimately disappears), and to this mass the term *morula* is applied. The segmentation of the mammalian ovum may not take place in the regular sequence of two, four, eight, &c., since one of the two first-formed cells may subdivide more rapidly than the other, giving rise to a three- or a five-cell stage. The cells of the morula are at first closely aggregated inside the zona pellucida; but soon they become arranged into an outer or peripheral layer, the *primitive ectoderm* or *trophoblast*, which does not contribute to the formation of the embryo proper, and an *inner cell-mass*, from which the embryo is developed (fig. 96). Fluid collects between the trophoblast and the greater part of the inner cell-mass, and thus the morula is converted into a vesicle, the *blastodermic vesicle*. The inner cell-mass remains in contact, however, with the trophoblast at one pole of the ovum; this is named the *embryonic pole*, since it indicates the situation where the future embryo will be developed. The cells of the trophoblast become differentiated into two strata: an outer, termed the *syncytium* or *plasmodioblast*, so named because it consists of a layer of protoplasm studded with nuclei, but

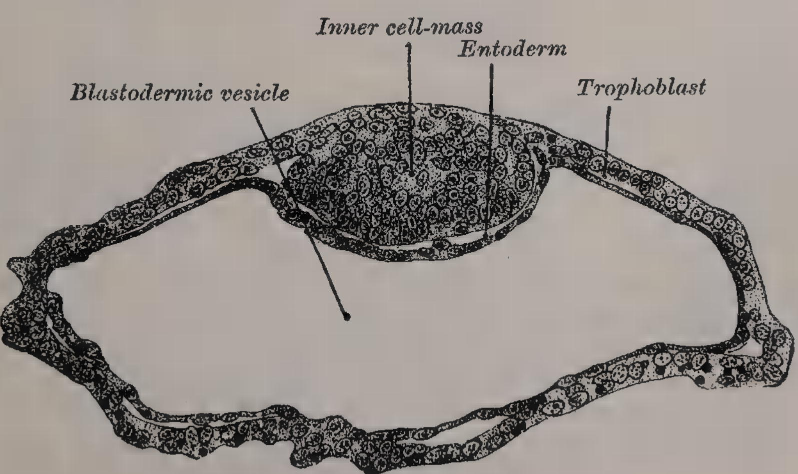
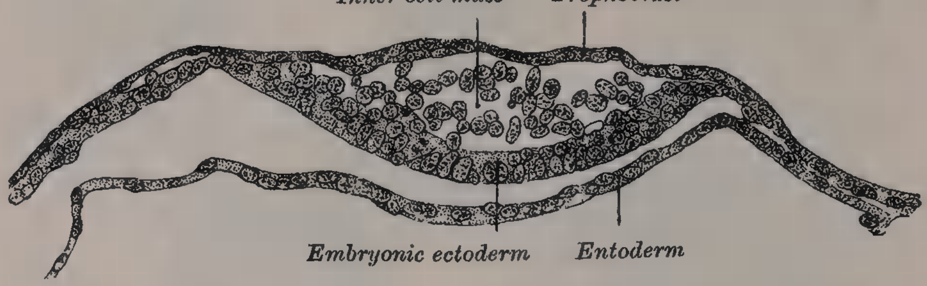
FIG. 96.—Blastodermic vesicle of Vespertilio murinus. (After Van Beneden.)



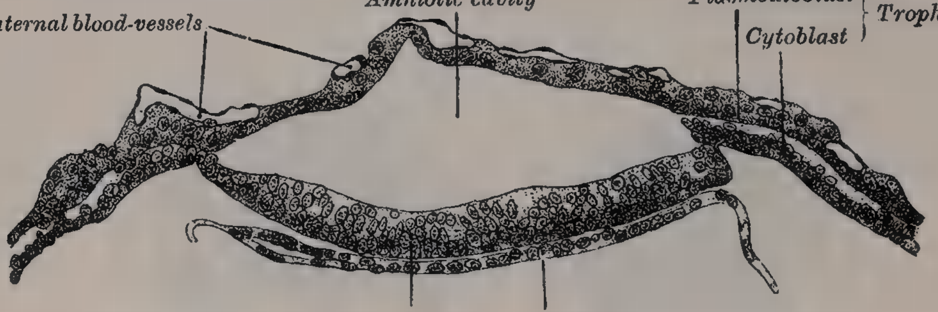
showing no evidence of subdivision into cells; and an inner layer of prismatic epithelium, which is named the *cytoblast* or *layer of Langhans*. As already stated, the cells of the trophoblast do not contribute to the formation of the embryo proper; they form the ectoderm of the chorion and play an important part in the development of the placenta. The inner cell-mass becomes differentiated into two layers: an outer, of prismatic cells, the *embryonic ectoderm*,

Fig. 97.—Section through embryonic area of Vespertilio murinus. (After Van Beneden.)



and an inner, of flattened cells, the *entoderm* (figs. 96 to 98); the latter is applied to the deep aspect of the former, and from there gradually extends around the inner surface of the trophoblast. Spaces appear between the cells of the inner cell-mass, and at the same time the central cells of the mass undergo atrophy, and in this way a cavity (figs. 97 and 98) is gradually developed between the

Fig. 98.—Section through embryonic area of Vespertilio murinus (after Van Beneden) to show the formation of the amniotic cavity.



embryonic ectoderm and the overlying trophoblast: this is termed the *primitive amniotic cavity*; it persists in certain of the bats, and probably also in man and monkeys, and forms in them the permanent amniotic cavity. In other animals the trophoblastic roof of this primitive amniotic cavity disappears, and the embryonic ectoderm assumes a superficial position, its margin being continuous with the trophoblast. The formation of the amnion will be again referred to.

THE EMBRYONIC AREA

In reptiles, birds, and mammals, only a part of the ovum is utilised in the development of the embryo proper, the remainder being used up in the formation of membranes and other appendages which are concerned with its protection and nutrition; the blastodermic membrane therefore may be divided into *embryonic* and *extra-embryonic areas* (figs. 99, 100). If the ovum, at this stage, be viewed from the surface it will be seen to exhibit a centrally placed, circular, opaque area surrounded by a more transparent portion. The central opaque part is the embryonic area (area embryonalis), and is equal in extent with the embryonic ectoderm already referred to; the peripheral clearer portion is the extra-embryonic area. The circumference of the embryonic region 'remains as a relatively slow-growing area, while the embryonic and extra-embryonic portions of the wall of the ovum rapidly increase in extent. Under these circumstances, it follows that the margin of the embryonic area will soon appear

as a ring between the upper embryonic and the lower or extra-embryonic parts of the ovum, both of which have expanded beyond it in all directions' (Robinson).* The circumference of the embryonic area corresponds with the future umbilicus.

The primitive streak; formation of the mesoderm.—The embryonic area becomes oval and then pear-shaped, the wider end being directed forwards. At the narrow, posterior end an opaque, crescentic or anchor-shaped patch makes its appearance, and gradually extends forwards as a dark streak along the middle line of the area for about one-half of its length; this is termed the *primitive streak* (figs. 99, 100), and indicates the commencing development of a third layer of cells, which constitutes the *mesoderm* or *mesoblast*. A shallow groove, the *primitive groove*, makes its appearance on the surface of the streak, and the anterior end of this groove communicates by means of an aperture, the *blastopore*, with that part of the blastodermic vesicle which ultimately forms the primitive alimentary canal. The cells of the axial part of the embryonic ectoderm multiply rapidly and, growing downwards, blend with those of the underlying entoderm; this thickening of the ectoderm gives rise to a linear opacity, the primitive streak. From the sides and posterior extremity of the primitive streak a layer of cells, the mesoderm or mesoblast, extends outwards between the ectoderm and entoderm, and so converts the bilaminar into a trilaminar blastoderm. Although the mesoderm is mainly derived from the cells of the ectoderm, possibly those of the entoderm also contribute to it.

FIG. 99.—Embryo of a rabbit. (After Kölliker.)

The extension of the mesoderm takes place throughout the whole of the embryonic and extra-embryonic areas of the ovum, except in certain regions. One of these is seen immediately in front of the neural tube. Here the mesoderm extends forward in the form of two crescentic masses, which curve inwards and meet in the middle line so as to enclose behind them an area which is devoid of mesoderm and is named the *oral plate* or *bucco-pharyngeal area*, since it afterwards forms the septum between the primitive mouth and primitive pharynx. In front of the bucco-pharyngeal area, where the lateral crescents of mesoderm have fused in the middle line, the pericardium is afterwards developed, and this region is therefore designated the *pericardial area*. A second region where the mesoderm is absent, at least for a time, is that immediately in front of the pericardial area. This is the region where the *pro-amnion* is developed; in man, however, a pro-amnion is apparently never formed.

* 'The Early Stages of the Development of the Pericardium,' by Professor Arthur Robinson. *Journal of Anatomy and Physiology*, vol. xxxvii.

THE NEURAL GROOVE AND TUBE

In front of the primitive streak two longitudinal ridges, caused by a looping or folding up of the ectoderm, make their appearance, one on either side of the middle line. These are named the *medullary folds* or *laminæ*; they commence some distance behind the anterior end of the embryonic area, where they are continuous with each other, and from there gradually extend backwards, one on either side of the primitive streak. Between these folds is seen a mesial, longitudinal furrow, the *neural* or *medullary groove* (figs. 100, 101), which gradually deepens as the medullary folds become elevated. Ultimately the folds meet and coalesce in the middle line and convert the neural groove into a closed tube, the *neural tube* or *canal* (fig. 104), the surrounding ectodermal wall of which forms the rudiment of the nervous system. By the coalescence of the medullary folds over the anterior end of the primitive streak, the blastopore no longer opens on the surface but into the closed canal of the neural tube, and thus a communication, the *neurenteric canal*, is established between the neural tube and the primitive alimentary canal. The coalescence of the medullary folds first occurs in the region of the hind-brain, and from there extends forwards and backwards. Before they fuse posteriorly, the hinder part of the neural groove presents a rhomboidal shape, and to this expanded portion the term *sinus rhomboidalis* has been applied (fig. 103). When the medullary folds are in the act of closing in to form the neural tube, a crest or ridge of cells is separated from their edges. This is termed the *neural crest* or *ganglion ridge* (fig. 138), and is at first situated between the dorsal aspect of the neural tube and the overlying ectoderm: it forms the rudiment of the ganglia of the spinal and cranial nerves.

Fig. 101.—Human embryo—length 2 mm. Dorsal view, with the amnion laid open. × 30. (After Graf Spee; reconstruction.)

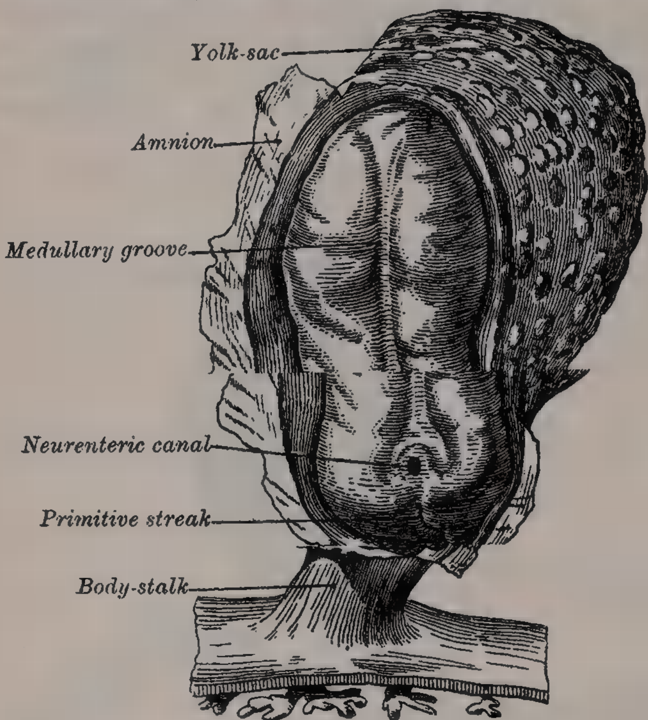

Fig. 102.—Section across the anterior part of the medullary groove. (By Schäfer. Modified from Quain's 'Anatomy.')

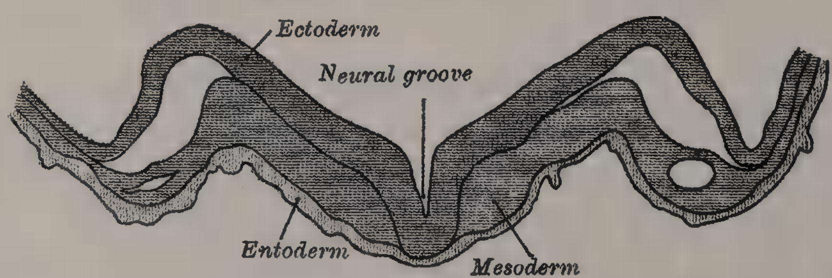


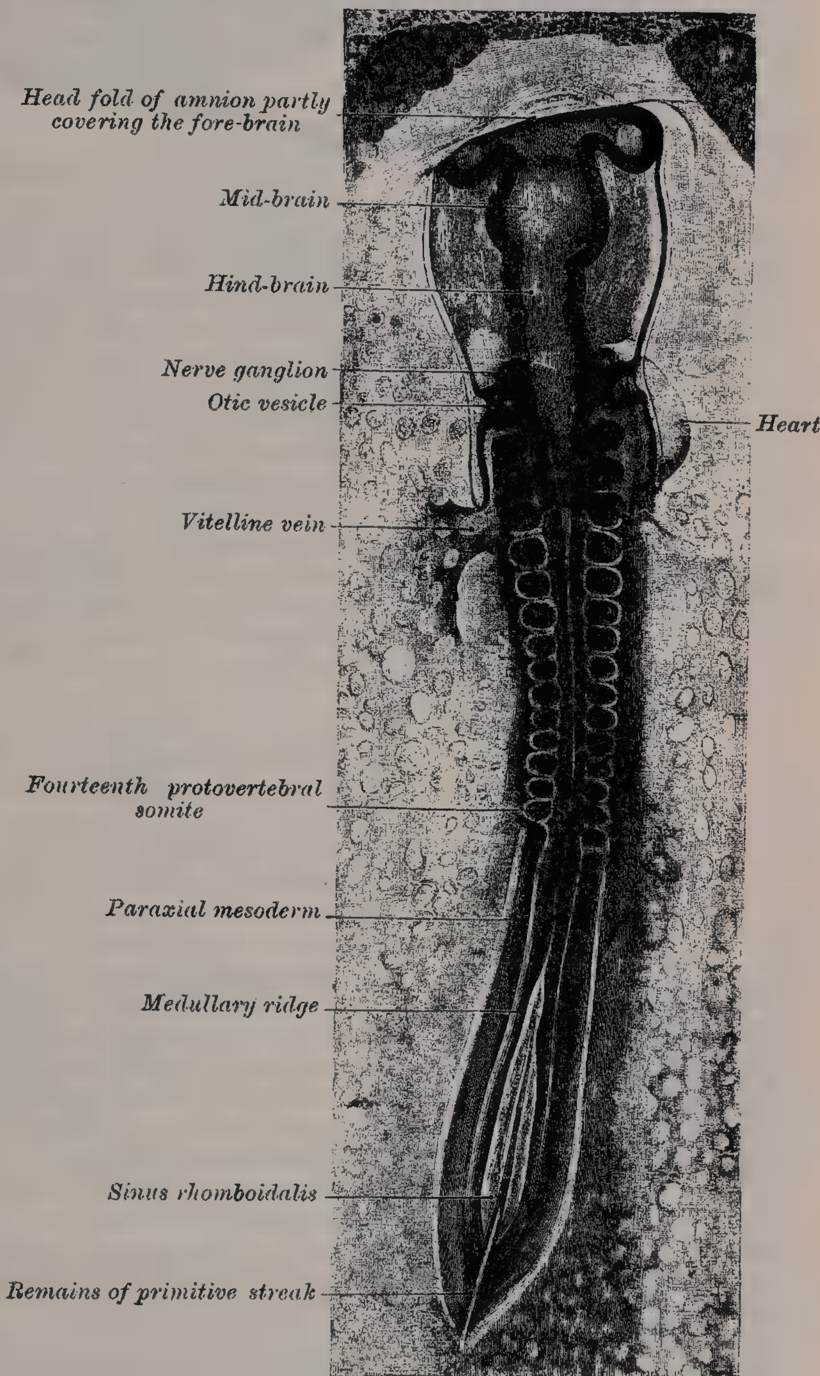
The cephalic end of the neural groove exhibits several dilatations, which, when the tube is closed, assume the form of three vesicles; these constitute the three primary cerebral vesicles, and correspond respectively to the future *fore-brain*, *mid-brain*, and *hind-brain* (fig. 103). Their walls are developed into the nervous

tissue and neuroglia of the brain, while their cavities become modified to form the brain ventricles. The remainder of the tube forms the central canal of the spinal cord, the neuroglial and nervous elements of which are formed from the ectodermal wall of the tube.

THE NOTOCHORD OR CHORDA DORSALIS

The notochord (figs. 104 and 106, 9, 10) consists of a rod of cells which is situated immediately below the neural tube and which constitutes the foundation of the axial skeleton, since around it are developed the bodies of the vertebræ and the intervertebral discs; it entirely disappears in the situation of the former, but persists in the centre of the latter as the *nucleus pulposus* (figs. 116 and 117). Its development is coincident with that of the neural tube. On the ventral aspect of the neural groove an axial thickening of the entoderm takes place; this thickening assumes the appearance of a furrow—the *chordal furrow*—the margins of which come into contact, and so convert it into a solid rod of cells — the *notochord* — which is then separated from the entoderm. It lies at first between the neural tube and the entoderm of the primitive alimentary canal, but soon becomes surrounded by the ingrowing mesoderm, which encloses it in a sheath, the *notochordal sheath.* It extends throughout the entire length of the future vertebral column, and its cephalic extremity reaches as far as the anterior end of the mid-brain. The cephalic portion is at first in contact with the entoderm of the fore-gut, and its anterior end lies immediately behind the pituitary invagination of the stomatodœum. It becomes partly surrounded by mesoderm, and is then seen to end in a hook-like extremity in the region of the future dorsum sellæ of the sphenoid bone.

Fig. 103.—Chick embryo of thirty-three hours' incubation, viewed from the dorsal aspect. × 30. (From Duval's 'Atlas d'Embryologie.')



FORMATION OF THE BODY CAVITY OR CŒLOM

As the mesoderm extends between the ectoderm and entoderm, it splits, except in the immediate neighbourhood of the neural tube, into an upper or *somatic*, and a lower or *splanchnic* layer. The former becomes applied to the inner surface of the ectoderm, and with it forms the *somatopleure*; while the latter adheres to the entoderm, and with it forms the *splanchnopleure* (figs. 104, 105, 106). The space between the two mesodermic layers is termed the *body cavity* or *cœlom*. The portion of this space which is enclosed within the embryo (embryonic cœlom) is developed into the cavities of the peritoneum, pleuræ, and pericardium. The portion outside the embryo (extra-embryonic cœlom) envelops the yolk-sac. That part of the mesoderm which remains undivided on either side of the neural tube is termed the *paraxial mesoderm*, to distinguish it from the more laterally placed portions which constitute the *lateral mesoderm*.

THE PROTOVERTEBRAL SOMITES, OR PRIMITIVE SEGMENTS

About the third week the paraxial mesoderm becomes transversely segmented and converted into a series of well-defined, more or less cubical areas, the *protovertebral* or *mesodermic somites* (figs. 103 and 104), which extend from the region of the hind-brain along the entire length of the trunk on either side of the middle line.

They lie immediately under the ectoderm on the lateral aspect of the neural tube and notochord, and are connected to the lateral mesoblast by a narrow isthmus of cells, the *intermediate cell-mass*, in which the genito-urinary organs are developed. The cells of each somite encircle a central cavity—the *myocœl*—which, however, soon becomes filled with angular and spindle-shaped cells. The somites of the trunk may be arranged in the following groups, viz.: cervical 8, thoracic 12, lumbar 5, sacral 5, and coccygeal

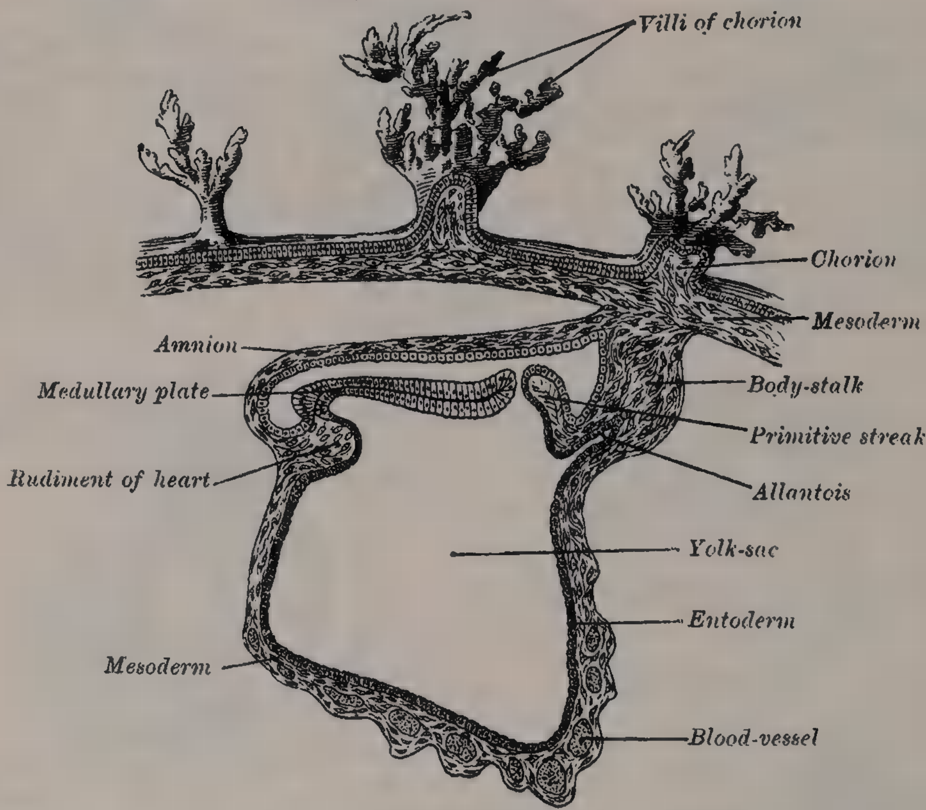
from 5 to 8. Those of the head are three or four in number, and extend forward as far as the primitive ear-capsule.

The three layers of the blastoderm are therefore named, from without inwards, the ectoderm, mesoderm, and entoderm (figs. 102 and 104). Each has distinctive characters and gives rise to certain tissues of the body.

The **ectoderm** consists of columnar cells, which are, however, somewhat flattened or cubical towards the margin of the embryonic area. It forms the whole of the nervous system, the epidermis of the skin, the lining cells of the sebaceous, sweat and mammary glands, the hairs and nails, the epithelium of the nose and adjacent air-sinuses, and that of the cheeks and roof of the mouth. From it also are derived the enamel of the teeth, and the anterior lobe of the pituitary body, the epithelium of the cornea, conjunctiva, and lachrymal glands, and the neuro-epithelium of the sense organs.

The **entoderm** consists at first of flattened cells, which subsequently become columnar. It forms the epithelial lining of the whole of the alimentary canal

FIG. 107.—Section through the embryo which is represented in fig. 101. (After Graf Spee.)



excepting part of the mouth and pharynx and the terminal part of the rectum (which are lined by involutions of the ectoderm), the lining cells of all the glands which open into the alimentary canal, including those of the liver and pancreas, the epithelium of the Eustachian tube and tympanic cavity, of the trachea, bronchi, and air-cells of the lungs, of the urinary bladder and part of the urethra, and that which lines the follicles of the thyroid and thymus glands.

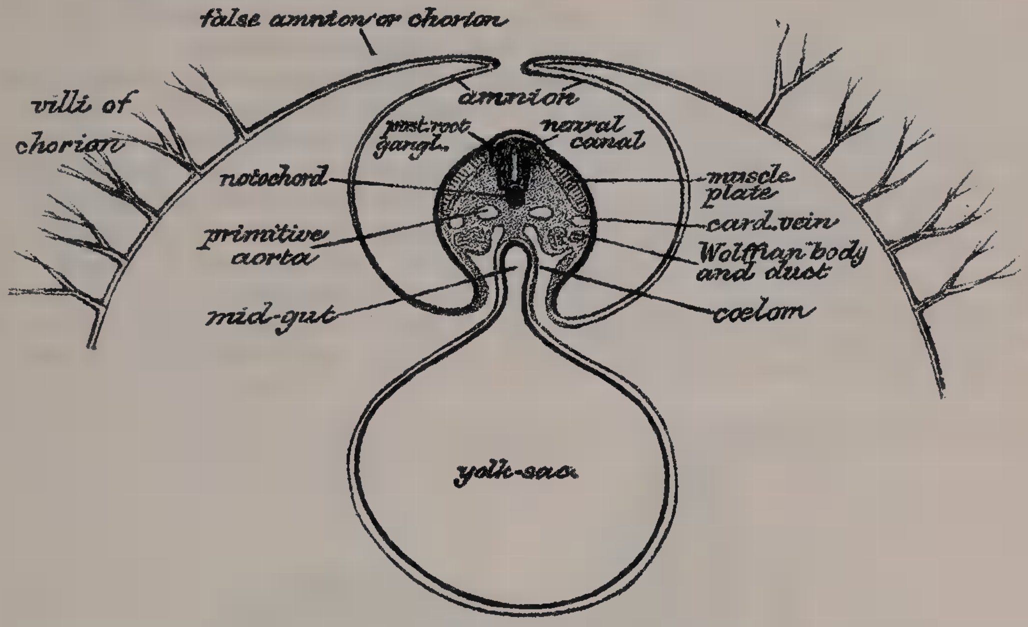
The **mesoderm** consists of loosely arranged branched cells surrounded by a considerable amount of intercellular fluid. From it the remaining tissues of the body are developed. The epithelial lining of the heart and blood-vessels is, however, regarded by some as being of entodermal origin.

DELIMITATION OF THE EMBRYO

As has been pointed out, the margin of the embryonic area is of relatively slow growth compared with the rapidly developing embryonic and extra-embryonic parts of the ovum, and thus it forms a ring of constriction between these two areas, which expand above and below it. The embryonic area is in this manner

constricted off from the blastodermic vesicle to form the *embryo*; and as this takes place, a small part of the blastodermic vesicle is enclosed within the embryo and

FIG. 108.—Diagram of a transverse section of an embryo, showing the mode of formation of the amnion. The amniotic folds have nearly united in the middle line. (From Quain's 'Anatomy,' vol. i. pt. 1, 1890.)



constitutes the *primitive alimentary canal*, while the larger portion of the vesicle is left outside the embryo, and is termed the *yolk-sac* or *umbilical vesicle* (fig. 108). The passage between the primitive alimentary canal and the yolk-sac is named the *vitelline* or *omphalo-mesenteric duct* (fig. 166). Although the embryo grows in all directions, it increases much more rapidly in length than in width; and coincident with this, the cephalic and caudal extremities are bent downwards to form the *cephalic* and *caudal folds* respectively (figs. 109 and 166). With the forward growth of the head the pericardial area is folded backwards under it, and comes to lie in the ventral wall of the primitive alimentary canal, its original upper surface, in this manner, becoming its under surface. When the cephalic and caudal flexures have been formed, the primitive alimentary canal presents the appearance of a nearly straight tube, closed at its two extremities. This tube is divided into three portions, viz.: (*a*) the *fore-gut*, between the pericardium and the notochord; (*b*) the *mid-gut*, opening directly into the yolk-sac; and (*c*) the *hind-gut*, contained within the caudal fold (fig. 166).

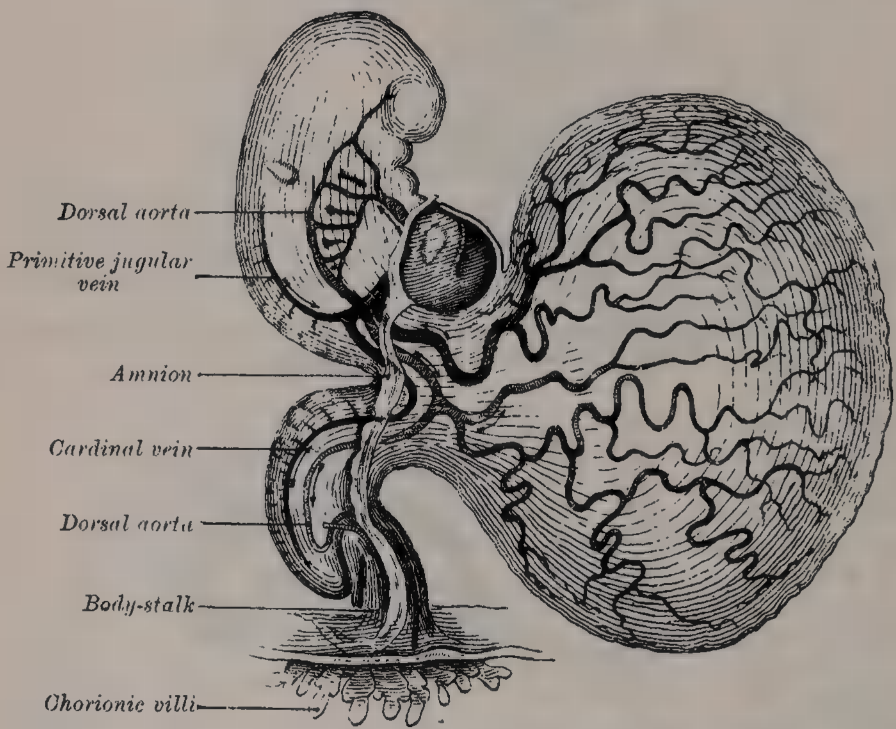
MEMBRANES AND APPENDAGES OF THE FŒTUS

These are concerned with the protection and nourishment of the embryo, and comprise (1) the yolk-sac, the amnion, the chorion, the allantois, and the umbilical cord, which are of fœtal origin; (2) the uterine decidua, which is produced by a modification of the mucous membrane of the uterus; and (3) the placenta, which is derived partly from fœtal and partly from maternal tissues.

The Yolk-sac (figs. 101, 107 and 108).—In the human embryo this is of small size, and only supplies nourishment to the embryo during the earlier stages of its existence. It is an appendage of the alimentary canal, and consists, as has been explained, of that portion of the blastodermic vesicle which is not enclosed within the body of the embryo to form the primitive alimentary canal, and like that tube it is lined by entoderm, outside of which is a layer of mesoderm. It assumes the form of an oval sac, which is filled with fluid, the *vitelline fluid*; it is situated on the ventral aspect of the embryo, and communicates with the mid-gut by means of the vitelline duct. Blood is conveyed to the wall of the sac by the primitive aortæ, and after circulating through a wide-meshed capillary plexus, termed the

Fig. 110.—Human embryo of about fourteen days old with yolk-sac. (After His.) (From Kollmann's 'Entwickelungsgeschichte.')



vascular area, is returned by the vitelline veins to the tubular heart. This constitutes the *vitelline circulation* (fig. 110), and by means of it nutritive material is absorbed from the vitelline fluid and conveyed to the embryo. The yolk-sac increases in size up to the end of the fourth week, and then presents the appearance of a pear-shaped vesicle, opening into the alimentary canal by a long narrow tube, the vitelline duct. This duct is sooner or later obliterated, but a trace of it is sometimes found in the adult as a diverticulum from the small intestine; this is known as *Meckel's diverticulum*, and is situated from two to four feet above the ilio-colic junction.

The **Amnion** is a membranous sac which surrounds and protects the embryo. It is at first of small size, but increases considerably towards the middle of pregnancy as the fœtus acquires the power of independent movement. It exists only in reptiles, birds, and mammals, which are hence called 'Amniota'; being absent in amphibia and fishes, which are consequently termed 'Anamnia.' In man, monkeys, and some of the bats the primitive amniotic cavity probably persists (fig. 98). As already explained (page 80), Van Beneden regards the amniotic cavity as being produced by a hollowing-out of the inner cell-mass, owing to the atrophy and

disappearance of some of its cells. Mall, on the other hand, suggests that the amnion is formed by an inversion of the blastoderm.

In reptiles, birds, and certain mammals it is developed in the following manner. At the point of constriction where the primitive alimentary canal of the embryo joins the yolk-sac—i.e. in the region of the future umbilicus—a reflection or folding upwards of the somatopleure takes place. This fold first makes its appearance at the cephalic extremity, and subsequently at the caudal end and sides of the embryo, and, gradually rising more and more, its different parts meet over the dorsal aspect of the embryo. After coming into contact they fuse, and the septum between them disappears, so that the inner layer of the cephalic part becomes continuous with the inner layer of the caudal and lateral parts, and the outer with the outer. Thus there are two membranes formed, one produced by the inner layer of the fold—the amnion—which encloses a space over the back of the embryo—the amniotic cavity; the outer membrane is termed the *scrosa, false amnion,* or *chorion* (figs. 106 and 108). The space between the amnion and the chorion constitutes the extra-embryonic cœlom, already referred to, and is at first in communication with the embryonic cœlom or primitive pleuro-peritoneal cavity. When first formed the amnion is in close contact with the body of the embryo, but about the fourth or fifth week fluid begins to accumulate within it. This fluid constitutes the *liquor amnii,* and, increasing in quantity, causes the amnion to expand and ultimately to adhere to the inner surface of the chorion, so that the extra-embryonic part of the cœlom is obliterated. The amnion therefore covers the inner surface of the chorion and the fœtal aspect of the placenta. The liquor amnii increases in quantity up to the sixth or seventh month of pregnancy, after which it diminishes somewhat in amount. It allows of the free movements of the fœtus during the later stages of pregnancy, and also protects it by diminishing the risk of injury from without. It contains less than 2 per cent. of solids, which consist of urea and other extractives, inorganic salts, a small amount of albumen, and frequently a trace of sugar. That part of the fluid is swallowed by the fœtus is proved by the fact that epidermal débris and hairs have been found among the contents of the fœtal alimentary canal.

The Chorion (figs. 109 and 112).—The chorion is developed from the wall of the blastodermic vesicle, and consists of two layers: an outer formed by the primitive ectoderm or trophoblast, and an inner by the somatic mesoblast (figs. 107 and 114). The trophoblast is made up of an internal layer of cubical or prismatic cells, the *cytoblast* or *layer of Langhans,* and an external layer of richly nucleated protoplasm devoid of cell boundaries, the *syncytium.* Numerous villous processes, the *chorionic villi,* project into the decidua from the entire outer surface of the chorion. These are at first small and non-vascular, and consist of trophoblast only, but they increase in size and undergo ramification; while the mesoderm, carrying branches of the umbilical vessels, grows into them, and in this way they

are vascularised. These villi invade and destroy the decidua of the uterus, and at the same time absorb from it nutritive materials for the growth of the embryo. Until about the end of the second month of pregnancy the villi which cover the chorion are of an almost uniform size (fig. 109), but after this they develop unequally. The greater part of the chorion is in contact with the decidua reflexa (fig. 115), and over this portion the villi, with their contained vessels, undergo atrophy, so that by the fourth month scarcely a trace of them is left, and hence this part of the chorion becomes smooth, and is named the *chorion læve*; as it takes no share in the formation of the placenta, it is also named the non-placental part of the chorion. On the other hand, the villi on that part of the chorion which is in contact with the decidua serotina increase greatly in size and complexity, and hence this part is named the *chorion frondosum*. Since it forms the fœtal

portion of the placenta, it is appropriately named the placental part of the chorion, and its villi, the placental villi (fig. 115).

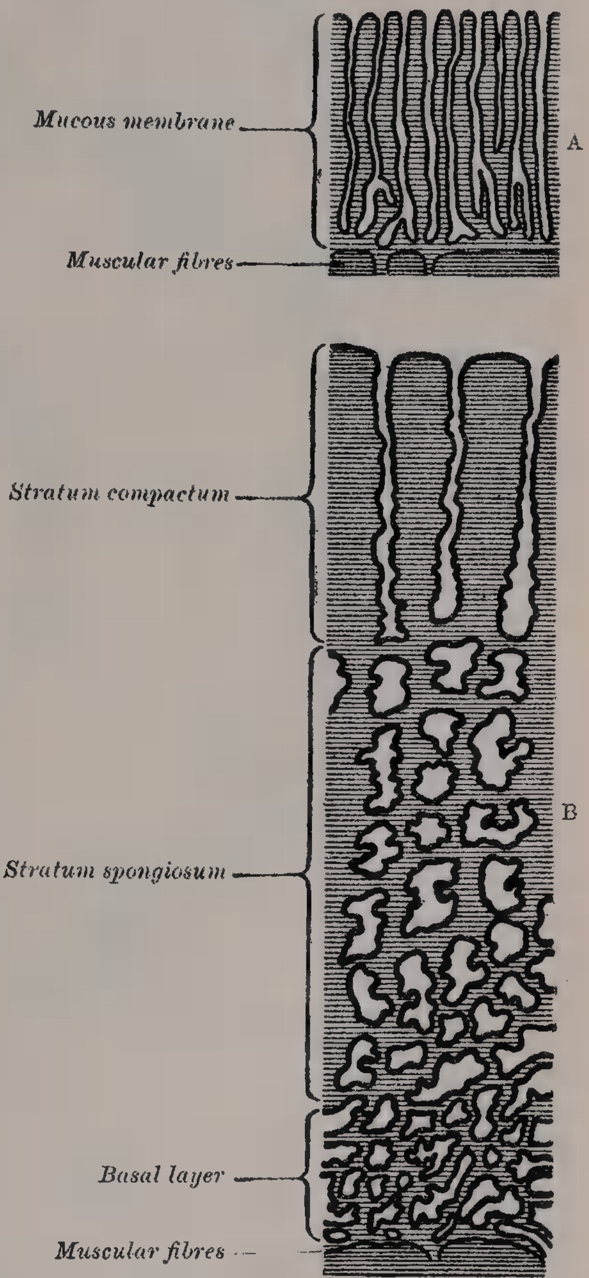
The Allantois (figs. 166 and 167).—The allantois arises as a diverticulum from that part of the hind-gut which later forms the cloaca: it grows out into a mass of mesoderm which lies below and around the tail end of the embryo. The diverticulum is lined by entoderm and covered by mesoderm, and in the latter are carried the allantoic or umbilical vessels.

In reptiles, birds, and many mammals the allantois becomes expanded into a vesicle (figs. 106 and 109) which projects into the extra-embryonic cœlom, i.e. into the space between the amnion and the chorion. If its further development be traced in the bird, it is seen to project to the right side of the embryo, and, gradually expanding, it spreads over its dorsal surface as a flattened sac between the amnion and the chorion, and, extending in all directions, ultimately surrounds the

yolk. Its outer wall becomes applied to, and fuses with, the chorion, which lies immediately inside the shell membrane. Blood is carried to the allantoic sac by the two allantoic or umbilical arteries which are continuous with the primitive aortæ, and, after circulating through the allantoic capillaries, is returned to the primitive heart by the two umbilical veins. In this way the allantoic circulation, which is of the utmost importance in connection with the respiration and nutrition of the chick, is established. Oxygen is taken from, and carbonic acid is given up to, the atmosphere through the egg-shell, while nutritive materials are at the same time absorbed by the blood from the yolk.

In man and other primates the nature of the allantois is entirely different from that just described. Here it exists merely as a narrow, tubular diverticulum of the hind-gut, and never assumes the form of a vesicle outside the embryo. With the formation of the amnion the embryo is, in most animals, entirely separated from the chorion, and is only again united to it when the allantoic mesoderm spreads over and becomes applied to its inner surface. The human embryo, on the other hand, as was pointed out by His, is never wholly separated from the chorion, its tail end being from the first connected with the chorion by means of a thick band of mesoderm, named the *body-stalk* (*Bauchstiel* of His—figs. 107 and 167); into this stalk the tube of the allantois extends (fig. 167). Moreover, in the human embryo the allantoic diverticulum is seen before the hind-gut is formed, and appears as a tubular protrusion from the blastodermic cavity (fig. 107). The body-stalk is at first attached to the hind-end of the embryo, but with the growth of the tail and the formation of the caudal flexure it assumes a ventral position, and the tubular allantois is then seen to open from the cloacal part of the hind-gut. The intra-abdominal part of the allantois becomes the fibrous cord of the *urachus*, and the body-stalk is elongated to form the umbilical cord.

FIG. 113.—Diagrammatic sections of the uterine mucous membrane: (A) of the non-pregnant uterus; (B) of the pregnant uterus, showing the thickened mucous membrane and the altered condition of the uterine glands.



The allantoic mesoderm gradually spreads itself over the inner surface of the chorion, and, invading the chorionic villi, supplies them with blood-vessels. The chorionic villi are embedded in the uterine decidua, and thus, by means of the allantoic circulation, nutritive substances are absorbed from the maternal blood and carried through the allantoic veins to the fœtus; at the same time, the waste products of the fœtus are passed into the maternal blood. Coincident with the atrophy of the non-placental villi of the chorion, the corresponding branches of the allantoic vessels become obliterated. Those vessels, on the other hand, which supply the placental villi undergo great enlargement, and constitute the fœtal blood-vessels of the placenta.

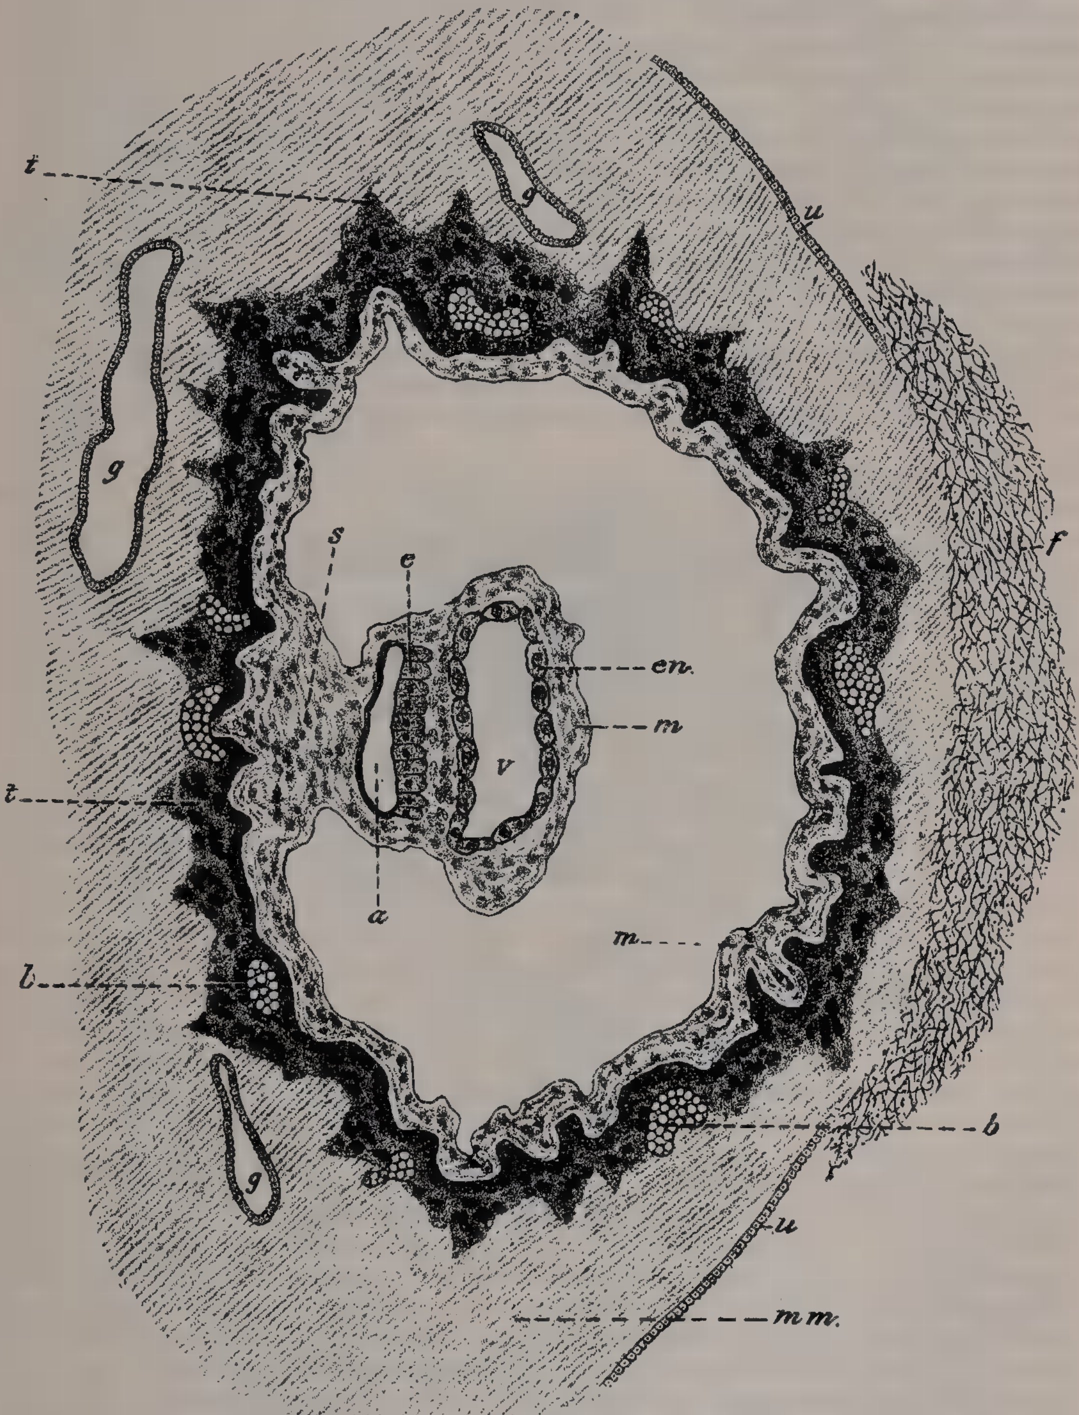
The decidua.—Some four or five days before each menstrual period, changes are initiated in the mucous membrane of the uterus in order to render it fit for the reception of a fertilised ovum. It becomes congested and hypertrophied, its connective-tissue cells are increased in number, and its glands are expanded. If the ovum be not fertilised, the superficial layer of the mucous membrane rapidly degenerates and is cast off, while the superficial vessels are at the same time ruptured, causing the hæmorrhage of menstruation. After the cessation of the menstrual flow, the mucous membrane is regenerated, and the epithelium of the glands spreads over its surface and forms a new epithelial covering. If the ovum be fertilised, these degenerative processes do not occur: the mucous membrane is retained *in situ* and undergoes further changes, which result in the formation of the *decidua.*

These further changes are as follows: Its thickness and its vascularity are greatly increased; its glands are elongated and open on its free surface by funnel-shaped orifices, while their deeper portions are tortuous and dilated into irregular spaces. The interglandular tissue is also increased in quantity, and is crowded with large round, oval, or polygonal cells, termed *decidual cells.* These changes are well advanced by the second month of pregnancy, and at this time the mucous membrane consists of the following strata (fig. 113): (1) *Stratum compactum,* next the free surface; in this the uterine glands are only slightly expanded, and are lined by columnar cells. (2) *Stratum spongiosum,* in which the gland tubes are greatly dilated and very tortuous, and ultimately come to be separated by only a small amount of interglandular tissue, while their lining cells are flattened or cubical. It is through the deep part of this layer that the placenta is separated after the birth of the child. (3) A thin *basal layer,* next the uterine muscular fibres, containing the deepest parts of the uterine glands, which are not dilated, and are seen to be lined with columnar epithelium. It is from this epithelium that the epithelial lining of the uterus is regenerated after pregnancy. The decidua lines the whole of the *body* of the uterus, without, however, occluding the orifices of the Fallopian tubes.

When the fertilised ovum reaches the interior of the uterus it attaches itself to the decidua, generally in the region of the fundus uteri. It has been customary to describe the decidua as growing up around the ovum so as ultimately to cover it in—the part which grows over and covers it in being named the *decidua reflexa* or *capsularis.* The portion of the decidua which intervenes between the ovum and the uterine muscular fibres is known as the *decidua serotina,* while that which lines the remainder of the body of the uterus is termed the *decidua vera* (fig. 115). In view, however, of the observations of Hubert Peters, who has investigated the placental development in a human ovum estimated to be less than a week old, this description must be somewhat modified. In Peters' specimen (fig. 114) the entire ovum was lenticular in shape, its longest diameter being parallel to the decidua serotina. The whole ovum was embedded in the decidua on the posterior wall of the uterus, forming a slight projection towards the uterine cavity. At the central part of this prominence the uterine epithelium was absent over an area measuring 1 mm. in diameter, and this aperture was closed by a blood-clot. Peters' observations therefore lead to the conclusion that as soon as the fertilised ovum enters the uterus it adheres to the decidua, and, destroying the surface epithelium, rapidly sinks into the substance of the stratum compactum, in which it becomes embedded. The ovum quickly expands, and excavates the stratum compactum both in width and depth, and the overhanging part of the decidua forms the decidua reflexa or capsularis; the original aperture by which the ovum entered being closed by blood-clot, which ultimately undergoes organisation. No remains of the surface epithelium of the uterus were found on the inner surface of the decidua reflexa, nor over the decidua serotina. The decidua reflexa contained no uterine glands, nor were any glands seen opening on the surface of the decidua serotina. Remains of dilated glands were present in the deeper part of the decidua serotina, but their communications with the surface no longer existed. Villous processes covered the whole surface of the ovum and projected into the surrounding decidua. Many of these villi consisted of trophoblast only, but some contained cores of mesoderm. Spaces filled with maternal blood were found in the trophoblastic syncytium, and the processes of the latter were seen to embrace the maternal capillaries. The amnion was quite closed over the rudiment of the embryo, and the latter consisted of a patch

of columnar ectodermal cells, on the ventral aspect of which there existed a small closed yolk-sac. The amnion and yolk-sac were enveloped by mesoderm, and the latter was continuous with the chorionic mesoderm by a cord of cells which represented the body-stalk.

FIG. 114.—Section through early ovum embedded in the uterine decidua. Semi-diagrammatic. (Modified from Peters.)



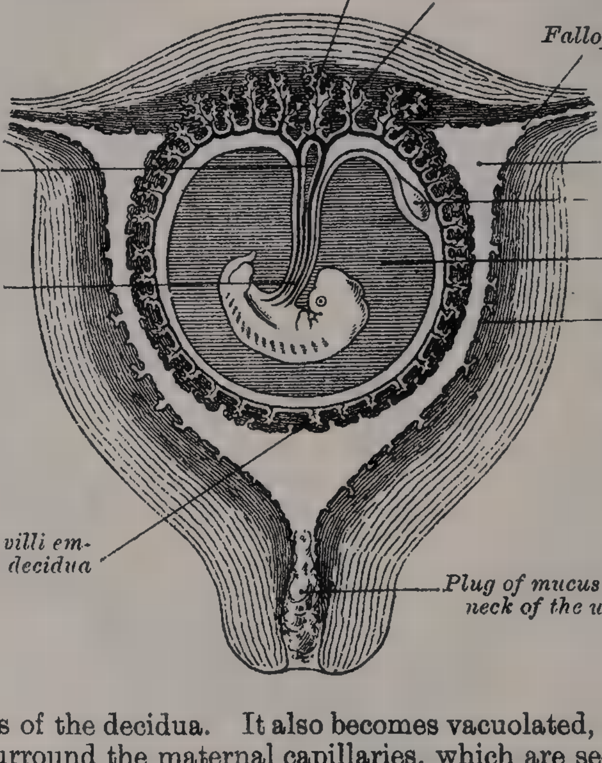
a. Amniotic cavity. *b.* Maternal blood-vessels. *e.* Embryonic ectoderm. *en.* Entoderm. *f.* Mass of fibrin. *g.* Uterine glands. *m.* Mesoderm. *mm.* Uterine decidua. *s.* Body-stalk. *t.* Trophoblast. *u.* Uterine epithelium. *v.* Yolk-sac.

Coincident with the growth of the embryo, the decidua reflexa is thinned and expanded (fig. 115). Its vascular supply is diminished, and it undergoes degeneration, and at the same time the non-placental villi atrophy and disappear. The space between the decidua reflexa and the decidua vera is gradually obliterated, so that by the third month of pregnancy the two are in contact. By the fifth month the decidua reflexa has practically disappeared, and, as a consequence, the chorion

læve comes directly into contact with the decidua vera. During the succeeding months of pregnancy the decidua vera also undergoes atrophy, owing to the increased pressure. The glands of the stratum compactum are obliterated, and their epithelium is lost. In the stratum spongiosum the glands are compressed and present the appearance of slit-like fissures, while their epithelium undergoes degeneration. In the deepest layer, however, the glandular epithelium retains a columnar or cubical form.

The Placenta.—The placenta connects the fœtus to the uterine wall, and is the organ by means of which the nutritive, respiratory, and excretory functions of the fœtus are carried on. It consists of two parts—fœtal and maternal—the former being derived from the villi of the chorion frondosum with their contained blood-vessels, the latter from the decidua serotina, i.e. the part of the uterine decidua which intervenes between the ovum and the muscular wall of the uterus (fig. 115). It has been pointed out that at first the chorionic villi consist of trophoblast only—viz. the layer of Langhans and the syncytium—and that later they are invaded by the allantoic mesoderm, which conveys to them branches of the umbilical arteries. The syncytium proliferates rapidly, and burrows into and

Fig. 115.—Sectional plan of the gravid uterus in the third and fourth month. (Modified from Wagner.)



absorbs the tissues of the decidua. It also becomes vacuolated, and the extremities of its processes surround the maternal capillaries, which are seen to open directly into the spaces in the syncytium; and thus the maternal blood comes to circulate through these spaces (fig. 114). Subsequently the non-placental villi of the chorion, which project into the decidua reflexa, become atrophied, and this part of the chorion is rendered smooth (chorion læve). On the other hand, the villi of the chorion frondosum, which project into the decidua serotina, increase enormously in size and complexity, and practically replace the whole of the superficial layer of this part of the decidua; and the greatly ramified villi come to be suspended in a series of freely communicating spaces, the *maternal blood-sinuses*, which are filled with maternal blood. The maternal blood is conveyed to these spaces by the uterine arteries, and, after circulating slowly through them, is drained away by the uterine veins.

The endothelial lining of the uterine vessels can only be traced for a short distance from the mouths of the vessels on to the walls of the spaces, and is then lost. Whether the spaces beyond this point are lined by modified decidual cells, or by an expansion of the trophoblastic syncytium, is not yet determined; it must, however, be clearly understood that they are not lined by uterine epithelium.

Each chorionic villus contains a branch of an umbilical artery and a tributary of the umbilical vein, with an intervening capillary plexus. These are surrounded by thin mesodermal walls, which, in turn, are covered by two strata of cells. These two strata are probably both of fœtal origin, and may represent the layer of Langhans and the modified syncytium. As to their nature there is, however, a marked difference of opinion—some observers regarding one (that next the maternal blood), others both, as being of maternal origin. The fœtal blood is separated by these thin layers from the maternal blood in the sinuses, and hence there is no intermingling of the fœtal and maternal blood-currents. Nevertheless, the fœtal blood is able to absorb, through the thin walls of the villi, oxygen and nutritive materials from the maternal blood, and give up to the latter its waste products. The blood, thus purified, is carried back to the fœtus by the umbilical vein. It will thus be seen that the placenta not only establishes a mechanical connection between the mother and the fœtus, but subserves for the latter the purposes of nutrition, respiration, and excretion. In favour of the view that the placenta possesses certain selective powers may be mentioned the fact that glucose is more plentiful in the maternal than in the fœtal blood. It is interesting to note also that the proportion of iron, and of lime and potash, is increased during the last months of pregnancy. Further, there seems evidence that the maternal leucocytes may migrate into the fœtal blood, since leucocytes are much more numerous in the blood of the umbilical vein than in that of the umbilical arteries.

Separation of the placenta.—After the child is born, the placenta and membranes are expelled from the uterus as the *after-birth*. The separation of the placenta from the uterine wall takes place through the deepest part of the stratum spongiosum, and necessarily causes rupture of the uterine vessels. The orifices of the torn vessels are, however, closed by the firm contraction of the uterine muscular fibres, and this, together with the formation of a blood-clot over the placental site, prevents *post partum* hæmorrhage. The epithelial lining of the uterus is regenerated by the proliferation of the epithelium which lines the persistent portions of the uterine glands in the basal layer of the decidua.

After its separation the placenta appears as a flattened disc, which weighs about a pound, and has a diameter of from six to eight inches. Its average thickness is about an inch and a quarter, but diminishes rapidly towards the circumference of the disc. Its outer or decidual surface is comparatively smooth, but on inspection is seen to be incompletely divided into a number of lobules or *cotyledons*; the fissures between the lobules correspond with septa which pass inwards towards the chorionic surface of the placenta. Most of these septa end in irregular or pointed processes after extending for a short distance; but others, especially those near the edge of the placenta, extend through its thickness and are attached to the chorion. In the early months these septa convey branches of the uterine arteries which open into the maternal sinuses on the surfaces of the septa. The inner or chorionic surface of the placenta is smooth, being closely invested by the amnion. Seen through the latter, the chorion presents a mottled appearance, consisting of grey, purple, or yellowish areas. The umbilical cord is usually attached near the centre of the placenta, but may be inserted anywhere between the centre and the margin. In some cases it is inserted into the membranes, i.e. the *velamentous* insertion. From the attachment of the cord the larger branches of the umbilical vessels radiate under the amnion, the veins being deeper than the arteries, and of a greater size. Occasionally remains of the vitelline duct and yolk-sac may be observed beneath the amnion, close to the cord, the former as an attenuated thread, the latter as a minute sac.

On section, the placenta presents a soft, spongy appearance, caused by the greatly branched villi, which are surrounded by a varying amount of maternal blood—the latter giving rise to the dark red colour of the placenta. Many of the larger villi extend from the chorionic to the decidual surface, while others are attached to the septa which extend inwards from the decidual surface of the placenta; but the great majority hang free in the maternal sinuses, like the branches of a tree. Owing to the rapid thinning of the placenta at the periphery of the disc, its decidual and chorionic surfaces come into contact.

The umbilical cord.—The rudiment of the umbilical cord is represented by the constricting ring which separates the rapidly growing embryo from the extra-embryonic area of the ovum. Included in this ring are the body-stalk and the

vitelline duct—the former containing the allantoic diverticulum and the umbilical vessels, the latter forming the communication between the alimentary canal and the yolk-sac. The body-stalk is a continuation of the tail end of the embryo, connecting the latter with the chorion. On transverse section, the amnion is seen to arch over its dorsal aspect, which is covered by thickened ectoderm and shows a trace of a medullary groove. Running through its mesoderm are the two umbilical arteries and the two umbilical veins, together with the canal of the allantois—the last being lined by entodermal epithelium. Its ventral surface is bounded by the extra-embryonic cœlom, and is in contact with the vitelline duct and yolk-sac. With the rapid elongation of the embryo and the formation of the tail fold, the body-stalk is carried forwards to the ventral surface of the embryo, where its mesoderm blends with that of the yolk-sac and the vitelline duct. The lateral leaves of somatopleure then grow round on each side, and, meeting on the ventral aspect of the allantois, enclose the vitelline duct and its vessels, together with a part of the embryonic cœlom; the latter is ultimately obliterated. The cord, therefore, is not covered by the amnion, but by a layer of ectoderm which is continuous with that of the amnion at the placental end of the cord, around which the amnion is attached. The various constituents of the cord are enveloped by embryonic gelatinous tissue (jelly of Wharton). The vitelline vessels and duct, together with the right umbilical vein, undergo atrophy, and disappear; and thus the cord, at birth, contains a pair of umbilical arteries and only one umbilical vein.

DEVELOPMENT OF THE EMBRYO

The further development of the embryo will, perhaps, be best understood by giving an outline of the principal facts relating to the development of the chief parts of which the body consists, viz. the skeleton, the pharyngeal cavity, mouth &c., the nervous centres, the organs of the senses, the circulatory system, the alimentary canal and its appendages, the respiratory and the genito-urinary organs. The reader is also referred to the chronological table of the development of the fœtus at the end of this section.

DEVELOPMENT OF THE SKELETON

The entire skeleton is of mesoblastic origin; it may be divided into (*a*) the skeleton of the trunk (axial skeleton), comprising the vertebral column, skull, ribs, and sternum, and (*b*) that of the limbs (appendicular skeleton).

The vertebral column.—The notochord (fig. 104) is the first rudiment of the vertebral column, and forms a central axis, around which its segments are developed. It is derived from the entoderm, and consists of a rod of cells, which lies on the ventral aspect of the neural tube and reaches from the anterior end of the mid-brain to the extremity of the tail. The paraxial mesoderm divides from before backwards into a number of segments, the protovertebral somites or primitive segments (fig. 103), which are arranged symmetrically on either side of the neural tube; and to each pair of somites a pair of spinal nerves is distributed. Each somite at first contains a central cavity or myocœl, which, however, is soon filled with a core or nucleus of angular and spindle-shaped cells. The cells of each somite become arranged into three groups: viz. (1) an external or dorsal, the *cutis plate*; (2) an internal, the *muscle plate* or *myotome*; and (3) a ventral, the *sclerotome*. The cells of the sclerotome are largely derived from those which constitute the core of the myocœl. Fusion of the individual sclerotomes in an antero-posterior direction soon occurs, and all trace of their originally segmented condition is lost; they then form a continuous strand of cells, the *scleratogenous layer*, which extends along the ventral and lateral aspects of the neural tube. The cells of this layer proliferate rapidly, and, gradually extending inwards, enclose the notochord in a continuous investment. From this investment the base of the skull, the vertebræ and their ligaments, and the membranes of the spinal cord are developed. It becomes thicker and more condensed opposite each protovertebral somite, and then extends outwards and backwards in the form of an arch, which is named the *primitive vertebral bow*. The mesial part of this bow lies below the notochord, and is named the *hypochordal bar* or *brace*. The

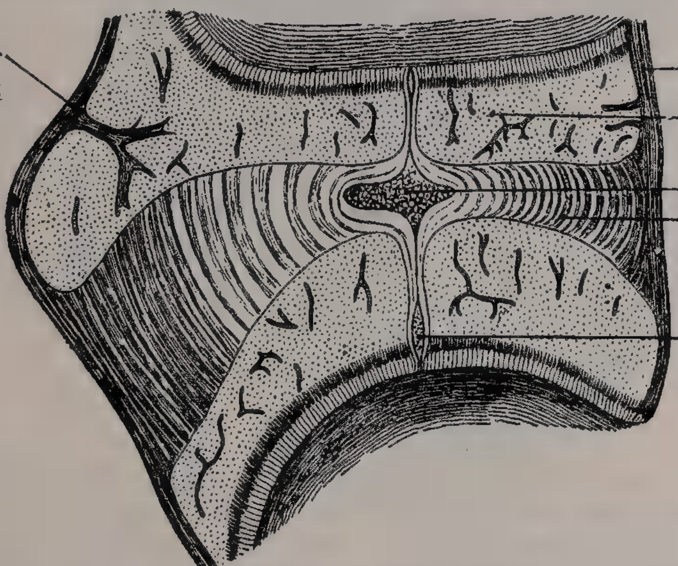
lateral portions of the bow extend both dorsally and ventrally—the dorsal extension surrounds the neural tube, and forms the future neural arch of the vertebra; while the ventral becomes the costal process. The body of the vertebra is developed from that part of the investing mass which lies on the dorsal aspect, the hypochordal bar, and immediately surrounds the notochord. It makes its appearance as two small cartilaginous nodules, one on each side of the notochord, around which they ultimately fuse to form the cartilaginous vertebral body.

Fig. 116.—Longitudinal section of vertebral column of an eight weeks' human fœtus. (Kölliker.)

Except in the case of the first cervical vertebra, the hypochordal bar of the primitive vertebral bow disappears by fusing with the intervertebral disc. In the first cervical vertebra, on the other hand, the entire bow persists, the hypochordal bar being developed into the anterior arch of this bone. The cartilaginous body of this vertebra fuses with that of the second cervical to form its odontoid process.

The portions of the notochord which are surrounded by the bodies of the vertebræ atrophy, and ultimately disappear, while the parts which lie in the centre of the intervertebral discs undergo enlargement and persist throughout life as the nucleus pulposus in the centre of these discs (figs. 116 and 117).

Fig. 117.—Sagittal section through the intervertebral disc and adjacent parts of two vertebræ of an advanced sheep's embryo. (Kölliker.)



Development of the ribs.—The ribs are formed from the ventral or costal processes of the primitive vertebral bows already referred to. Each of these processes grows ventrally into the body wall, inclining at first backwards and outwards, so as to pass on the caudal aspect of the corresponding muscle-plate. They are at first continuous with the primitive vertebræ; but when the latter become cartilaginous, the direct continuity is lost at the costo-vertebral articulations. Normally, there are only twelve pairs of ribs, but the costal processes of the last cervical or of the first lumbar vertebra are sometimes developed into movable ribs.

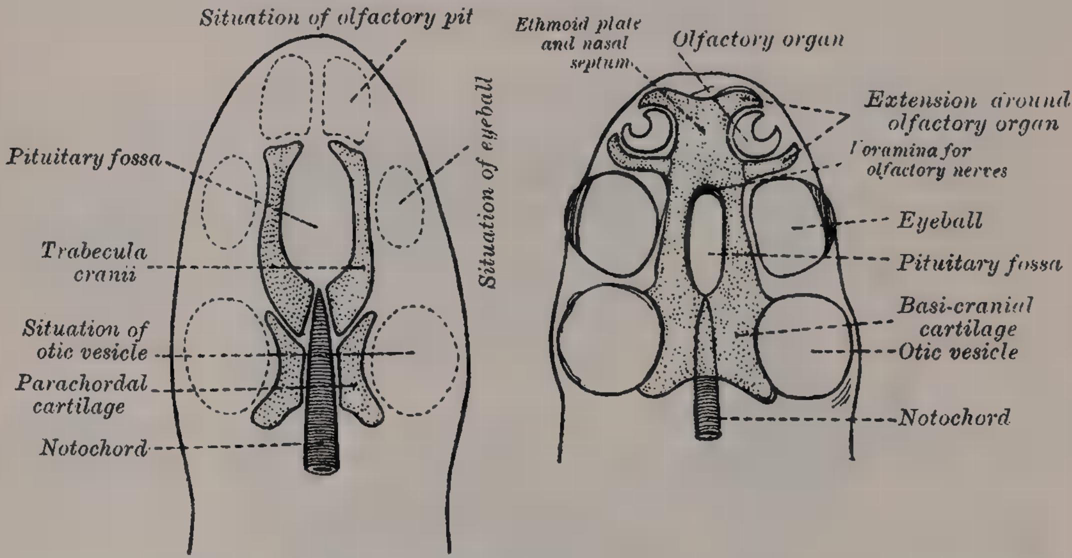
Development of the sternum.—The view generally held regarding the development of the sternum is that it arises as a paired structure from the ventral ends of the ribs, and that the two halves fuse in the middle line. The anterior ends of the nine upper costal bars join to form a cartilaginous strip on each side of the middle line—the two strips being at first connected by membrane. They then become united in the middle line from before backwards, and so give rise to a longitudinal piece of cartilage, which represents the manubrium and gladiolus. The ventral ends of the eighth and ninth cartilages fuse to form the xiphoid

appendix, and subsequently lose their connection with the sternum. Sometimes the eighth retains its original connection, and constitutes an eighth true rib, which occurs more frequently on the right than on the left side. This bilateral condition of the primitive sternum would serve to explain the occurrence of fissures or holes in the bone, as well as that rare anomaly, a completely divided sternum.

Paterson,* on the other hand, after reviewing the literature on this subject, and giving the results of his own observations on the embryonic and adult conditions of the sternum in man and some of the lower animals, says: 'The weight of evidence is all on the side of the primary association of the sternum with the shoulder girdle and its secondary connection with the ribs.'

Development of the skull.—Up to a certain stage the development of the skull corresponds with that of the vertebral column; but it is modified later in association with the expansion of the brain-vesicles, the formation of the organs of smell, sight, and hearing, and the development of the mouth and pharynx. The notochord, which extends as far forwards in the base of the future skull as the anterior end of the mid-brain, becomes partly surrounded by mesoderm. The posterior part of this mesodermal investment corresponds with the future basi-occiput, and shows a subdivision into four segments, which are separated by the roots of the hypoglossal nerve. The mesoderm then extends over the brain-

FIG. 118.—Diagrams of the cartilaginous cranium. (Wiedersheim.)



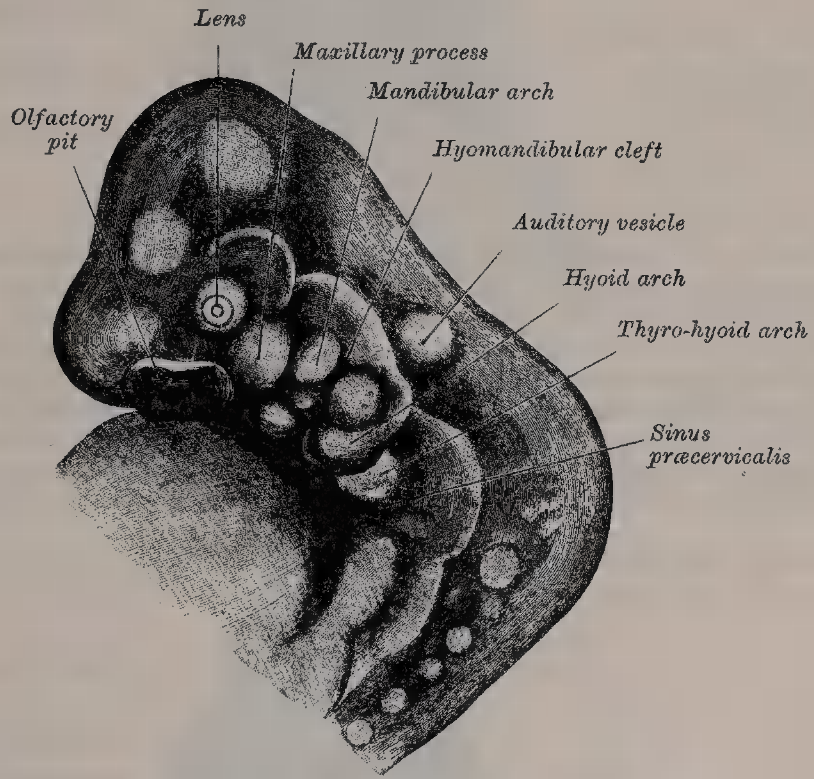
vesicles, and thus the entire brain is enclosed by a mesodermal investment, which is termed the *membranous primordial cranium*. From this are developed the bones of the skull and the membranes of the brain, together with the muscles, blood-vessels, true skin, and subcutaneous tissues of the scalp. In the shark and dog-fish this membranous cranium undergoes complete chondrification, and forms the cartilaginous skull or *chondro-cranium* of these animals. In mammals, on the other hand, the process of chondrification is limited to the base of the skull—the roof and sides being covered in by membrane. Thus, the bones of the base of the skull are preceded by cartilage, those of the roof and sides by membrane. The posterior part of the base of the skull is developed around the notochord, and exhibits a segmented condition analogous to that of the vertebral column, while the anterior part arises in front of the notochord. The base of the skull may therefore be divided into (a) *chordal* or *vertebral*, and (b) *prechordal* or *prevertebral* portions.

In the lower vertebrates two pairs of cartilages are developed: viz. a pair of parachordal cartilages, one on either side of the notochord; and a pair of prechordal cartilages, the *trabeculæ cranii*, in front of the notochord. The *parachordal cartilages* (fig. 118) unite to form a cartilaginous plate, from which the basi-occiput and basi-sphenoid are developed. On the lateral aspect of the parachordal cartilages the *otic* or *auditory vesicles* are situated, and the mesoderm

* *The Human Sternum*, by Professor A. Melville Paterson, 1904.

enclosing them is soon converted into cartilage, forming the *cartilaginous ear-capsules.* These cartilaginous ear-capsules, which are of an oval shape, fuse with the lateral aspects of the basilar plate, and from them arise the petro-mastoid portions of the temporal bones. The *trabeculæ cranii* (fig. 118) are two curved bars of cartilage which embrace the region of the future pituitary fossa; their posterior ends soon unite with the basilar plate, while their anterior ends join to form the *ethmoidal plate,* which extends forwards between the fore-brain and the olfactory pits. Later, the trabeculæ extend across and fuse below the pituitary body, forming the floor of the pituitary fossa, and so cutting off the anterior lobe of the latter from the mouth cavity. The mesial part of the ethmoidal plate forms the bony and cartilaginous parts of the nasal septum, while its lateral prolongations form the roof and upper part of the outer wall of the nose. From the posterior parts of the trabeculæ cranii the sphenoid bone and its external pterygoid plates are developed. Thus, it will be seen that the bones which form the base of the skull are preceded by the cartilaginous chondro-cranium. Those of the vault, on the other hand, are of membranous formation, and are termed *dermal* or *covering*

FIG. 119.—Profile view of the head of a human embryo, estimated as twenty-seven days old. (After His.)



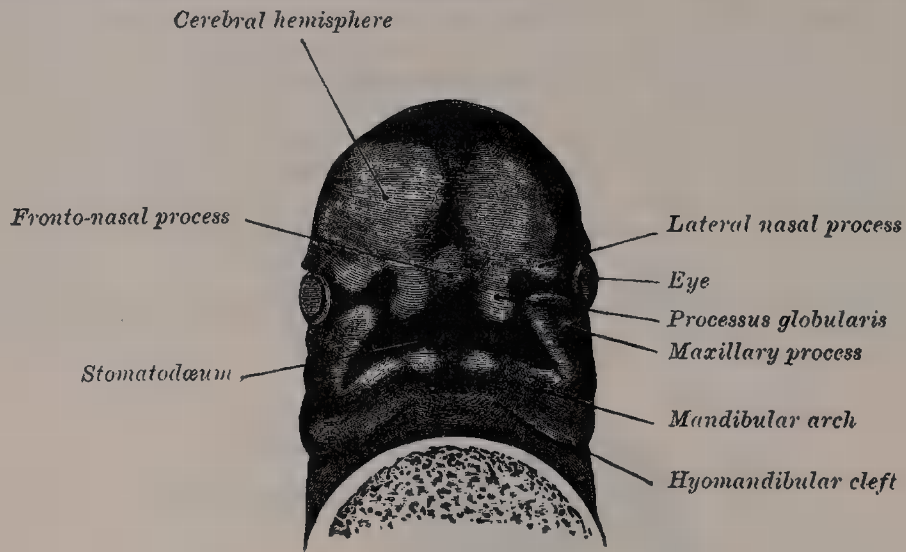
bones. They are partly developed from the mesoderm which lies superficial to the primordial cranium, and partly from that which lies outside the entoderm of the fore-gut. They comprise the upper part of the tabular portion of the occipital (interparietal), the squamous-temporals and tympanic rings, the parietals, the frontal, the vomer, the internal pterygoid plates, and the bones of the face. Some of them remain distinct throughout life (e.g. parietal and frontal), while others join with the bones of the chondro-cranium (e.g. interparietal, squamous-temporals, and internal pterygoid plates).

Recent observations have shown that, in mammals, the basi-cranial cartilage, both in the chordal and prechordal regions of the base of the skull, is developed as a single plate, which extends from behind forwards. In man, however, its posterior part shows an indication of its being developed from two chondrifying centres which fuse rapidly in front and below. The relation of this cartilaginous plate to the notochord differs in different animals. In the rat embryo it lies beneath the notochord (Robinson); in the sheep, pig, calf, and ferret, the cranial part of the notochord is enclosed within it; in man, the anterior and posterior thirds of the cartilage surround the notochord, but its middle third lies

on the dorsal aspect of the latter, which in this region is placed between the cartilage and the wall of the pharynx.

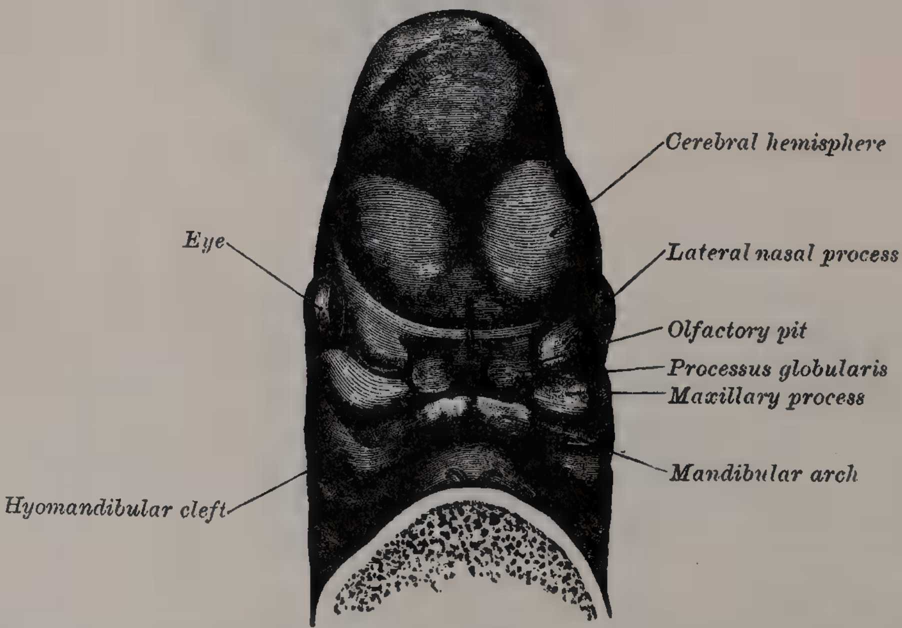
Development of the limbs.—The limbs begin to make their appearance in the third week as small elevations or buds at the side of the trunk. Prolongations from several protovertebral somites extend into each bud, and carry with them

FIG. 120.—Under surface of the head of a human embryo about twenty-nine days old. (After His.)



the anterior or ventral divisions of the corresponding spinal nerves. By the sixth week the three chief divisions of the limb are marked off by furrows—the upper into arm, forearm, and hand; the lower into thigh, leg, and foot. The limbs are at first directed backwards nearly parallel to the long axis of the trunk, and each presents two surfaces and two borders. Of the surfaces, one—the future *flexor* surface of the limb—is directed ventrally; the other, the

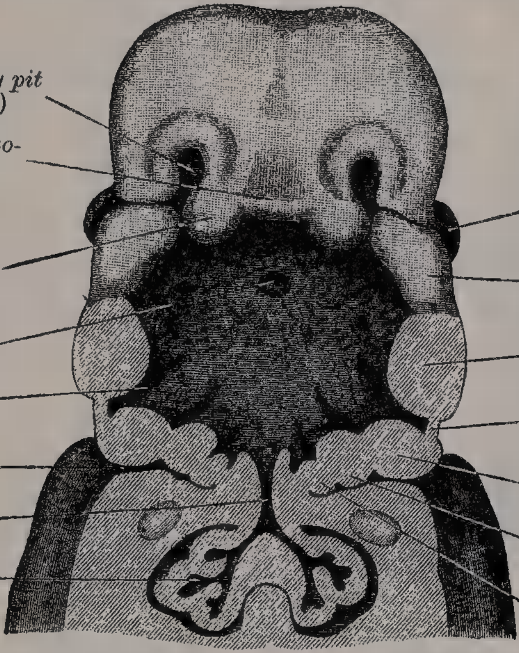
FIG. 121.—Under surface of the head of a human embryo about thirty days old. (After His.)



extensor surface, dorsally; while one border, the *pre-axial*, looks forward towards the cephalic end of the embryo, and the other, the *post-axial*, backwards towards the caudal end. The external condyle of the humerus, the radius and the thumb lie along the pre-axial border in the case of the upper limb; and the internal condyle of the femur, the tibia and the great toe along the corresponding border of the lower

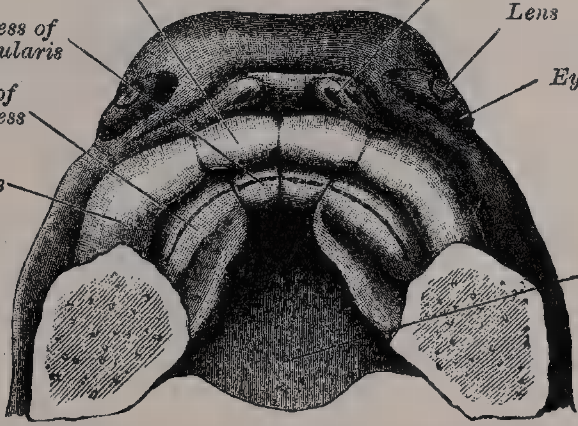
limb. The pre-axial part is derived from the anterior somites, the post-axial from the posterior somites of the limb bud; and this explains, to a large extent, the innervation of the adult limb, the nerves of the more anterior somites being distributed along the pre-axial (radial or tibial), and those of the more posterior segments along the post-axial (ulnar or fibular) border of the limb. The limbs next undergo

FIG. 122.—The head and neck of a human embryo thirty-two days old, seen from the ventral surface. The floor of the mouth and pharynx have been removed. (His.) (From Marshall's 'Vertebrate Embryology.')



a rotation or torsion through an angle of 90° around their long axes. This rotation takes place in an opposite direction in the fore as compared with the hind limb, being outwards and forwards in the former, and inwards and backwards in the latter. In this manner the pre-axial (radial) border of the fore-limb is directed outwards, while the pre-axial (tibial) border of the hind-limb is directed

FIG. 123.—The roof of the mouth of a human embryo about two and a half months old, showing the mode of formation of the palate. (His.) (From Marshall's 'Vertebrate Embryology.')



inwards; and thus the flexor surface of the fore-limb is turned forwards, and that of the hind-limb backwards.

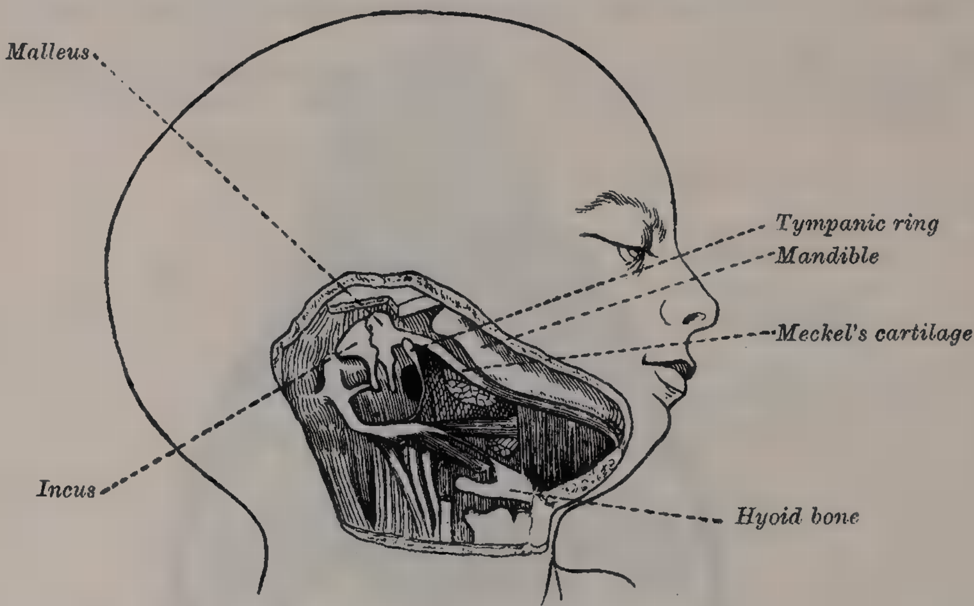
Development of the pharynx.—The pharynx is developed from the anterior part of the fore-gut, in the lateral walls of which a series of furrows or incomplete clefts appear (figs. 122 and 160). These are named the *visceral clefts*, and take origin as paired grooves or pouches from the side of the fore-gut; over each

groove a corresponding indentation of the ectoderm occurs, so that the latter comes into contact with the entodermal lining of the fore-gut, and the two layers unite to form thin septa along the bottom of the grooves between the fore-gut and the exterior. In gill-bearing animals these septa disappear, and the grooves become complete clefts—the gill-clefts—opening from the pharynx on to the exterior; perforation, however, does not occur in birds and mammals. By the thickening of the mesoderm in front of and behind each cleft, a series of rounded bars or arches, the *visceral arches*, is formed. The dorsal ends of these arches are attached to the sides of the head, while their ventral extremities ultimately meet in the middle line of the neck. Six arches in all make their appearance, of which the first four are visible externally, while the last two are never elevated above the surface. In each arch there is developed a cartilaginous bar, which gives to it firmness and stability; and in each there is also found one of the primitive aortic arches. The first arch is named the *mandibular*; the second, the *hyoid*; the third, the *thyro-hyoid* (fig. 122); while the others have no distinctive names.

Fig. 124.—Head of a human embryo of about eight weeks, in which the nose and mouth are formed. (His.)

The mandibular arch lies between the first visceral cleft and the stomatodœum, and is developed into the lower lip and mandible. Its cartilaginous bar is known as *Meckel's cartilage* (fig. 125). The upper and lower ends of this cartilage are ossified: the upper to form the malleus, and probably the incus;* the lower to form the part of the mandible adjacent to the symphysis menti. The intervening part of the cartilage disappears, but the membrane surrounding its lower part becomes ossified to form a large part of the jaw, while the upper part of its enveloping membrane is represented

Fig. 125.—Head and neck of a human embryo eighteen weeks old, with Meckel's cartilage and hyoid bar exposed. (After Kölliker.)

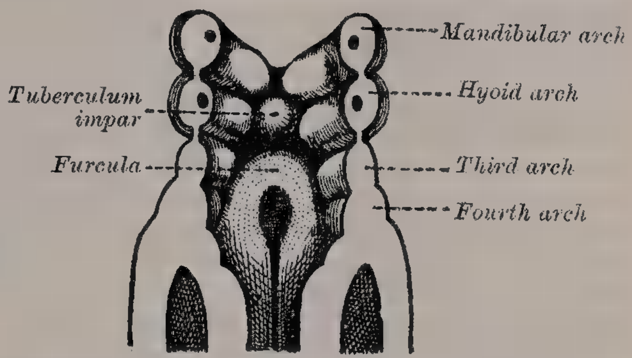


by the internal lateral or spheno-mandibular ligament. The second or hyoid arch assists in forming the side and front of the neck. From its cartilage are developed the styloid process, stylo-hyoid ligament, and lesser cornu of the hyoid

* Some regard the incus as arising from the proximal end of the hyoid bar, while Gadow (*Phil. Trans.* vol. clxxix.) inclines to the view that the malleus, incus, and stapes arise from a cartilaginous plate, the hyo-mandibula, which binds the proximal ends of the mandibular and hyoid bars together.

bone. The cartilage of the third or thyro-hyoid arch gives origin to the great cornu of the hyoid bone. The lower ends of the second and third arches unite with those of the opposite side, and form a transverse band between the furcula behind and the tuberculum impar in front (fig. 126). This band soon becomes V-shaped, its two limbs extending forward, one on either side of the tuberculum impar; from it are developed the body of the hyoid bone, and the posterior third of the tongue. The lower portions of the cartilages of the fourth and fifth arches unite to form the thyroid cartilage.

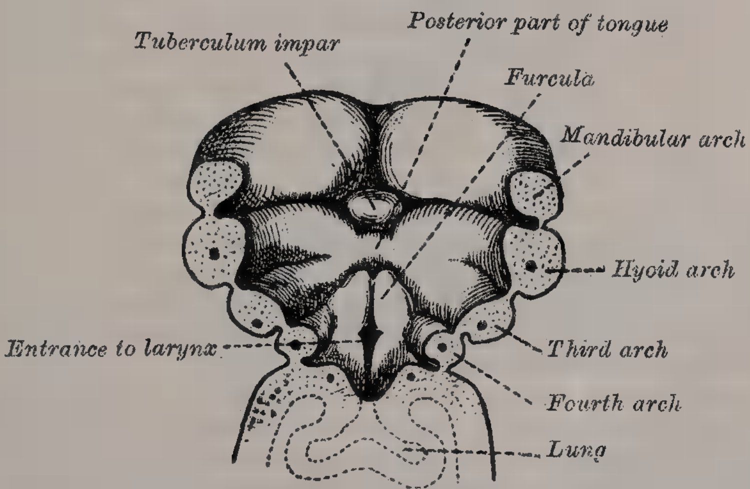
FIG. 126.—The floor of the pharynx of a human embryo about fifteen days old. × 50. (From His.)



The first and second arches grow more rapidly than those behind them, with the result that the latter become, to a certain extent, telescoped within the former, and a deep depression, the *sinus præcervicalis*, (fig. 122) is formed on the side of the neck. This sinus is bounded in front by the hyoid arch, and ultimately becomes obliterated by the fusion of its anterior and posterior walls. The outer part of the first cleft becomes the external auditory meatus, while the inner part of the same cleft forms the Eustachian tube and tympanic cavity. The septum between the outer and inner parts of this cleft becomes invaded by mesoderm, and forms the membrana tympani. No traces of the outer parts of the second, third, and fourth clefts persist. The inner part of the second cleft is subdivided into an upper and a lower portion by the palate. The former persists as the fossa of Rosenmüller, or lateral recess of the naso-pharynx; in the latter the tonsil is developed, above which a trace of the cleft persists as the supratonsillar fossa. From the pharyngeal aspect of the third cleft the thymus gland arises as an entodermal diverticulum on each side, and from the corresponding part of the fourth cleft similar diverticula give origin to the lateral parts of the thyroid body.

Development of the tongue (figs. 126 to 128).—The tongue is developed in the floor of the pharynx. The rudiment of the anterior or buccal portion

FIG. 127.—The floor of the pharynx of a human embryo about twenty-three days old. × 30. (From His.)

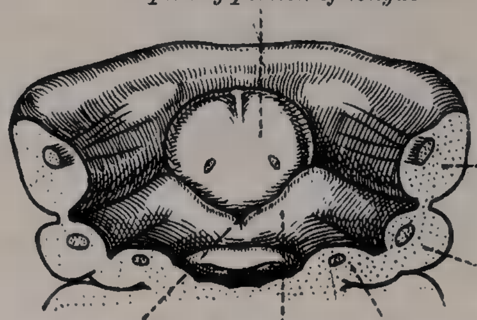


appears during the third week as a rounded elevation, immediately behind the ventral ends of the mandibular arches. This elevation is named the *tuberculum impar* (figs. 126 and 127); it extends forwards on the oral surface of the mandibular arch, and increases markedly in size by the development of a pair of lateral tongue-elevations, which raise themselves from the inner surface of the maxillary arch, and, blending with the tuberculum impar, form the tip and greater portion of the buccal part of the tongue. These lateral growths

correspond with similar structures which were described by E. Kallius in the development of the tongue of the lizard. (Consult article by E. Göppert in Hertwig's 'Entwickelungslehre.') From the ventral ends of the fourth arch there arises a second and larger elevation, in the centre of which is a median groove or furrow. This second elevation is named the *furcula* (fig. 126), and at first is merely separated from the tuberculum impar by a depression. Soon, however, they become separated by a ridge formed by the forward growth and fusion of the ventral ends of the second and third arches. The posterior or pharyngeal part of the tongue is developed from this ridge, which extends forwards in the form of a V, so as to embrace between its two limbs the tuberculum impar (figs. 127 and 128). At the apex of the V a pit-like invagination occurs, to form the middle thyroid rudiment, and this depression persists in the adult as the *foramen cæcum* of the tongue. The union of the anterior and posterior parts of the tongue is marked by a V-shaped depression (sulcus terminalis), the apex of which is at the foramen cæcum, while the two limbs run outwards and forwards, parallel to, but a little behind, the circumvallate papillæ. The prominent anterior part of the furcula forms the epiglottis; the furrow behind it is the entrance to the larynx; and the anterior parts of its lateral margins constitute the aryteno-epiglottidean folds.

Development of the mouth.—The mouth is developed partly from the stomatodœum, and partly from the floor of the anterior portion of the fore-gut. By the growth of the head end of the embryo, and the formation of the cephalic flexure, the pericardial area and the oral plate or bucco-pharyngeal area are

Fig. 128.—Floor of mouth of an embryo slightly older than that shown in fig. 127. × 16. (From His.)



carried to the ventral surface of the embryo. With the further expansion of the brain, and the bulging forwards of the pericardium, the oral plate comes to occupy a depression between these two prominences. This depression constitutes the *stomatodœum* (fig. 120). It is lined by ectoderm, and is separated from the anterior end of the fore-gut by the oral plate, which is now named the *pharyngeal septum* (fig. 167). This septum is devoid of mesoderm, being formed by the apposition of the stomatodœal ectoderm with the fore-gut entoderm; at the end of a fortnight it disappears, and thus a communication is established between the mouth and the future pharynx. No trace of the pharyngeal septum is found in the adult; and the communication just mentioned must not be confused with the isthmus faucium, since His has shown that the anterior pillars of the fauces are developed from the second visceral arches.

The visceral arches extend forwards between the stomatodœum and the pericardium; and with the completion of the mandibular arch and the formation of the maxillary processes, the mouth assumes the appearance of a pentagonal orifice, which is bounded in front by the fronto-nasal process which covers the fore-brain and contains the anterior part of the coalesced trabeculæ cranii, behind by the mandibular arch, and laterally by the maxillary processes (fig. 120). With the inward growth and fusion of the palatal processes, the upper portion of the stomatodœum is shut off to form the nasal cavities, while from its lower or buccal portion the roof and anterior part of the mouth, together with the teeth, are developed.

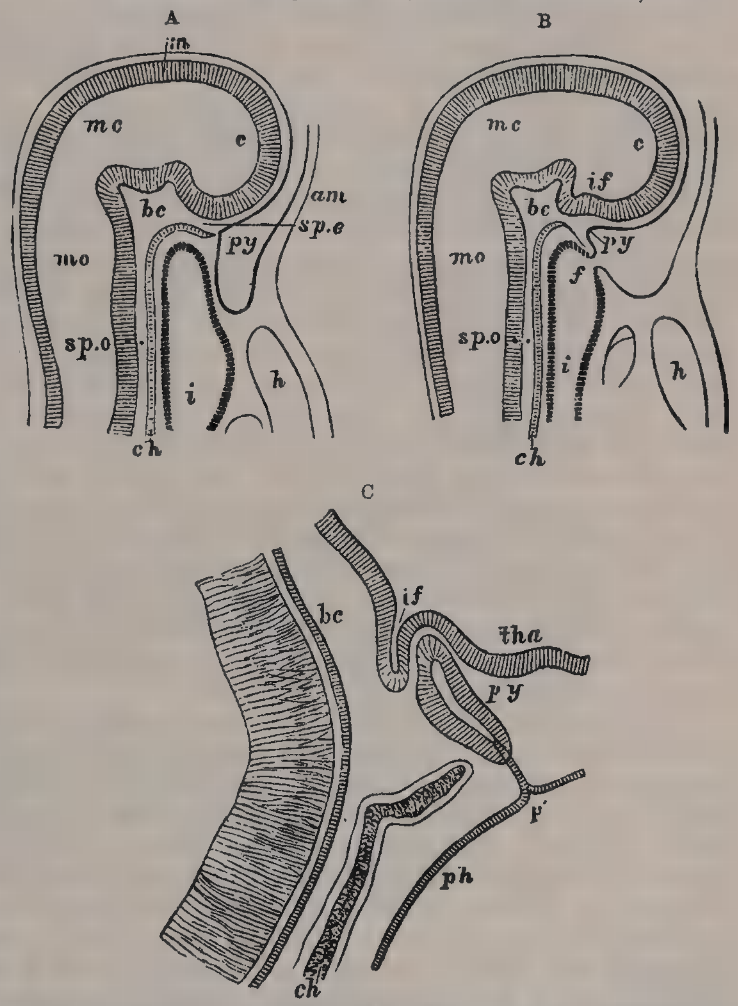
The **salivary glands** arise as diverticula from the epithelial lining of the mouth, and their rudiments appear in the following order, viz.: the parotid during the

fourth week, the submaxillary in the sixth week, and the sublingual during the ninth week (Hammar).

The **tonsils** are developed from the lower part of the second visceral cleft, immediately behind the anterior pillars of the fauces. The entoderm which lines this shallow pouch grows in the form of a number of solid buds into the surrounding mesoderm. These buds become hollowed out by the degeneration and casting off of their central cells, and by this means the tonsillar crypts are formed. Lymphoid cells accumulate around the crypts, and become grouped to form the lymphoid follicles; the latter, however, are not well defined until after birth.

The **thymus gland** first appears in the form of two flask-shaped entodermal diverticula, which arise, one on either side, from the third visceral cleft. Each diverticulum extends outwards and backwards into the surrounding mesoderm, and, although its opening into the pharynx is soon obliterated, the neck of the flask persists for some time as a cellular cord. By further proliferation of the cells which line the flask, buds of cells are formed, which become surrounded and isolated by the invading mesoderm. In the latter, numerous lymphoid cells make their appearance, and are aggregated to form lymphoid follicles. These lymphoid cells are probably derivates of the entodermal cells which lined the original diverticulum and its subdivisions.

FIG. 129.—Vertical section of the head in early embryos of the rabbit. Magnified. (From Mihalkovics.)



A. From an embryo of five millimetres in length. B. From an embryo of six millimetres in length. C. Vertical section of the anterior end of the notochord and pituitary body, &c., from an embryo sixteen millimetres long. In A the bucco-pharyngeal membrane is still present. In B it is in the process of disappearing, and the stomatodœum now communicates with the primitive pharynx. *c.* Fore-brain. *mc.* Mid-brain. *mo.* Hind-brain. *m.* Wall of brain cavity. *if.* Infundibulum. *am.* Amnion. *sp.e.* Spheno-ethmoidal; *bc.* Central; and *sp.o.* Spheno-occipital parts of basis cranii. *h.* Heart. *f.* Anterior extremity of fore-gut, *i.* *tha.* Thalamus. *p.* Original position of pituitary diverticulum. *py.* *ch.* Notochord. *ph.* Pharynx.

The **thyroid body** is developed from a median and two lateral diverticula. The median diverticulum appears about the fourth week, immediately behind the tuberculum impar of the tongue, between the mandibular and hyoid arches. It grows downwards and backwards as a tubular duct, which bifurcates and subsequently subdivides to form a series of cellular cords. The lateral diverticula arise from the inner aspect of the fourth visceral cleft, and fuse with the median portion. The connection of the lateral diverticula with the pharynx disappears early. That of the median rudiment is termed the *thyro-glossal duct*; its continuity is subsequently interrupted by the development of the body of the hyoid bone, above which it is represented by the foramen cæcum of the tongue, and below by the pyramidal lobe of the thyroid body.

The pituitary body, or hypophysis cerebri.—This consists of a large anterior, and a small posterior, lobe: the former is derived from the ectoderm of the stomatodœum, the latter from the floor of the fore-brain. About the fourth

week there appears a pouch-like diverticulum of the ectodermal lining of the roof of the stomatodœum. This, the pituitary involution or *pouch of Rathke* (fig. 129), is the rudiment of the anterior lobe of the pituitary body, and extends upwards in front of the cephalic end of the notochord and the remnant of the pharyngeal septum, and comes into contact with the under surface of the fore-brain. It is then constricted off to form a closed vesicle, but remains for a time connected to the ectoderm of the stomatodœum by a solid cord of cells. The vesicle sends out hollow processes into the surrounding mesoderm, and is gradually converted into a mass of small, tortuous tubules lined with columnar or cubical cells. The upwardly directed pituitary involution becomes applied to the antero-lateral aspect of a downwardly directed diverticulum from the base of the fore-brain. This diverticulum constitutes the future infundibulum in the floor of the third ventricle, while its lower extremity becomes modified to form the posterior lobe of the pituitary body. In some of the lower animals this lobe contains nerve-cells and nerve-fibres, but in man and the higher vertebrates these are replaced by connective tissue. A canal (*cranio-pharyngeal canal*) is sometimes found extending from the pituitary fossa to the under surface of the skull, and marks the original position of Rathke's pouch.

Development of the nose and face (figs. 120 to 124).—The nasal cavities are formed from the stomatodœum, while the outer nose is derived from its antero-lateral boundaries. Two areas of thickened ectoderm, the *olfactory areas*, appear immediately under the fore-brain in the anterior wall of the stomatodœum, one on either side of the *fronto-nasal process.* By the upgrowth of the surrounding mesoderm and ectoderm these areas are converted into pits, the *olfactory pits* (fig. 119), which divide the fronto-nasal process into a *mesial* and two *lateral nasal processes* (fig. 120). The rounded lateral angles of the mesial nasal process constitute the *globular processes* of His (figs. 121, 122). The olfactory pits form the rudiments of the nasal cavities, and extend backwards between the mesial and lateral nasal processes into the roof of the stomatodœum. From their ectodermal lining the olfactory epithelium and part of the olfactory bulb are derived. The globular processes are prolonged backwards as plates, termed the *nasal laminæ*: these laminæ are at first some distance apart, but, gradually approaching, they ultimately fuse, and form the nasal septum; while the processes themselves meet in the middle line, and form the premaxillæ and central part of the upper lip (fig. 123).

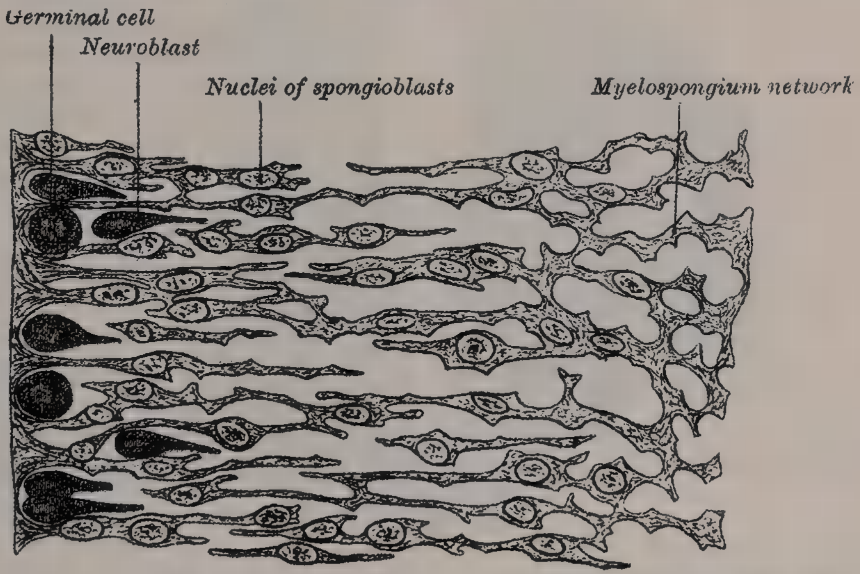
The depressed part of the fronto-nasal process between the globular processes forms the lower part of the nasal septum or *columella*; while above this is seen a prominent angle, which becomes the future point, and still higher a flat area, the future bridge, of the nose (fig. 124). The lateral nasal processes form the alæ of the nose. Continuous with the dorsal end of the mandibular arch, and growing forwards from its cephalic border, is a triangular process—the *maxillary process*—the ventral extremity of which is separated from the mandibular arch by a >-shaped notch (fig. 120). The maxillary process grows forwards to form the outer wall and floor of the orbit, and meets with the lateral nasal process, from which, however, it is separated for a time by a groove—the *oculo-nasal sulcus*—which extends from the furrow encircling the eyeball to the olfactory pit. The maxillary processes ultimately fuse with the lateral nasal and globular processes, converting the oculo-nasal sulci into the lachrymal sacs and nasal ducts, and at the same time forming the lateral parts of the upper lip and the posterior boundary of the anterior nares. The maxillary processes also give rise to the lower portion of the lateral wall of the nasal cavity—the upper part of this wall, together with the roof, being developed from the ethmoid plate of the cartilaginous chondro-cranium. The nasal cavity is shut off from the buccal part of the stomatodœum by the development of the palate, the greater part of which is formed by a pair of shelf-like *palatal processes* which extend inwards from the maxillary processes (fig. 123); these coalesce with each other in the middle line, and constitute the entire palate, except a small part in front which is formed by the premaxillary bones. The union of the palatal processes with the premaxillæ is deficient in the middle line, where an aperture remains—the naso-palatine canal. The union of the parts which form the palate commences in front, the premaxillary and palatal processes joining in the eighth week, while the region of the future hard palate is completed by the ninth, and that of the soft palate by the eleventh week. The deformity known as cleft palate results

from a non-union of the palatal processes, and that of hare-lip through a non-union of the maxillary and globular processes. The nasal cavity becomes divided into the two nasal fossæ by a vertical septum, which extends downwards and backwards from the fronto-nasal process and nasal laminæ, and which unites below with the palatal processes. Into this a plate of cartilage extends from the under aspect of the ethmoid plate of the chondro-cranium. The anterior part of this persists as the septal cartilage of the nose, but the posterior and upper parts are replaced by the vomer and mesethmoid. On each side of the nasal septum, at its lower and anterior part, the ectoderm is invaginated to form a blind pouch or diverticulum, which extends backwards and upwards into the nasal septum. This forms the rudiment of *Jacobson's organ*, which opens below, close to the junction of the premaxillary and maxillary bones.

DEVELOPMENT OF THE NERVOUS SYSTEM

The entire nervous system is of ectodermal origin, and its first rudiment is seen in the medullary or neural groove which extends along the dorsal aspect of the embryo (fig. 100). By the elevation and ultimate fusion of the medullary ridges, the groove is converted into the neural tube (fig. 104). Along the line

FIG. 130.—Transverse section of the spinal cord of a human embryo at the beginning of the fourth week. (After His.) The left edge of the figure corresponds to the lining of the central canal.



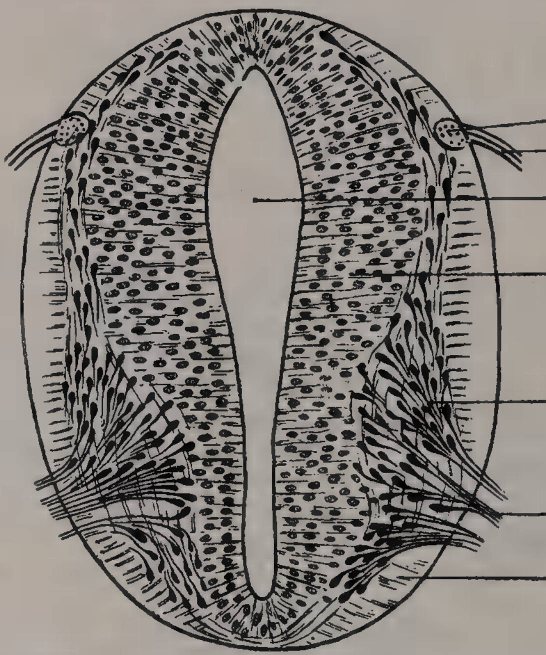
of fusion of the medullary ridges a flattened crest of ectodermal cells—the *neural crest* or *ganglion ridge*—attaches, for a time, the neural tube to the overlying ectoderm (fig. 138). This crest is, however, soon cut off from the ectoderm, and, adhering to the neural tube, forms the rudiment of the ganglia of the cranial and spinal nerves and sympathetic system. The anterior end of the neural tube becomes expanded to form the three primary brain-vesicles which are subsequently modified to form the ventricular cavities of the brain (except the fifth); the remainder of the tube forms the central canal of the spinal cord (fig. 103). From its surrounding wall the nervous elements and the neuroglia of the brain and spinal cord are developed. It will be convenient to study (1) the development of the spinal cord, (2) that of the brain.

Development of the Spinal Cord.—At first the wall of the neural tube is composed of a single layer of columnar ectodermal cells. Soon the lateral parts of the wall become thickened, while the dorsal and ventral parts remain thin, and are named the *roof* and *floor plates*, or the *dorsal* and *ventral laminæ* (figs. 131 and 132). A transverse section of the tube at this stage presents an oval outline, while its lumen has the appearance of a slit. The cells which constitute the wall of the tube are differentiated into two sets: viz. (a) *spongioblasts* or young neuroglia cells, and (b) *germinal cells*, which are the parents of the *neuroblasts* or young nerve-cells (fig. 130). The spongioblasts are elongated and columnar, and

extend from the lumen of the tube to its peripheral wall—their inner and outer ends being modified to form the inner and outer limiting membranes of the cord. The parts of the spongioblasts abutting against the central canal retain their columnar character, and ultimately form the layer of ciliated columnar epithelium which lines this canal. Their outer parts, on the other hand, undergo ramification and form a sponge-like network, termed the *myelospongium*, from which the neuroglia or sustentacular tissue of the cord is developed. The branching of the spongioblasts is most marked near the periphery of the cord, and this outer part, in consequence, assumes the appearance of a fine reticulum.

The germinal cells are large, round or oval, and first make their appearance between the inner ends of the neuroglia cells on the lateral aspects of the central canal. They increase rapidly in number, so that by the fourth week they form an almost continuous layer on each side of the tube. No germinal cells are found in the roof or floor plates; the roof-plate retains, in certain regions of the brain, its epithelial character; elsewhere, its cells become spongioblasts. The nuclei of many of the germinal cells exhibit mitotic changes, indicating that the cells are undergoing rapid subdivision. By such subdivision they give rise to the neuroblasts or young nerve-cells. The neuroblasts migrate outwards from

FIG. 131.—Section of spinal cord of a four weeks' embryo. (His.)



the sides of the central canal, and at the same time they become pear-shaped; the tapering part of the cell undergoes still further elongation, and forms the axis-cylinder or axon of the cell.

A transverse section of the cord exhibits three layers, viz.: (1) a *marginal layer* or *marginal veil*, consisting of a fine neuroglia network, in which the future white matter of the cord is developed. (2) An intermediate layer, the representative of the future grey matter of the cord. This is crowded with neuroblasts, and is sometimes termed the *mantle layer*. (3) An internal or *ependymal layer*, next the central canal, in which the germinal cells were first seen, but which, after their subdivision and migration, becomes the epithelium of the central canal. The lateral walls of the slit-like canal increase in thickness, and the canal itself widens out near its dorsal extremity, and assumes a somewhat lozenge-shaped appearance. The widest part of the canal serves to subdivide the lateral wall of the neural tube into a *dorsal* or *alar*, and a *ventral* or *basal lamina* (fig. 132), a subdivision which extends forwards into the brain.

The ventral part of the mantle layer becomes thickened, and on cross-section appears as a triangular patch between the marginal and ependymal layers. This thickening is the rudiment of the anterior horn of grey matter, and contains many neuroblasts, the axis-cylinders of which pass out through the marginal layer and form the anterior root of the spinal nerve (fig. 131). The thickening of the mantle layer gradually extends backwards, and forms the posterior horn of grey

matter. The axons of many of the neuroblasts in the alar lamina pass forward, and cross in the floor-plate to the opposite side of the cord; these form the rudiment of the anterior white commissure of the cord. The cells of the neural crest having lost their original connection with the overlying ectoderm, become differentiated into a series of oval masses which constitute the rudiments of the spinal ganglia and, except in the region of the tail, are equal in number to the protovertebral somites. They are arranged symmetrically on the two sides of the cord, and consist at first of round or oval cells. These cells, however, soon become bipolar or spindle-shaped, and are drawn out into central and peripheral processes. The former grow backwards and inwards, and, becoming connected with the spinal cord, constitute the posterior or dorsal roots of the spinal nerves; while the latter grow outwards, and, joining the fibres of the anterior nerve-root, form, together with them, the spinal nerve. In the spinal cord of a six weeks' embryo the central processes form a well-defined *oval bundle* in the marginal layer of the alar lamina (fig. 131); but with the subsequent development of the posterior horn of grey matter, this bundle is displaced inwards, and forms the rudiment of the posterior white column of the cord. The two processes of the ganglion cell become gradually more and more approximated, and ultimately arise from a single stem in a T-shaped manner; the original bipolar condition of the cells is, however, retained in the ganglia of the auditory nerve. The central processes of the ganglion cells are generally regarded as axons, while the peripheral are by many classed as dendrites. The anterior and lateral white columns consist at first of the axons of the neuroblasts; they are, however, at a later stage, largely augmented by the pyramidal tracts which descend from the cerebral cortex. By the growth of the anterior horns of grey matter, and by the increase in size of the anterior columns, a furrow is formed between the lateral halves of the cord anteriorly; this gradually deepens to form the anterior median fissure. The mode of formation of the posterior fissure is somewhat uncertain. Many believe that it is produced by a growing together of the walls of the posterior part of the central canal. Robinson * traverses this view, and points out that the so-called posterior fissure is occupied by a fibrillated tissue, which is probably of a spongioblastic origin, since its fibrils can be traced directly into the posterior grey commissure.

Fig. 132.—Section of the medulla in the cervical region, at six weeks. Magnified 50 diameters.

Up to the fourth month of fœtal life the spinal cord occupies the entire length of the spinal canal, and the spinal nerves pass outwards at right angles to the cord. From this time onwards, the spinal column grows more rapidly than the cord, and the latter, being fixed above through its continuity with the brain, gradually assumes a higher position within the canal. By the sixth month its lower end reaches only as far as the upper end of the sacral canal; at birth it is on a level with the third lumbar vertebra, and in the adult it terminates at the lower border of the first or upper border of the second lumbar segment. A delicate filament, the *filum terminale*, extends from its lower end as far as the coccyx.

The ganglia of the sympathetic system are generally regarded as being developed as off-shoots from the ganglia on the roots of the cranial and spinal nerves.

Development of the brain.—The brain is developed from the anterior end of the neural tube, which at an early period becomes expanded into three vesicles, the primary cerebral vesicles (figs. 103 and 133). These are marked off from each other by intervening constrictions, and are named the *fore-brain* or *prosencephalon*, the *mid-brain* or *mesencephalon*, and the *hind-brain* or *rhombencephalon*—the last

* *Studies in Anatomy*, Owens College, 1891.

being continuous with the spinal cord. Soon after the appearance of these vesicles the embryonic brain becomes bent upon itself in a somewhat zigzag fashion. This results from the unequal growth of its different parts, and gives rise to three flexures. The first of these to appear is seen in the region of the mid-brain, and is named the *primary cephalic* or *mid-brain flexure* (fig. 133, A, above the letters *Pm*). By means of it, the fore-brain is bent in a ventral direction around the anterior end of the notochord and fore-gut, with the result that the floor of the fore-brain comes to lie almost parallel with that of the hind-brain (fig. 133, C). This flexure causes the mid-brain to become, for a time, the most prominent part of the brain, since its dorsal surface corresponds with the convexity of the curve. The second bend to appear is at the junction of the hind-brain and spinal cord. This is termed the *cervical* or *nuchal flexure* (fig. 133, B, *NK*), and increases from the third to the end of the fifth week, when the hind-brain forms nearly a right angle with the spinal cord. These two flexures affect the whole head, but the cervical bend is diminished when the erection of the head takes place—a process which commences after the fifth week. The third bend is named the *Varolian* or *pontine flexure* (fig. 133, A and B, *Br*), because it is found in the region of the future pons Varolii. It differs from the other two as follows: (*a*) its convexity is forwards, and (*b*) it does not affect the head. The lateral walls of the brain-tube, like those of the spinal cord, are divided by an internal furrow into alar or dorsal and basal or ventral laminæ.

The hind-brain or rhombencephalon.—The cavity of the hind-brain becomes the fourth ventricle. If measured at the time when the primary cephalic flexure makes its appearance, the length of the hind-brain will be found to exceed the combined length of the other two vesicles. Immediately behind the mid-brain it exhibits a marked constriction, which is named the *isthmus rhombencephali* (fig. 133, *J*), and is best seen when the brain is viewed from the dorsal aspect. It is customary to divide the hind-brain into two parts: viz. an upper, called the *metencephalon*, and a lower, the *myelencephalon*. The cerebellum is developed by a thickening of the roof, the pons by a similar change in the floor and lateral walls of the metencephalon. The floor and lateral walls of the myelencephalon are thickened to form the medulla oblongata, while its roof, on the other hand, remains thin, and, retaining to a great extent its epithelial nature, is expanded in a lateral direction; moreover, by the growth and backward extension of the cerebellum, it is folded inwards towards the cavity of the fourth ventricle. It assists in forming the dorsal wall of this cavity, and is also invaginated as the epithelial covering of its choroid plexuses. From its upper part is developed the inferior medullary velum; below, it is continuous with the obex and ligulæ.

The development of the medulla oblongata resembles that of the spinal cord, but at the same time exhibits one or two interesting modifications. On transverse section the myelencephalon at this stage is seen to consist of two lateral walls, connected across the middle line by floor and roof plates, as in the cord (figs. 136 and 137). Each lateral wall consists of an alar and a basal lamina, separated by an internal furrow, the remains of which are represented in the adult brain by the foveæ on the floor of the fourth ventricle. The contained cavity is more or less triangular in outline, its base being formed by the roof-plate, which is thin and greatly expanded transversely. Neuroblasts are developed in the alar and basal laminæ; they become pear-shaped, and their narrow stalks are elongated to form the axis-cylinders of the nerve-fibres. Opposite the furrow or boundary between the alar and basal laminæ a bundle of nerve-fibres attaches itself to the outer surface of the alar lamina. This is named the *tractus solitarius* (fig. 137), and is formed by the sensory fibres of the glosso-pharyngeal and vagus nerves. It is the homologue of the *oval bundle* seen in the cord, and, like it, is developed by an ingrowth of fibres from the ganglia of the neural crest. At first it is applied to the outer surface of the alar lamina, but it soon becomes buried, owing to the growth over it of the neighbouring parts. By the fifth week the dorsal part of the alar lamina bends in an outward direction along its entire length, to form what is termed the *rhombic lip* (fig. 137). Within a few days this lip becomes applied to, and unites with, the outer surface of the main part of the alar lamina, and so covers in the tractus solitarius and also the spinal root of the fifth nerve.

Neuroblasts accumulate in the mantle layer: those in the basal lamina correspond with the cells in the anterior horn of the spinal cord, and, like them, give

origin to motor nerve-fibres; in the medulla they are, however, arranged in groups or nuclei, instead of forming a continuous column. From the alar lamina and its rhombic lip, neuroblasts migrate into the basal lamina, and become aggregated to form the olivary nuclei, while many send their axis-cylinders through the floor-plate to the opposite side of the medulla, and thus constitute the rudiment of the raphé of the medulla. By means of this thickening of the ventral portion of the medulla the motor nuclei are buried deeply from the surface, and, in the adult, are found close to the floor of the fourth ventricle. This is still further accentuated: (*a*) by the development of the anterior pyramids, which are formed about the fourth month by the downward growth of the motor fibres from the cerebral cortex; and (*b*) by the fibres which pass to and from the cerebellum. The isthmus rhombencephali represents the future valve of Vieussens, or superior medullary velum, and the superior peduncles of the cerebellum.

The *pons Varolii* is developed from the ventro-lateral wall of the metencephalon by a process similar to that which has been described for the medulla.

The *cerebellum* is developed in the roof of the anterior part of the hind-brain (fig. 135). The alar laminæ become thickened to form two lateral plates, which fuse in the middle line. The outer surface of the cerebellum is at first smooth and convex, but is soon divided by two fissures into three primary lobes, anterior, middle, and posterior. The fissure between the anterior and middle lobes is named the *fissura prima*, and represents the preclival fissure of the adult cerebellum; that separating the middle and posterior lobes is termed the *fissura secunda*, and is the rudiment of the post-pyramidal fissure. The lingula, the central lobe and its alæ, the culmen monticuli, and anterior crescentic lobes are developed from the anterior primary lobe; while the uvula, nodule, and flocculus arise from the posterior primary lobe. The remainder of the cerebellum is developed from the middle primary lobe, which undergoes great lateral expansion, and forms the larger portions of the cerebellar hemispheres. These are subsequently subdivided by the great horizontal fissure, which, although an important feature in the adult, is developmentally of secondary interest. The rudiment of the cerebellum at first projects in a dorsal direction; but, by the backward growth of the cerebrum, it is folded downwards and somewhat flattened, and the thin roof-plate of the fourth ventricle, originally continuous with the posterior border of the cerebellum, is projected inwards towards the cavity of the ventricle.

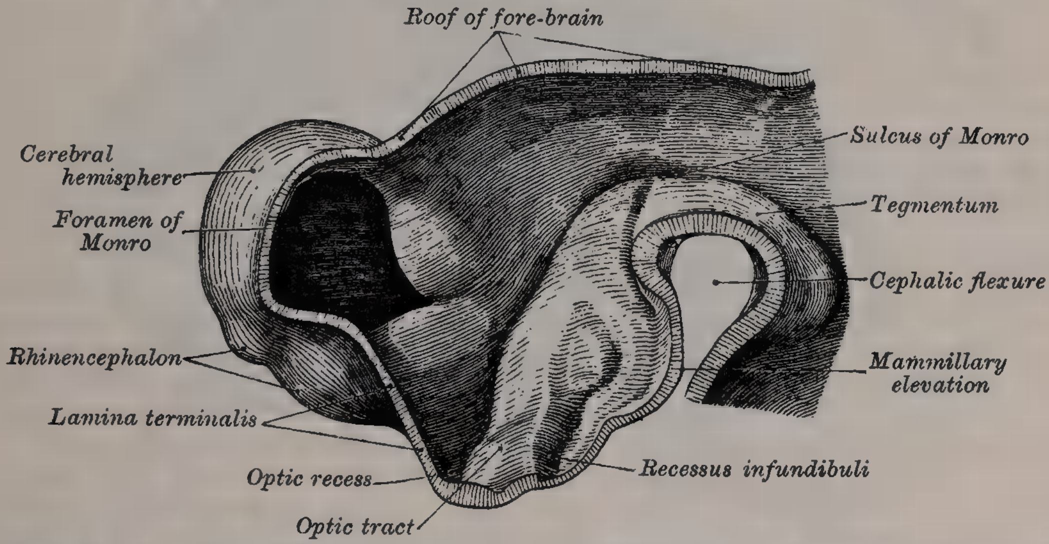
The mid-brain or mesencephalon.—The mid-brain (fig. 135) exists for a time as a thin-walled cavity of some size, and is separated from the isthmus rhombencephali behind, and from the fore-brain in front, by slight constrictions. Its cavity is reduced in diameter, and forms the Sylvian aqueduct of the adult brain. Its basal laminæ become thickened to form the crura cerebri, which are at first of small size, but rapidly increase after the fourth month. The neuroblasts of these laminæ are grouped in relation to the sides and floor of the Sylvian aqueduct, and constitute the nuclei of the third and fourth nerves, and of the descending root of the fifth nerve. By a similar thickening process its alar laminæ are developed into the corpora quadrigemina. The dorsal part of the wall for a time undergoes expansion, and presents an internal median furrow and a corresponding external ridge; these, however, disappear, and the latter is replaced by a groove. Subsequently two oblique furrows extend inwards and backwards, and the thickened lamina is thus subdivided into the quadrigeminal bodies.

The fore-brain.—At a very early stage of its existence—in some animals, even before the fusion of the medullary laminæ—the fore-brain expands on each side in the form of a hollow diverticulum; these diverticula are termed the *optic vesicles*. The central part of the fore-brain grows forwards and upwards between these vesicles, while at the same time the outer parts of the vesicles become enlarged; and thus the entire fore-brain exhibits an early subdivision into three parts—an intermediate portion, or fore-brain proper, and two lateral portions, the optic vesicles (fig. 153). These vesicles may therefore be looked upon as hollow appendages of the lower and outer aspect of the fore-brain. With the subsequent expansion of the fore-brain and of the outer parts of the optic vesicles, the latter communicate with the former by narrow tubular stalks, the *optic stalks*. The optic stalk represents the future optic nerve, while the optic vesicle gives rise to the retina and portions of the ciliary body and iris. The fore-brain proper next grows in a downward and forward direction; and from the lateral walls of this part, the cerebral hemispheres arise as hollow diverticula, which rapidly expand

to form two large pouches, one on each side; these diverticula form the rudiments of the lateral ventricles, and communicate with the cavity of the fore-brain proper by relatively wide openings which ultimately form the *foramen of Monro* in the adult brain (fig. 134).

This anterior part of the fore-brain, together with the cerebral hemispheres, constitutes the *telencephalon*, while the hinder part of the fore-brain is named the *thalamencephalon* or *diencephalon*; both of these contribute to the formation of the third ventricle. In the middle line between the cerebral hemispheres the anterior wall of the brain-vesicle is formed by a thin lamina, the *lamina terminalis* (fig. 134), which reaches from the optic stalks to the foramen of Monro. A transverse section of the thalamencephalon at the fifth week shows the same parts as the spinal cord and medulla, viz. a pair of lateral walls connected across the middle line by floor and roof plates. Moreover, each lateral wall shows a division into alar and basal laminæ, which are separated internally by a furrow which was named by Reichert the *sulcus of Monro*. The roof-plate is thin and longitudinally folded, while the floor-plate is bulged downwards. The alar lamina of the thalamencephalon becomes thickened to form the optic thalamus of its own side, while from the corresponding part of the telencephalon the cerebral hemisphere is derived. At first the optic thalami are seen on the outer surface of the brain, but are subsequently hidden by the growth over them of the cerebral

FIG. 134.—Median section of fore-brain of a human embryo of 12·5 mm. in length. (After His.) (From Kollmann's 'Entwickelungsgeschichte.')



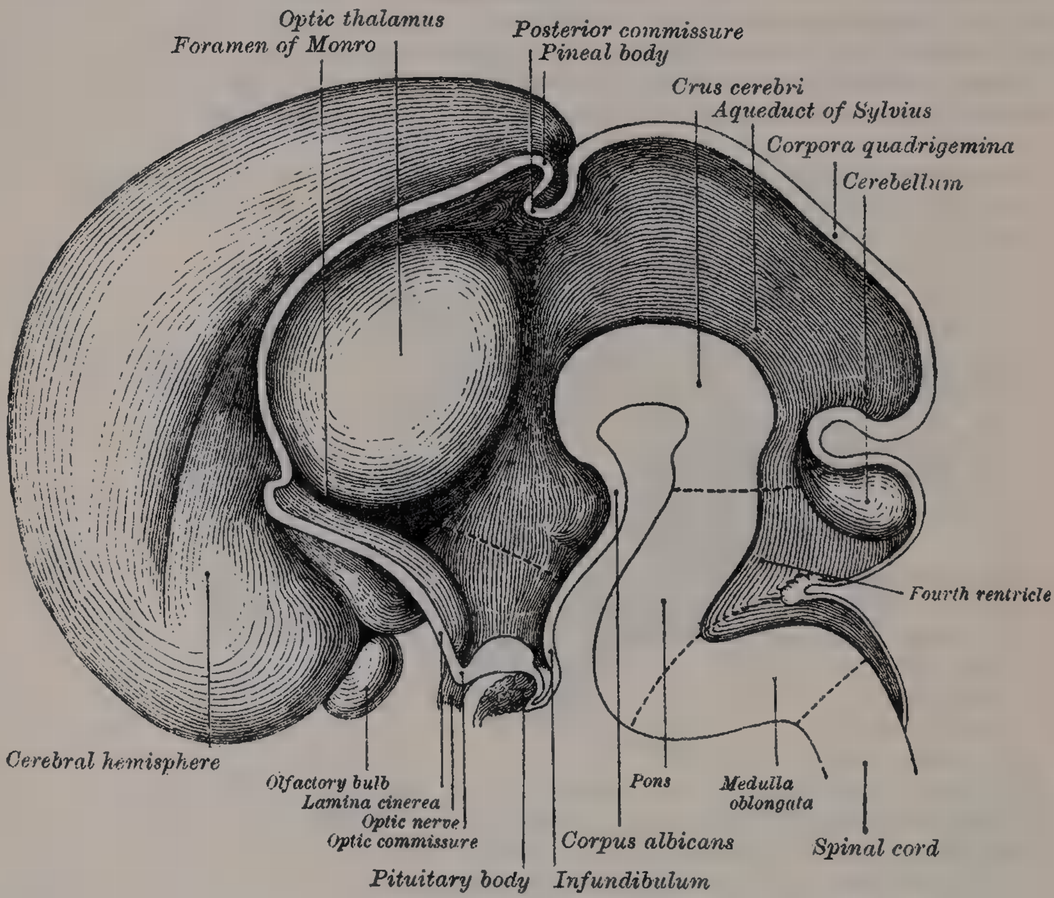
hemispheres. The thalami grow inwards, and thus gradually narrow the cavity between them into a slit-like aperture which forms the greater part of the third ventricle. The mesial surfaces of the optic thalami ultimately adhere, in part, to each other across the cavity, and by this means the middle or grey commissure takes its rise. From the basal laminæ and floor the parts which occupy the interpeduncular space in the adult brain are developed, and their early condition can be recognised in a mesial section of the fore-brain at the fifth week. On examining the floor of such a section (fig. 134) from behind forwards, the following structures are seen: (1) an elevation, convex inferiorly, which, by the fourth month, is subdivided by a median groove into two tubercles, the corpora mammillaria; (2) a slight swelling, the tuber cinereum; the lower part of this is ultimately narrowed into a funnel-shaped diverticulum—the infundibulum—while the most dependent part of it is modified to form the posterior lobe of the pituitary body; the anterior lobe of this body has been seen to arise as a diverticulum of the ectoderm of the stomatodœum. The anterior wall of the vesicle is formed by the lamina terminalis, and at the angle of union of the floor and anterior wall is the recessus opticus, leading into the optic stalk (fig. 135); this angle corresponds with the optic chiasma in the adult brain. Above the lamina terminalis is the foramen of Monro, or passage leading into the cavity of the cerebral hemisphere. From the optic recess a groove, the sulcus of Monro, already referred to, passes backwards on the lateral wall of the thalamencephalon, and indicates its division between the alar and basal laminæ. A trace of this sulcus is seen in the adult

brain in the form of a slight groove extending from the foramen of Monro towards the Sylvian aqueduct.

The greater part of the roof-plate of the thalamencephalon remains thin and epithelial, and is subsequently invaginated by the choroid plexuses of the third ventricle. The posterior part of the roof, however, is modified to form the pineal gland and posterior commissure.

The pineal gland arises about the sixth week as an upward evagination of the roof-plate, immediately in front of the mid-brain (fig. 135). This ultimately becomes solid, except its proximal part, which persists as the recessus pinealis. In lizards the pineal evagination is elongated into a stalk, resembling the optic stalk, and its peripheral extremity is expanded into a hollow sac in which a rudimentary lens and retina are formed. The stalk becomes solid, and in it nerve-fibres can be recognised; in these animals, therefore, the pineal body forms a

FIG. 135.—Median section of brain of human fœtus during the third month. (After His.)



rudimentary eye. The posterior commissure first appears as a thickening of the dorsal wall of the fore-brain immediately behind the pineal evagination.

The cerebral hemispheres (figs. 134, 135).—It has been already stated that the cerebral hemispheres arise as lateral diverticula of the alar laminæ of the anterior part of the fore-brain; these diverticula expand rapidly and soon attain a large size. In the fourth week a longitudinal ridge appears on the under surface of each hemisphere, close to the lamina terminalis. This ridge is named the *olfactory area*, or *rhinencephalon* (fig. 134), and corresponding with it, there is an internal groove. Subsequently it is divided by a furrow or constriction into an anterior and a posterior part; the anterior part grows forwards as a hollow stalk continuous with the anterior part of the ventricular cavity. The stalk becomes solid, and forms the rudiment of the olfactory peduncle or tract and the trigonum olfactorium, while its free extremity is enlarged to form the olfactory bulb; a strand of gelatinous substance in the interior of the latter indicates the site of the original cavity. The posterior part forms the locus perforatus anticus and the peduncles of the corpus callosum (gyrus subcallosus). The rhinencephalon

remains rudimentary in man, but forms a conspicuous part of the brain in osmatic animals.*

The cerebral hemispheres and their olfactory lobes grow forward on either side of the lamina terminalis. The hemispheres also expand upwards and backwards, their mesial surfaces being separated from each other by a septum of mesodermic tissue continuous with the membranous cranium ; this septum is the rudiment of the falx cerebri, and is continuous behind with a similar septum which passes between the occipital part of the cerebrum and the cerebellum and constitutes the rudimentary tentorium cerebelli. The hemispheres also grow backwards and downwards, covering first the thalamencephalon, and next the mid-brain, while by the seventh month they have extended so as to overlap the upper surface of the cerebellum ; this great expansion of the cerebral hemispheres is characteristic of the brains of mammals, and attains its maximum in the brain of man. The floor of the hemisphere is thickened to form the corpus striatum. This thickening begins to appear about the second month, and extends to the posterior end of the primitive hemisphere ; and, as a consequence, when this part of the hemisphere grows downwards to form the temporal lobe, the posterior part of the corpus striatum is carried into the roof of the descending horn of the ventricle, where it is seen as the tail of the caudate nucleus in the adult brain. Corresponding with this internal thickening, a shallow depression makes its appearance on the lateral surface of the hemisphere ; this constitutes the rudiment of the Sylvian fissure, and is named the *Sylvian fossa.* The floor of the fossa represents the future island of Reil, which is gradually submerged by the growth over it of the surrounding parts of the vesicle ; and thus, in the adult, the island lies deeply in the bottom of the Sylvian fissure. The parts of the cerebral vesicle which grow over it constitute the temporal, fronto-parietal, and orbital opercula of the adult brain. The cavity of the hemisphere forms the lateral ventricle, and is at first of a hemispherical or semilunar shape ; but, coincident with the growth of the hemisphere, it becomes extended into three prolongations, the anterior, posterior, and descending cornua of the adult cavity, the last representing the original posterior extremity of the vesicle.

The roof-plate which connects the hemispheres above the foramen of Monro remains thin, and by the fifth week is invaginated as lateral folds into the ventricular cavities. The vascular mesoderm which lies between the hemispheres extends into these folds, and forms the rudiment of the choroid plexuses ; these at the fifth month are of large size, and nearly fill the cavities of the ventricles.

Fissures of the cerebrum.—The surface of the cerebral hemisphere is at first smooth, but ultimately becomes indented by depressions or furrows, which constitute its fissures or sulci. These were formerly described as being of three kinds, viz. : *transitory*, *complete*, and *partial.*

Certain furrows or infoldings of the thin cerebral wall have been described as occurring during the second and third months, and subsequently undergoing, with one or two exceptions, complete obliteration. These, from their temporary nature, have been named *transitory fissures.* It has been pointed out, however, that if the brain be hardened *in situ* before post-mortem changes have taken place, its surface is found to be destitute of any such furrows, and the balance of evidence is in favour of the view that the so-called transitory fissures are artificially produced after death.

A *complete fissure* is one which indents the whole thickness of the wall of the cerebral hemisphere, and which, as a consequence, gives rise to a corresponding elevation in the ventricular cavity. To this category belong the hippocampal and calcarine and collateral fissures, which were regarded as owing their existence to the persistence of certain of the so-called transitory fissures just referred to. The Sylvian fissure is sometimes described as a complete fissure, but strictly speaking this is not correct ; its development has already been referred to.

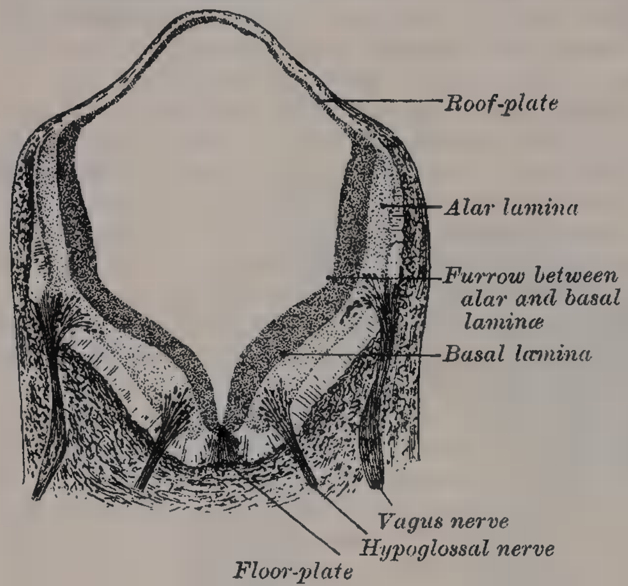
The *incomplete fissures* are superficial foldings of the grey matter, and produce no corresponding elevations in the interior of the ventricle.

* In addition to the parts mentioned, the rhinencephalon includes the septum lucidum, fornix, gyrus supracallosus, gyrus dentatus, hippocampus, and uncus.

The Nerves

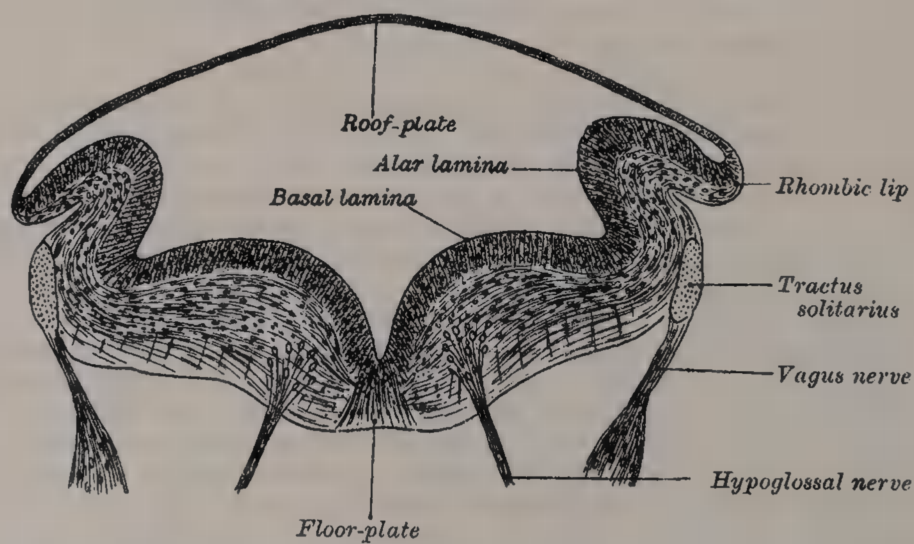
1. *The spinal nerves.*—Each spinal nerve arises from the spinal cord by a dorsal or afferent, and a ventral or efferent root, and, as already stated (pages 108, 109), the fibres of the former root are developed as outgrowths of the cells of the spinal ganglia, while those of the latter consist of the axons of the neuroblasts of the anterior horn of the cord. The afferent and efferent roots join, immediately beyond the spinal ganglion, to form the spinal nerve, which then divides into its anterior and posterior primary divisions, fibres from both roots being carried into each of the two divisions.

Fig. 136.—Transverse section of medulla oblongata of human embryo. × 32. (From Kollmann's 'Entwickelungsgeschichte.')



2. *The cranial nerves.*—With the exception of the olfactory and optic nerves, which will be specially considered, the cranial nerves are developed in a similar manner to the spinal nerves. The sensory or afferent nerves are derived from the cells of the ganglion rudiments of the neural crest. The central processes of these cells grow into the brain and form the roots of the nerves, while the peripheral processes extend outwards and constitute their fibres of distribution. It has been seen, in considering the development of the medulla oblongata (page 110), that the *tractus solitarius* (fig. 137), derived from the fibres which grow inwards from the ganglion rudiments of the glosso-pharyngeal and vagus nerves, is the homologue of the *oval bundle* in the cord which had its origin in the posterior nerve-roots. The efferent or motor nerves arise as outgrowths of the neuroblasts situated in the basal laminæ of the mid-

Fig. 137.—Transverse section of medulla oblongata of human embryo. (After His.)



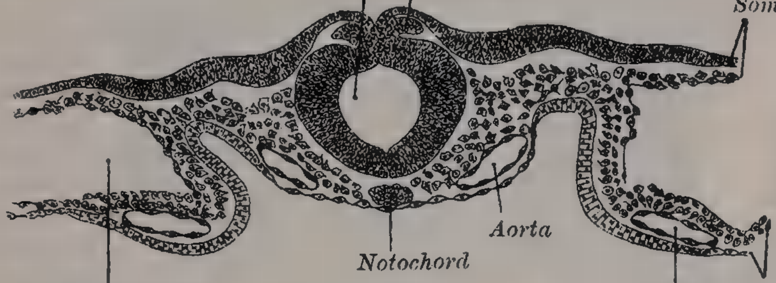
and hind-brain. While, however, the anterior spinal nerve-roots arise in one series from the basal lamina, the cranial motor nerves are grouped into two sets, according as they arise from the mesial or lateral parts of the basal lamina. To the former set belong the third, fourth, sixth, and twelfth nerves; to the latter, the spinal accessory and the motor fibres of the fifth, seventh, ninth, and tenth nerves.

The *olfactory nerves* are outgrowths of neuroblasts which are developed from the ectoderm of the olfactory pit (page 106). These neuroblasts pass out from the ectoderm, and form a ganglion which subsequently fuses with the olfactory bulb. From the neuroblasts of this ganglion processes grow, centripetally to form the nerve-roots, and centrifugally to form the olfactory nerves.

The development of the optic nerve will be considered with that of the eye.

Development of the Eye.—The optic nerve and retina are developed as an outgrowth from the rudimentary brain, which extends towards the side of the head,

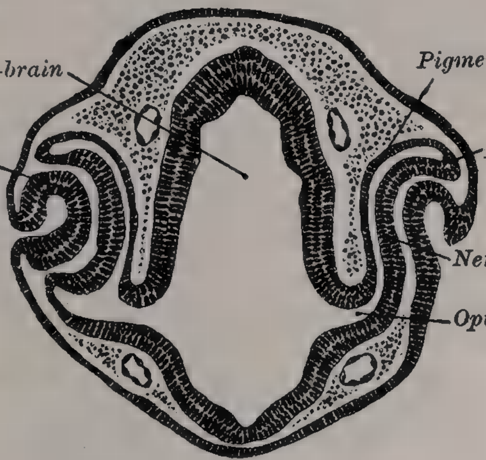
FIG. 138.—Transverse section of a chick embryo of twenty-nine hours' incubation. (From Duval's 'Atlas d'Embryologie.')



and is there met by an ingrowth from the ectoderm, out of which the fibres of the crystalline lens and the epithelium of the conjunctiva, cornea, and lachrymal gland are developed.

The first appearance of the eye consists in a hollow, laterally directed protrusion of the fore-brain; this is called the *optic vesicle* (fig. 139). It is at first an open cavity communicating by a hollow stalk with that of the cerebral vesicle. As it is prolonged outwards, the ectoderm lying immediately over it becomes thickened, and then forms a depression which gradually encroaches on the most prominent part of the optic vesicle; this in its turn appears to recede before it,

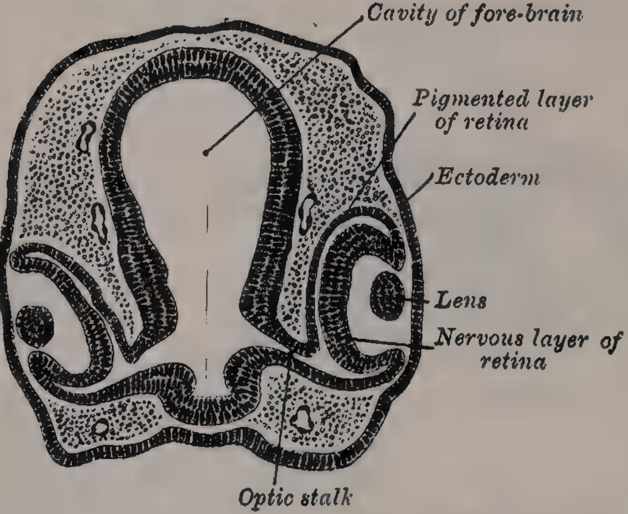
FIG. 139.—Transverse section of head of chick embryo of forty-eight hours' incubation. (From Duval's 'Atlas d'Embryologie.')



so as to become at first depressed and then inverted in the manner indicated in figs. 139 and 140, so that the cavity of the vesicle is almost obliterated by the folding back of its anterior half, and the original vesicle converted into a cup, the *optic cup*, in which the involuted ectodermal layer, the rudiment of the lens, is received (fig. 140); at the same time the proximal part of the vesicle becomes elongated and narrowed into a hollow stalk, the *optic stalk*. This cup-shaped cavity consists therefore of two layers which are continuous with each other at the cup-margin; the outer is thin, and eventually forms the pigmented layer of the retina; the inner is thick, and is converted into the nervous layers of the

retina (fig. 140).* Between the two is the remnant of the cavity of the original optic vesicle, which finally becomes obliterated by the union of its two layers. The mouth of the optic cup overlaps the equator of the lens as far as the future aperture of the pupil. In this region the inner or retinal layer of the cup is not differentiated into nervous elements, but remains as a single layer of columnar cells, which becomes applied to the cells of the pigmented layer, and the conjoined strata form the *pars ciliaris* and *pars iridica retinæ* of the adult (fig. 143). As development proceeds the optic cup increases in size, and thus a space is formed between it and the rudimentary lens, in which the vitreous humour is developed (figs. 141 and 143). The folding in of the optic vesicle to produce the optic cup takes place not only opposite the lens, but also along its postero-inferior aspect, where a cleft or fissure is formed, the *choroidal fissure*, through which the mesoderm extends to form the vitreous humour. This gap or cleft is continued for some distance into the stalk of the optic vesicle, and thus allows a process of mesoderm, with the arteria centralis retinæ, to extend along the cleft (fig. 142). After a time the gap or fissure becomes closed, by a coalescence of its margins, and the arteria centralis retinæ assumes its permanent position in the centre of the optic nerve.

Fig. 140.—Transverse section of head of chick embryo of fifty-two hours' incubation. (From Duval's 'Atlas d'Embryologie.')



The lens is at first a thickening of the ectoderm, then a depression or involution takes place, thus forming an open follicle, the margins of which gradually approach each other and coalesce, forming a cavity, the *lens vesicle*, enclosed by

Fig. 141.—Diagrammatic sketch of a vertical longitudinal section through the eyeball of a human fœtus of four weeks. (After Kölliker.) Magnified 100 diameters. The section is a little to the side, so as to avoid passing through the ocular cleft.

c. The ectoderm. *l.* The lens. *op.* Optic stalk with its cavity, *vp.* *p.* The pigmented layer of the retina. *r.* The inner layer from which the nervous elements of the retina are formed. *vs.* Rudiment of the vitreous humour.

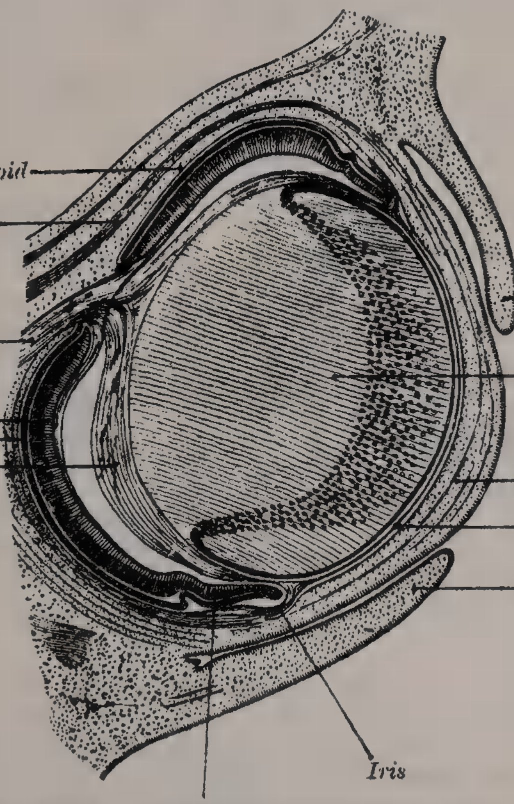
* The cells of the inner or retinal layer of the optic cup become differentiated into spongioblasts and germinal cells, and the latter by their subdivision give rise to neuroblasts. As in the spinal cord, the spongioblasts ramify to form a myelospongium, from which the sustentacular fibres of Müller, the outer and inner limiting membranes, together with the ground-work of the molecular layers of the retina are formed. The neuroblasts become arranged to form the ganglionic and nuclear layers. Cameron, after careful study of the neuroblasts in the retina, spinal cord, and brain, maintains that they consist of nuclei only, and that they possess no cytoplasmic investment; the 'clear protoplasm,' which has been described as surrounding them during mitotic division, being merely the achromatic nuclear substance set free owing to the disappearance of the nuclear membrane. He further maintains that the nuclei of the nuclear layers undergo subsequent multiplication by *direct* division. The layer of rods and cones is first developed in the central part of the optic cup, and from there gradually extends towards the cup-margin. The rods and cones first appear as clear globules, which, after being protruded through the inner limiting membrane, rapidly increase in size—a process which would seem to depend on their power of digesting and absorbing the pigment from the cells of the pigmented layer. ('Development of the Retina in Amphibia,' *Journal of Anatomy and Physiology*, vol. xxxix., 1905.)

ectodermal cells. At the point of involution the external layer of ectoderm separates from the lens and passes freely over the surface, so that the lens becomes disconnected from the general ectoderm, and recedes into the optic cup,

FIG. 142.—Optic cup and choroidal fissure seen from below, from a human embryo of about four weeks. (Kollmann.)

while the cuticular layer covering it is developed into the corneal epithelium. The cells forming the posterior or inner wall of the lens vesicle rapidly increase in size, becoming elongated and developed into the lens fibres, and, filling up the

FIG. 143.—Horizontal section through the eye of an eighteen days' embryo rabbit. × 30. (Kölliker.)



cavity, convert it into a solid body. The cells on the anterior wall retain their cellular character, and form the anterior lens epithelium of the adult. The optic cup contains a quantity of mesodermal tissue continuous with the general

mesoderm through the choroidal fissure. This tissue becomes converted into the vitreous humour, and surrounds the lens with a vascular membrane—the *vascular capsule of the lens.* From the central artery of the retina several branches are prolonged forwards through the vitreous body to the capsule of the lens, but by the sixth month these have all undergone atrophy except one, which persists till the ninth month as the *arteria hyaloidea.* It disappears, however, before birth, and its position is indicated in the adult by the *canalis hyaloideus of Stilling.* The front part of the vascular capsule of the crystalline lens forms the *membrana pupillaris,* and also attaches the iris to the capsule of the lens. It disappears about the seventh month.

The optic stalk becomes solid by the union of the margins of the choroidal fissure and by the obliteration of the stalk cavity. By far the greater number of the optic nerve-fibres arise as the axis-cylinder processes of the nerve-cells in the retina, and pass along the optic stalk to the brain. Some of the fibres, however, are centrifugal, and arise from nerve-cells in the brain. The outer layer of the optic cup forms the pigmentary layer of the retina, while its inner layer becomes differentiated into (*a*) spongioblasts, which are the rudiments of the supporting tissues of the retina, and (*b*) neuroblasts, which form its nervous elements (see page 118).

The sclera, cornea, and choroid are developed from the mesoderm surrounding the optic vesicle.

The eyelids are formed as small cutaneous folds (fig. 143), which at the end of the third month come together and unite in front of the globe and cornea. This union is broken up and the eyelids separate before the end of fœtal life.

The lachrymal sac and nasal duct result from a thickening of the ectoderm in the groove between the lateral nasal and maxillary processes. This thickening becomes hollowed out into a channel, and the lips of the groove meet over it, enclose it, and convert it into a duct, which eventually opens into the nasal fossa. The epithelium of the cornea and conjunctiva, and that which lines the ducts and alveoli of the lachrymal gland, are of ectodermal origin, as are also the eyelashes and the lining cells of the glands which open on the lid-margins.

Development of the Ear.—The first rudiment of the ear appears shortly after that of the eye, in the form of a thickening of the ectoderm covering the hind-brain. The thickening is followed by an involution of the ectoderm to form the *auditory pit* (fig. 144), which becomes deeper and deeper, and sinking towards the base of the skull, forms a flask-shaped cavity. The mouth of the flask is then closed, and thus a shut sac is formed, the *otic vesicle* (fig. 145), which by its

FIG. 144.—Section through the head of a human embryo, about twelve days old, in the region of the hind-brain. (Kollmann.)

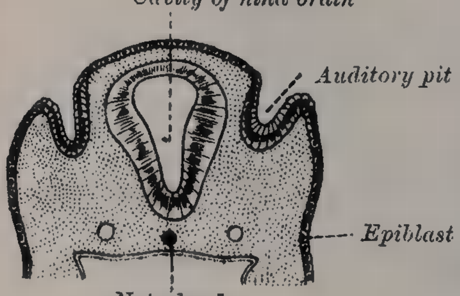


FIG. 145.—Section through hind-brain and otic vesicle of an embryo more advanced than that of fig. 144. (After His.)

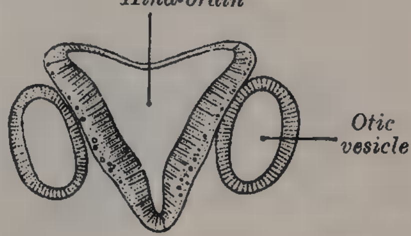

sinking inwards comes to be placed between the ali-sphenoid and basi-occipital matrices. From it the epithelial lining of the labyrinth is formed. The otic vesicle is embedded in a mass of mesoblastic tissue, which rapidly undergoes chondrification and ossification to form the bony labyrinth. The vesicle becomes pear-shaped; and the neck of the flask, or *recessus labyrinthi,* prolonged upwards, forms the aquæductus vestibuli. From it are given off certain diverticula, from which the various parts of the labyrinth are formed. One from the anterior end gradually elongates, and, forming a tube, bends on itself and becomes the cochlea. Three others, which appear on the surface of the vesicle, form the semicircular

canals, of which the external canal is the last to be developed (figs. 147 and 148). Subsequently, a constriction takes place in the original vesicle, which nearly divides it into two, and from these are formed the utricle and saccule (fig. 148). Finally, the auditory nerve, which has been developed from the 'neural crest'

Fig. 146.—Left auditory vesicle of a human embryo of four weeks, seen from the outer surface. (W. His, jun.)

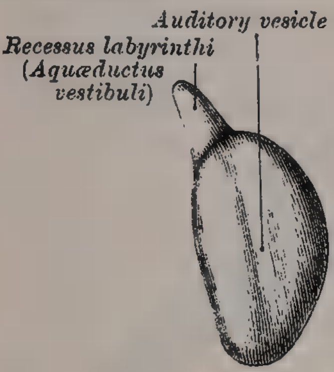

Fig. 147.—Left auditory vesicle of a human embryo of five weeks, seen from the outer surface. (W. His, jun.)

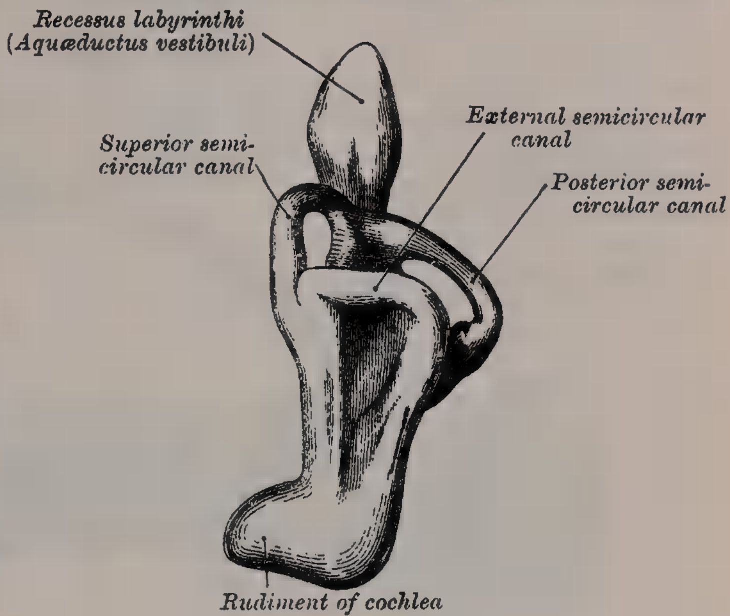
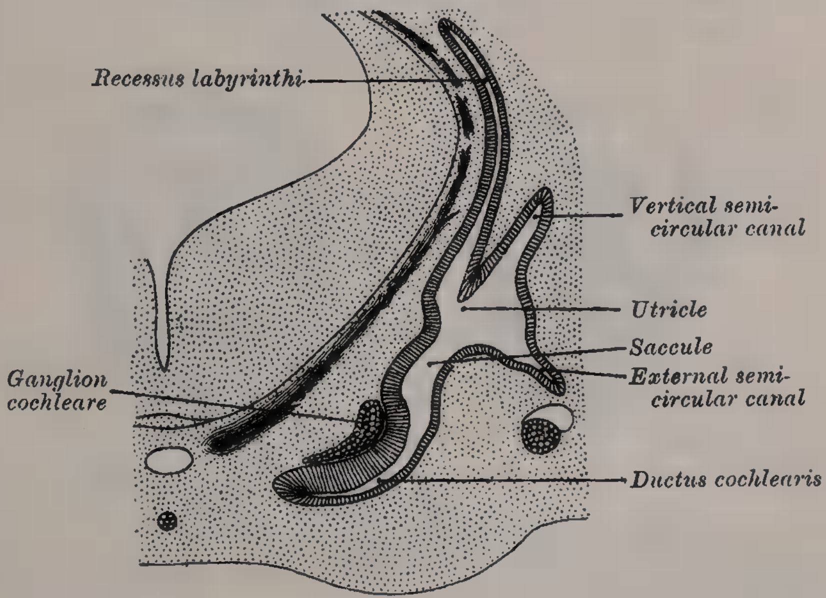


in the manner above described (page 116), pierces the auditory capsule in two main divisions—one for the vestibule, the other for the cochlea. The middle ear and Eustachian tube are the remains of the inner part of the first branchial cleft (hyomandibular), and are closed externally by the membrana tympani, which originally consists of a layer of epiblast externally, and a layer of hypoblast internally; between these two layers the mesoblast extends to form the substantia

Fig. 148.—Transverse section through head of fœtal sheep, in the region of the labyrinth. × 30. (After Boettcher.)

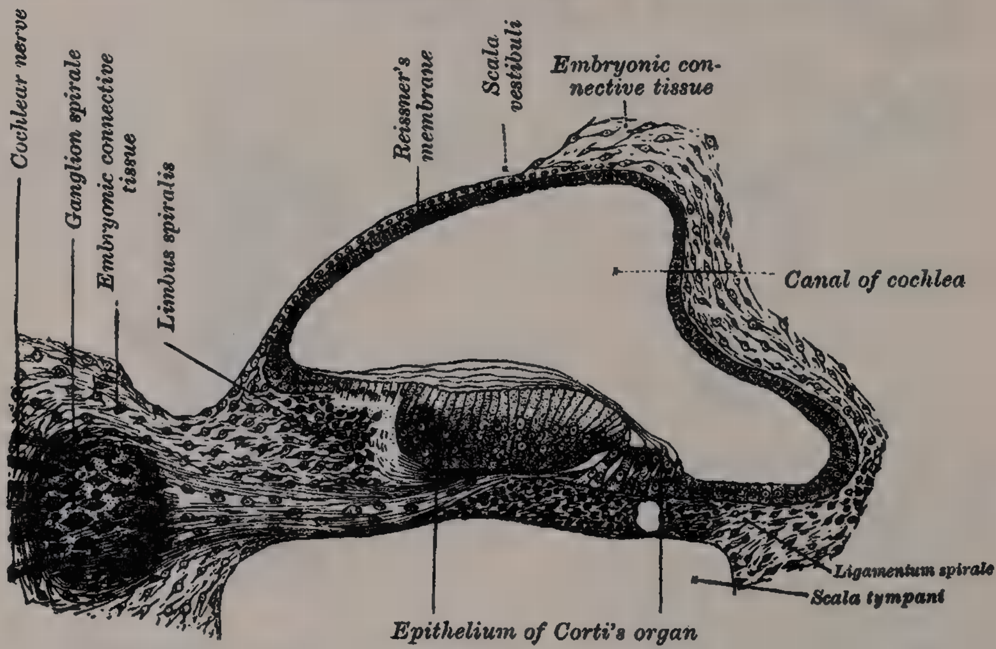


propria of the membrane. With regard to the exact mode of development of the ossicles of the middle ear there is some difference of opinion. The view generally maintained is that the *incus* and *malleus* are developed from the proximal end of the mandibular (Meckel's) cartilage (fig. 125); that the base of the *stapes* is formed by the ossification of the mesoderm which fills in the foramen ovale, while its arch is developed around a small vessel, the stapedial artery, which

subsequently undergoes atrophy. As already stated (footnote, page 102), Gadow regards all three ossicles as being derived from the hyomandibula.

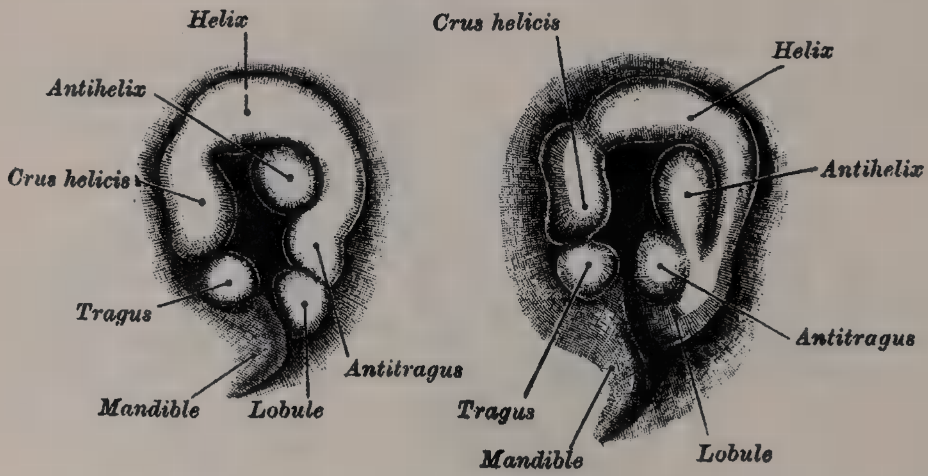
The external auditory meatus is formed from the outer part of the hyomandibular cleft, while the pinna is developed by the gradual differentiation of six tubercles which appear around the outer margin of the cleft. Two tubercles

FIG. 149.—Transverse section of the canal of the cochlea of a fœtal cat. (After Boettcher and Ayres.)



appear on the posterior edge of the mandibular arch; these represent the rudiments of the tragus and crus helicis. Three are found on the hyoid arch, and indicate, from below upwards, the lobule, antitragus, and antihelix. One

FIG. 150.—Left ears of human embryos estimated at thirty-five and thirty-eight days respectively. (After His.)



arises above the cleft, and grows downwards behind the antitragus and antihelix; from it and its downward prolongation the upper and posterior parts of the helix are developed (fig. 150).

Development of the Skin, Glands, and Soft Parts.—The epidermis and its appendages, consisting of the hairs, nails, sebaceous and sweat glands, are developed from the ectoderm, while the corium or true skin is of mesodermic origin, being derived from the cutis plates of the protovertebral somites. About the fifth week the epidermis consists of two layers of cells, the deeper one corresponding to the rete mucosum. The subcutaneous fat appears about the fourth

month, and the papillæ of the true skin about the sixth. A considerable desquamation of epidermis takes place during fœtal life, and this desquamated epidermis, mixed with a sebaceous secretion, constitutes the *vernix caseosa*, with which the skin is smeared during the last three months of fœtal life. The nails are formed at the third month, and begin to project from the epidermis about the sixth. The hairs appear between the third and fourth months in the form of solid downgrowths of the deeper layer of the epidermis, which then become inverted by papillary projections from the corium. About the fifth month, the fœtal hairs (*lanugo*) appear, first on the head and then on the other parts; they drop off after birth, and give place to the permanent hairs. The cellular structures of the sudoriferous and sebaceous glands are formed from the ectoderm, while the connective tissue and blood-vessels are derived from the mesoderm. The mammary gland is also formed partly from mesoderm and partly from ectoderm—its blood-vessels and connective tissue being derived from the former, its cellular elements from the latter. Its first rudiment is seen about the third month, in the form of a number of small inward projections of the ectoderm which invade the mesoderm; from these, secondary tracts of cellular elements radiate and subsequently give rise to the glandular follicles and ducts. The development of the former, however, remains imperfect, except in the adult female.

Development of the Muscles.—The voluntary muscles are developed from the muscle-plates or myotomes of the protovertebral somites. By the end of the third week the cells of the muscle-plates commence to elongate in an antero-posterior direction, and, losing their cellular character, are converted into striped muscular fibres. By the fusion of the myotomes in an antero-posterior direction, the longitudinal muscles of the back are developed; and from extensions of the myotomes into the body wall and limb buds, the muscles of these parts arise. The involuntary muscles are derived from the splanchnopleure mesoblast, and are therefore not connected in any way with the protovertebral somites.

Development of the Blood-vascular System.—There are three distinct stages in the development of the circulatory system, each in accordance with the manner in which nourishment is provided for at different periods of the existence of the individual. In the first stage there is the *vitelline circulation*, during which nutriment is extracted from the *vitellus* or contents of the yolk-sac. In the second stage there is the *placental circulation*, during which nutrition is obtained by means of the placenta from the blood of the mother. In the third stage there is the *complete circulation of the adult*, commencing after birth, during which nutrition is provided for by the organs of the individual itself.

Blood-vessels first make their appearance in the mesodermal wall of the yolk-sac, i.e. outside the body of the embryo. Here the mesodermal cells become arranged into solid strands or cords which join to form a close-meshed network. The peripheral cells of these strands become flattened and joined to each other by their edges to form the walls of the primitive blood-vessels, which at this stage are simple endothelial tubes. Fluid collects within these tubes, and the more centrally situated cells of the cell-cords are thus pushed to the sides of the vessels and appear as masses of loosely arranged cells which project towards the lumen of the tube. These masses are termed *blood islands*, and their cells acquire colouring matter (hæmoglobin), and are then detached to form the blood-corpuscles.* The earliest blood-corpuscles are all nucleated: they are also capable of subdivision and of executing amœboid movements, and in these respects they resemble white blood-corpuscles. Soon, however, true white blood-corpuscles make their appearance, and, according to Beard,† are first derived from the rudiments of the thyroid gland.

Coincident with the development of the blood-vessels in the vascular area, the first rudiment of the heart appears within the body of the embryo as a pair of tubular vessels which are developed in the splanchnopleure of the pericardial area. These are named the *primitive aortæ*, and a direct continuity is soon

* Some observers incline to the view that the blood-corpuscles are of entodermal origin, being developed from the endothelium of the vessels, the sequence of the development of the different structures being: first the heart, then the blood-vessels, and lastly the blood-corpuscles. (Consult Dr. E. Mehnert's *Biomechanik*, Jena, 1898.)

† *Anatomischer Anzeiger*, December 1900.

established between them and the vessels of the vascular area. Each receives anteriorly a vein—the vitelline vein—from the yolk-sac, and is prolonged backwards on the lateral aspect of the notochord under the name of the dorsal aorta. The dorsal aortæ end at first on the yolk-sac; but with the development of the allantois, they are continued backwards through the body-stalk as the umbilical arteries to the villi of the chorion.

By the forward growth and flexure of the head the pericardial area and the anterior portions of the primitive aortæ are folded backwards on the ventral aspect of the fore-gut, and the original position of the somatopleure and splanchnopleure layers of the pericardial area is reversed, the latter being placed on the dorsal aspect of the former. Each primitive aorta now consists of a ventral and a dorsal part connected anteriorly by an arch. These three parts are named respectively the anterior ventral aorta, the dorsal aorta, and the first cephalic arch. The vitelline veins which enter the embryo through the anterior wall of the umbilical orifice are now continuous with the posterior ends of the anterior ventral aortæ. With the formation of the tail-fold the posterior parts of the primitive aortæ are carried forward in a ventral direction to form the posterior ventral aortæ and primary caudal arches.* In the pericardial region the two primitive vessels grow together and fuse to form a single tubular heart (fig. 151), the posterior end of which receives the two vitelline veins, while from its anterior

Fig. 151.—Diagram to illustrate the simple tubular condition of the heart. (Drawn from Ecker-Ziegler model.)

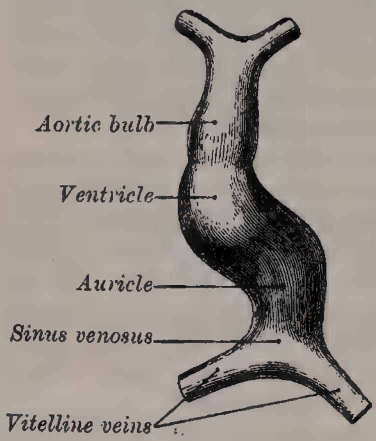


Fig. 152.—Heart further advanced than in fig. 151. (Drawn from Ecker-Ziegler model.)

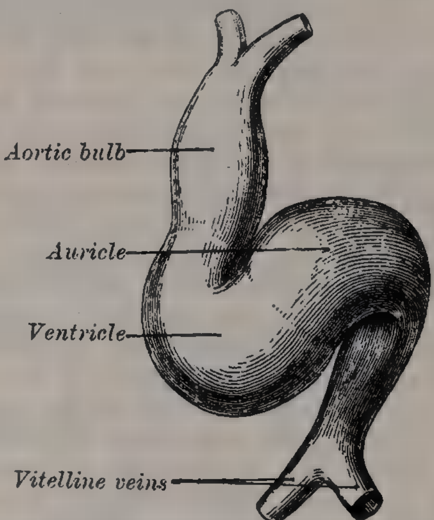


end there arise the two anterior ventral aortæ.† By the rhythmical contraction of the tubular heart the blood is forced through the aortæ and blood-vessels of the vascular area, from which it is returned to the heart by the vitelline veins. This constitutes the vitelline circulation (fig. 110), and by means of it nutriment is absorbed from the vitellus.

The vitelline veins at first open separately into the posterior end of the tubular heart, but after a time their terminal portions fuse, and the two vessels communicate with the heart through a common orifice. The vitelline veins ultimately drain the blood from the alimentary canal, and are modified to form the portal vein. This is caused by the growth of the liver, which interrupts their direct continuity with the heart; and the blood returned by them circulates through the liver before reaching the heart.

Coincident with the atrophy of the yolk-sac the vitelline circulation diminishes and ultimately ceases, while more and more blood is simultaneously carried through the umbilical arteries to the villi of the chorion. Subsequently, as the non-placental chorionic villi atrophy, their vessels disappear; and then the umbilical arteries convey the whole of their contents to the placenta, whence it is returned to the heart by the umbilical veins. In this manner the placental

* Young and Robinson, *Journal of Anatomy and Physiology*, vol. xxxii.
† In most fishes and in the amphibia the heart originates as a single median tube.

circulation is established, and by means of it nutritive materials are absorbed from, and waste products given up to, the maternal blood.

The umbilical veins, like the vitelline, become interrupted by the liver, and the blood returned by them passes through this organ before reaching the heart. Ultimately the right umbilical vein shrivels up and disappears, as will be explained later on.

During the occurrence of these changes great alterations take place in the primitive heart and blood-vessels, and now require description.

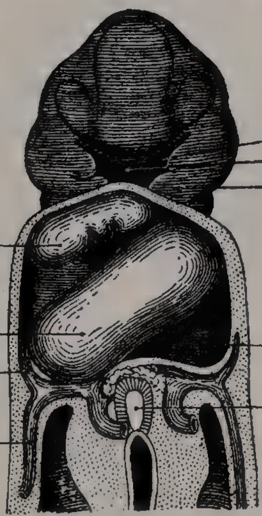
Further Development of the Heart.—The following is an outline of the changes which take place during the further development of the heart.

The simple tubular heart, already described, becomes elongated and bent on itself so as to form an **S**-shaped loop (figs. 151 and 152), the anterior part bending to the right and the posterior part to the left. The intermediate portion

FIG. 153.—Head of chick embryo of about thirty-eight hours' incubation, viewed from the ventral surface. × 26. (From Duval's 'Atlas d'Embryologie.')

arches transversely from right to left, and then turns sharply forwards into the anterior part of the loop. Slight constrictions make their appearance in the tube and divide it from behind forwards into four parts, viz.: (1) the *sinus venosus* (*sinus reuniens* of His); (2) the common auricle; (3) the common ventricle; (4) the aortic bulb (figs. 151 to 153). From the aortic bulb the two ventral

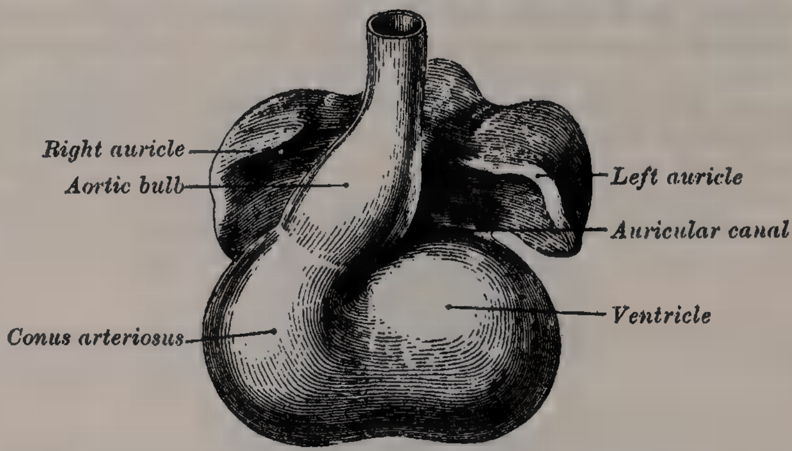
FIG. 154.—Heart of human embryo of about fifteen days. (Reconstruction by His.)



aortæ extend forwards in the floor of the pharynx. The constriction between the auricle and ventricle is well marked and constitutes the *auricular canal*, while that between the ventricle and the aortic bulb is less distinct and is termed the *fretum Halleri*. The former indicates the site of the future auriculo-ventricular valves, the latter that of the semilunar valves.

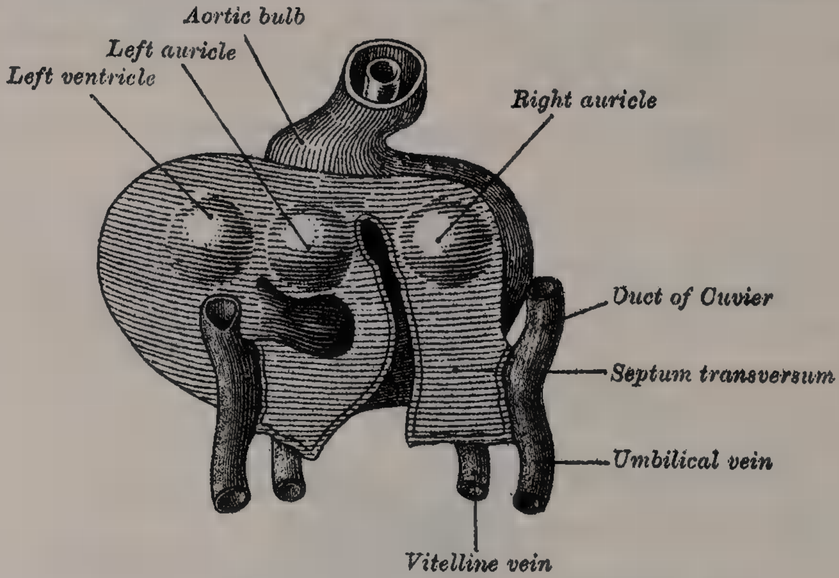
The sinus venosus is at first situated in the septum transversum (a layer of mesoderm in which the liver and the central tendon of the Diaphragm are developed) behind the common auricle, and is formed by the union of three pairs of veins, viz.: (1) the veins or ducts of Cuvier from the body of the embryo; (2) the omphalo-mesenteric veins from the yolk-sac; (3) the umbilical veins from the placenta (fig. 156). The sinus is at first placed transversely, and opens by a median aperture into the common auricle. Soon, however, it assumes an oblique position, and its right half or horn becomes larger than the left, while the

FIG. 155.—Heart showing expansion of auricles. (Drawn from Ecker-Zeigler model.)



opening into the auricle now communicates with the right portion of the auricular cavity. The right horn ultimately becomes incorporated with and forms a part of the right auricle, the line of union between it and the auricle proper being indicated in the interior of the adult auricle by a vertical crest, the *crista terminalis* of His. The left horn, which ultimately receives only the left duct of Cuvier, persists as the coronary sinus (fig. 162). The omphalo-mesenteric and umbilical veins are soon replaced by a single vessel, the inferior vena cava, and

FIG. 156.—Heart of human embryo, 4·2 mm. long, seen from behind. (His.)



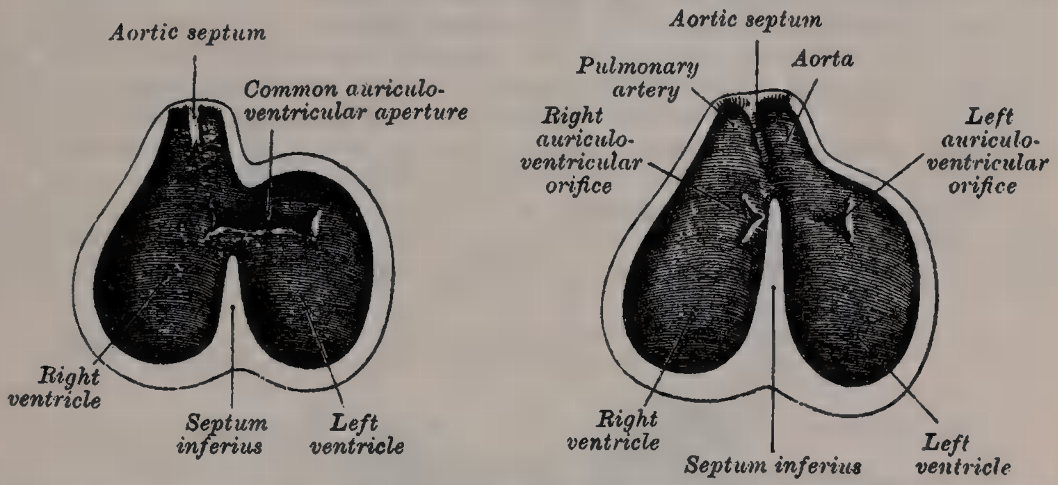
the three veins (inferior vena cava and right and left Cuvierian ducts) open into the dorsal aspect of the auricle by a common slit-like aperture. The upper part of this aperture represents the opening of the permanent superior vena cava, the lower that of the inferior vena cava, and the intermediate part the orifice of the coronary sinus. The slit-like aperture lies obliquely, and is guarded by two valve-like folds of endocardium, the *right* and *left venous valves*. The left venous valve disappears, while the right is subsequently divided to form the Eustachian and Thebesian valves. At the lower extremity of the slit is a triangular

thickening, the *spina vestibuli* of His, which partly closes the aperture between the two auricles, and which, according to His, takes a part in the formation of both the interauricular and interventricular septa.

The common auricle and ventricle are each subdivided into two cavities, and the aortic bulb is divided into the pulmonary artery and aorta as follows:

The auricular canal is at first a short straight tube connecting the auricular with the ventricular portion of the heart, but it becomes overlapped by the growing

Fig. 157.—Diagrams to show the development of the septum of the aortic bulb and of the ventricles. (Born.)

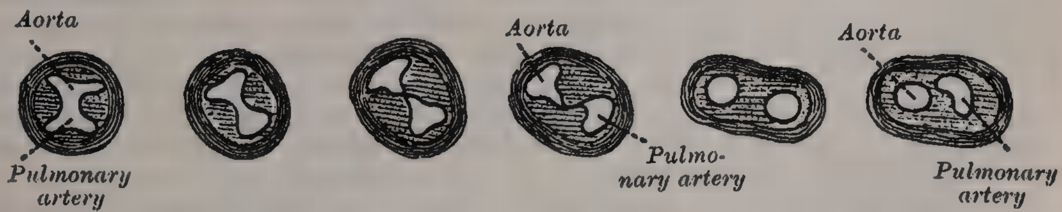


auricles and ventricles so that its position on the surface of the heart is only indicated by an annular constriction (fig. 155). Its lumen is reduced to a transverse slit, and two thickenings appear, one on its dorsal and another on its ventral wall. These thickenings, or *endocardial cushions* (fig. 159) as they are termed, project into the canal, and, meeting in the middle line, unite to form the *septum intermedium* which divides the canal into two channels, the future right and left auriculo-ventricular orifices.

The common auricular cavity becomes subdivided into right and left auricles by a septum, the *septum superius*, which grows downwards into the auricular cavity so that the two auricles communicate with each other only below the margin of the septum. This communication (ostium primum of Born) does not, however, represent the foramen ovale, for the septum grows downwards and blends with that of the auricular canal formed by the fusion of the endocardial cushions. The foramen ovale (ostium secundum of Born) results from a perforation of the primary septum. A second septum grows downwards from the upper wall of the auricle to the right of the primary septum, and forms the annulus ovalis. Shortly after birth it fuses with the primary septum, and by this means the foramen ovale is closed. Sometimes this fusion is incomplete and the upper part of the foramen remains patent.

The common ventricle becomes divided by a septum, the *septum inferius* (fig. 157), which grows upwards from the lower part of the ventricle, its position

Fig. 158.—Transverse sections through the aortic bulb to show the growth of the aortic septum. The lowest section is on the left, the highest on the right of the figure. (After His.)



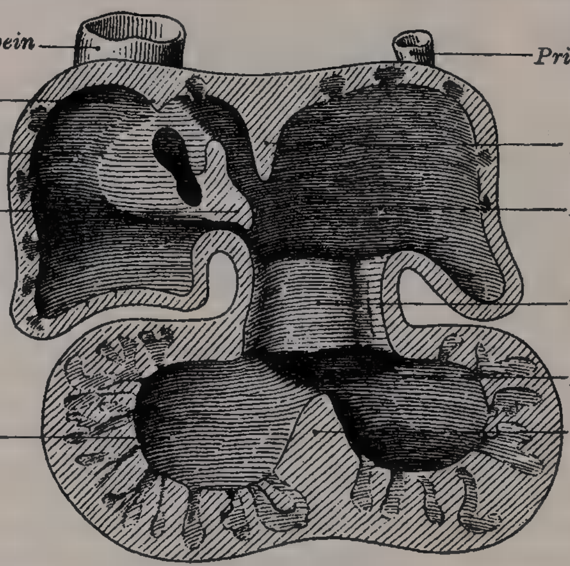
being indicated on the surface of the heart by a furrow. It extends upwards almost as far as the auricular canal, but for some time an interventricular foramen exists between it and the septum of the auricular canal (septum intermedium).

The aortic bulb is divided by the *aortic septum*. This makes its appearance at the distal end of the bulb as two ridge-like thickenings of its endothelial

lining; these increase in size, and, projecting into the lumen, ultimately fuse to form the septum, and thus the aortic bulb is divided into the pulmonary artery and the aorta. The aortic septum takes a spiral course towards the proximal end of the bulb, so that the two vessels lie side by side above; but near the heart the pulmonary artery is in front of the aorta (fig. 158). The septum grows down into the ventricle as an oblique partition, which ultimately blends with the septum inferius of the ventricles in such a way as to bring the right ventricle into communication with the pulmonary artery, and through the latter with the sixth pair of aortic arches; while the left ventricle is brought into continuity with the aorta which communicates with the remaining aortic arches.

The Valves of the Heart.—The auriculo-ventricular valves are developed in relation to the auricular canal. By the upward expansion of the bases of the ventricles this canal becomes invaginated into the ventricular cavities. This invaginated part forms the rudiment of the lateral cusps of the auriculo-ventricular valves; their mesial or septal cusps are developed as downward prolongations of the septum intermedium. The aortic and pulmonary valves are formed from four endocardial cushions which appear within the lower end of the aortic bulb, two of which are placed laterally, the third in front and the fourth behind. The lateral cushions merely represent the lower parts of the ridge-like

Fig. 159.—Interior of dorsal half of heart from a human embryo 10 mm. long. (After His.) (From Kollmann's 'Entwickelungsgeschichte.')



thickenings which grow in to form the aortic septum. When the aortic septum is completed these lateral cushions are each subdivided into two, thus giving rise to six thickenings—the rudiments of the semilunar valves—three at the aortic and three at the pulmonary orifice.

Peculiarities of the fœtal heart.—In early fœtal life the heart is placed directly under the head and is relatively of large size. Later it assumes its position in the thorax, but lies at first in the middle line; towards the end of pregnancy it gradually becomes oblique in direction. Its auricular portion is at first larger than the ventricular part, and the two auricles communicate freely through the foramen ovale. In consequence of the communication between the pulmonary artery and the aorta, through the ductus arteriosus, the contents of the right ventricle are mainly carried into the latter vessel instead of to the lungs, and hence the wall of the right ventricle is as thick as that of the left. At the end of fœtal life, however, the left ventricle is thicker than the right, a difference which becomes more and more emphasised after birth.

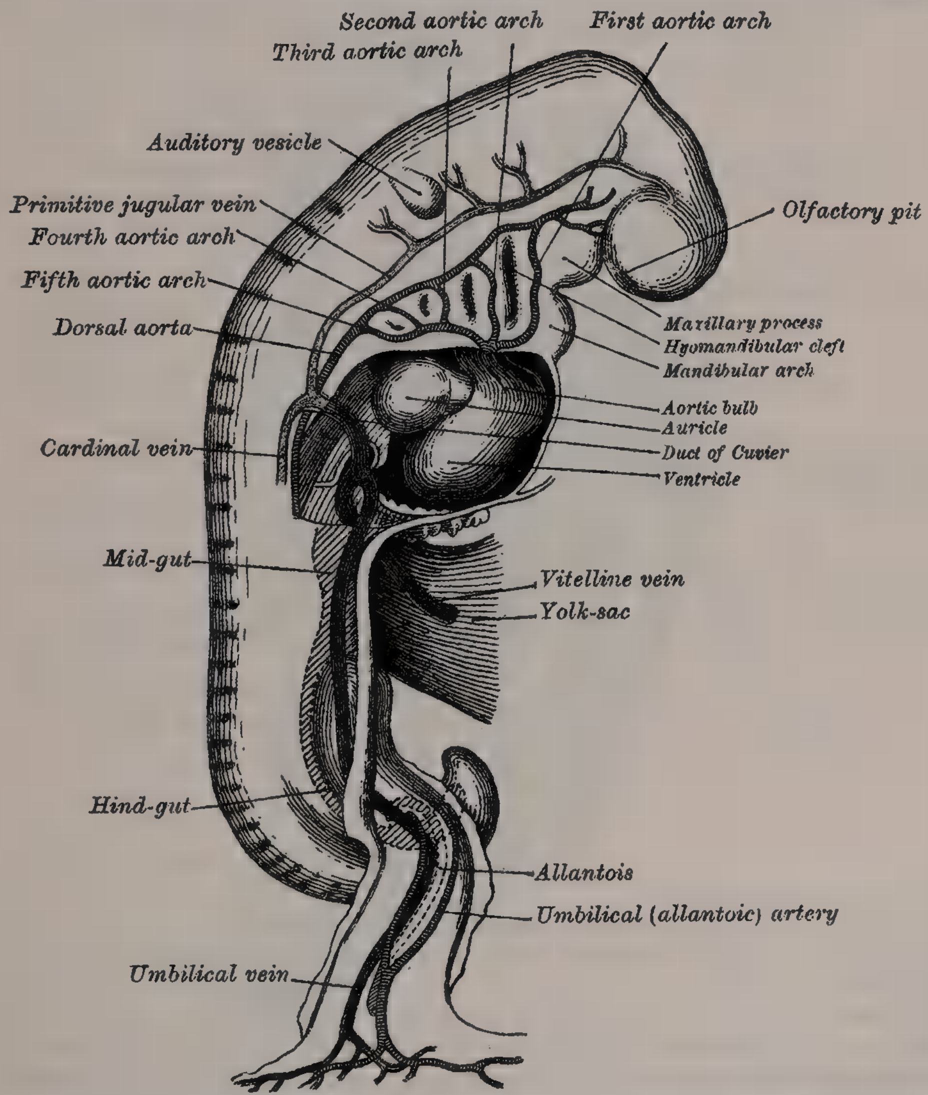
Further Development of the Arteries.—It has been seen (page 124) that the primitive aortæ arise from the aortic bulb, and that each consists of a ventral and a dorsal part which are continuous through the first aortic arch. The dorsal aortæ run backwards at first on either side of the notochord, but after a time they fuse to form a single trunk, which constitutes the greater part of the future descending aorta. The first aortic arches pass through the mandibular arches, and behind

them five additional pairs are developed within the corresponding visceral arches; so that, in all, six pairs of aortic arches are formed (fig. 161). The first and second arches pass between the ventral and dorsal aortæ, while the others arise at first by a common trunk from the aortic bulb. As the neck elongates, the ventral aortæ are drawn out, and the third and fourth arches arise directly from these vessels.

In fishes these arches persist and give off branches to the gills, in which the blood is oxygenated. In mammals some of them remain as permanent structures, while others disappear or become obliterated (fig. 161).

The ventral aortæ.—These persist on both sides. The right forms (*a*) the innominate artery, (*b*) the right common and external carotid arteries. The left

Fig. 160.—Profile view of a human embryo estimated at twenty or twenty-one days old. (After His.)



gives rise to (*a*) the short portion of the aortic arch, which reaches from the origin of the innominate artery to that of the left common carotid artery; (*b*) the left common and external carotid trunks.

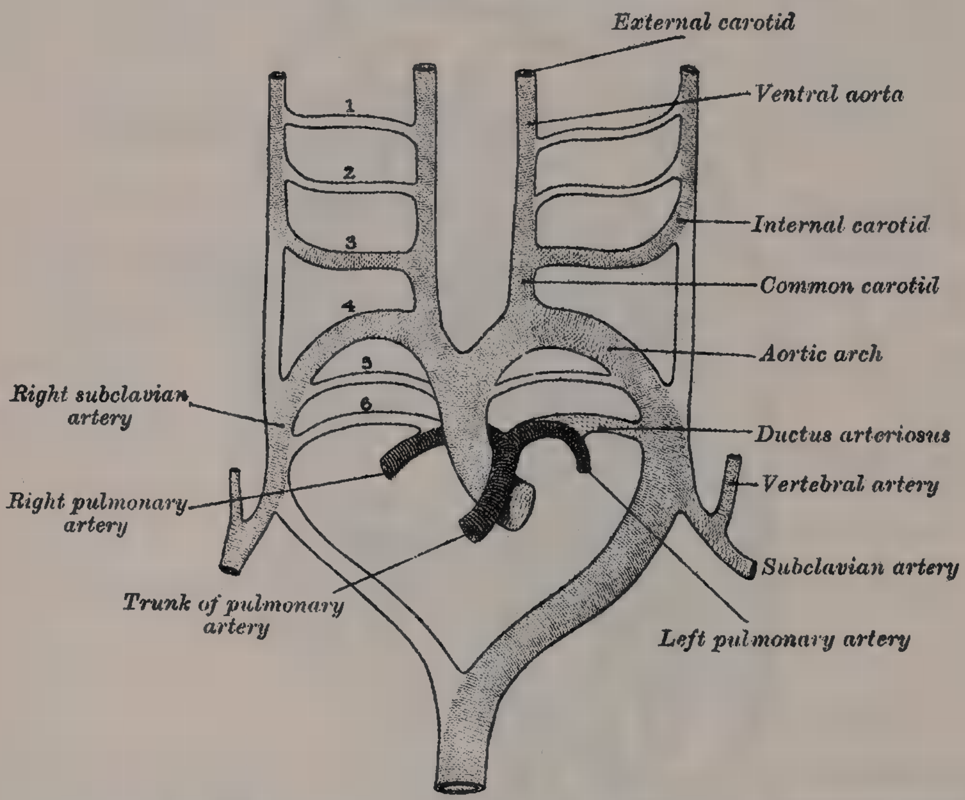
The aortic arches.—The first and second disappear; the third constitutes the commencement of the internal carotid artery, and is therefore named the *carotid arch.* The fourth right arch forms the right subclavian as far as the origin of its internal mammary branch; while the fourth left arch constitutes the arch of the aorta between the origin of the left carotid artery and the termination of the ductus arteriosus. The fifth arch disappears on both sides. The sixth right arch disappears; that on the left side gives off the pulmonary arteries and persists as the ductus arteriosus. This duct remains pervious during the whole of fœtal life, but after birth becomes obliterated. His found that in the

early embryo the right and left arches each gave a branch to the lungs, but that later both pulmonary arteries took origin from the left arch.

The dorsal aortæ.—In front of the third aortic arches the dorsal aortæ persist and form the forward continuation of the internal carotid arteries. Behind the third arch the right dorsal aorta disappears as far as the point where the two dorsal aortæ fuse to form the descending aorta. The part of the left dorsal aorta which intervenes between the third and fourth arches disappears, while the remainder persists to form the descending part of the arch of the aorta. A constriction, the *aortic isthmus*, is sometimes seen in the aorta between the origin of the left subclavian and the attachment of the ductus arteriosus.

Sometimes the right subclavian artery arises from the aortic arch beyond the origin of the left subclavian and passes upwards and to the right behind the trachea and œsophagus. This condition may be explained by the persistence of the right dorsal aorta and the obliteration of the fourth right arch.

Fig. 161.—Scheme of the aortic arches and their destination. (Modified from Kollmann.)



In birds the fourth right arch forms the permanent arch of the aorta; in reptiles the fourth arch on both sides persists and gives rise to the double aortic arch in these animals.

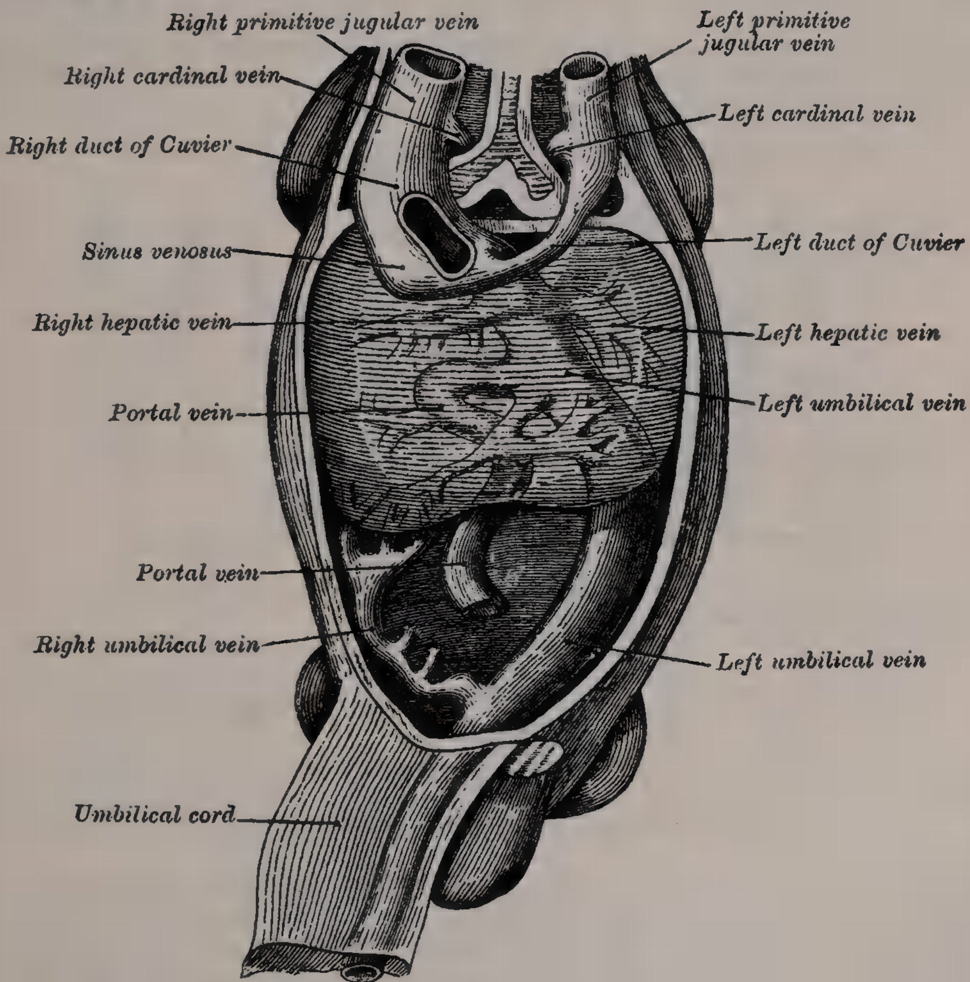
The heart originally lies on the ventral aspect of the pharynx, immediately behind the stomatodœum. With the elongation of the neck and development of the lungs it recedes within the thorax, and, as a consequence, the ventral aortæ are drawn out and the original position of the fourth and fifth arches is greatly modified. Thus, on the right side the fourth recedes to the root of the neck, while on the left side it is withdrawn within the thorax. The recurrent laryngeal nerves originally passed to their distribution on the outer sides of the sixth pair of arches, and therefore become pulled backwards with the descent of these structures, so that in the adult the left hooks round the ductus arteriosus; owing to the disappearance of the fifth and sixth right arches the right nerve hooks round that immediately above them, i.e. the commencement of the subclavian artery. A series of segmental arteries arises from the primitive dorsal aortæ, those in the neck alternating with the cervical segments of the spine. The segmental artery which lies between the sixth and seventh cervical segments is of special interest, since it forms the lower part of the vertebral artery and, when the fore-limb bud appears, sends a branch to it (i.e. the subclavian artery); the upper part of the

vertebral artery is formed by an antero-posterior anastomosis between the higher segmental arteries. From this segmental artery the entire left subclavian and the greater part of the right subclavian are formed.

The subclavian artery is prolonged into the limb under the names of the axillary and brachial arteries, and these together constitute the arterial stem for the upper arm. The direct continuation of this stem in the forearm is formed by the anterior interosseous artery; while the radial and ulnar vessels, which ultimately exceed this vessel in size, are in reality lateral branches of the main stem.

The formation of the primary caudal arches has already been referred to (page 124), and the fusion of the dorsal aortæ to form the greater part of the systemic aorta has also been pointed out (page 128). The middle sacral artery of the adult was formerly regarded as the direct continuation of the adult aorta, but

FIG. 162.—Human embryo with heart and anterior body wall removed to show the sinus venosus and its tributaries. (After His.) (From Kollmann's 'Entwickelungsgeschichte.')



Young and Robinson (*op. cit.*) maintain that it 'is a secondary branch, probably representing fused segmental arteries.' They have further pointed out that while the dorsal and ventral extremities of the primary caudal arches remain, their middle portions 'disappear and are replaced by "secondary" caudal arches which lie to the outer sides of the Wolffian ducts.' 'The vessels which are to be looked upon as the posterior continuations of the primitive aorta in the adult in man, rodents, &c., are the common iliac, internal iliac, and hypogastric arteries.'

The hypogastric arteries are continued into the umbilical cord as the umbilical arteries. After birth they become obliterated from the umbilicus as far as the origin of the superior vesical arteries.

The primary arterial stem for the lower limb is formed by the sciatic artery, which accompanies the great sciatic nerve along the posterior aspect of the thigh to the back of the knee, whence it is continued as the peroneal artery. This arrangement exists in reptiles and amphibians. The femoral artery arises later

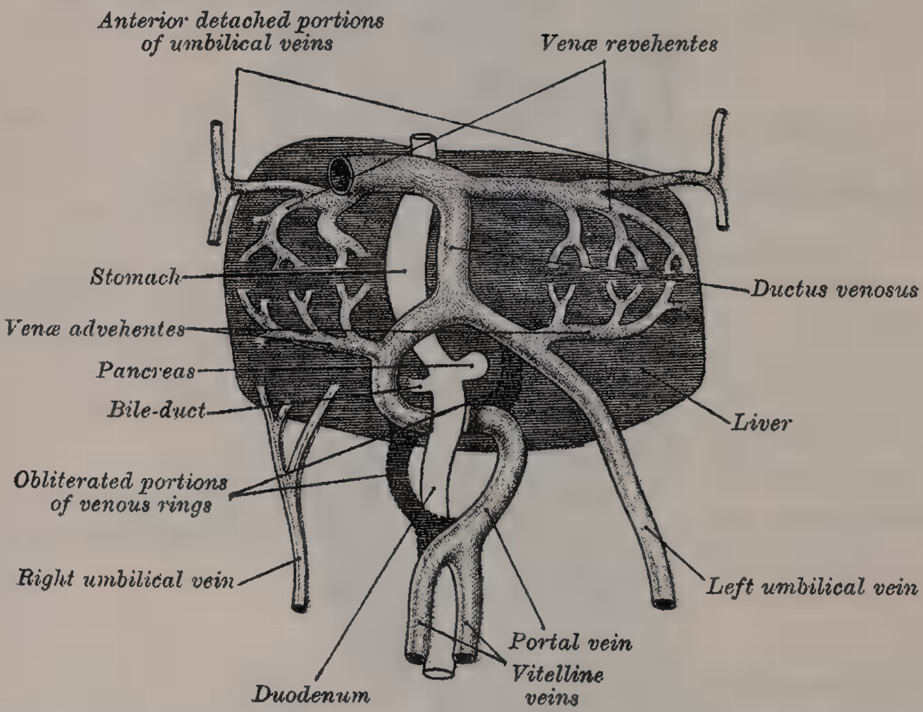
as a branch of the common iliac, and, passing down the front and inner side of the thigh to the bend of the knee, joins the sciatic artery. The femoral quickly enlarges, and, coincident with this, the part of the sciatic immediately above the knee undergoes atrophy. The anterior and posterior tibial arteries, like the radial and ulnar in the forearm, are branches of the main arterial stem.

Development of the Veins.—The formation of the great veins of the embryo may be best considered under two groups, visceral and parietal.

The *visceral veins* are the two vitelline or omphalo-mesenteric veins bringing the blood from the yolk-sac, and the two umbilical or allantoic veins returning the blood from the placenta; these four veins open close together into the sinus venosus (fig. 156).

The vitelline veins run upwards at first in front, and subsequently on either side of the intestinal canal. They unite on the ventral aspect of the canal, and then encircle the duodenal portion of the intestinal tube by forming around it two venous rings, the first on its dorsal, the second on its ventral aspect. The portions of the veins above the upper ring become invaded by the developing

Fig. 163.—The liver, and the veins in connection with it, of a human embryo, twenty-four or twenty-five days old, as seen from the ventral surface. (After His.) (Copied from Milnes Marshall's 'Embryology.')



liver and broken up by it into a network of smaller vessels, the central part of the network consisting of a capillary plexus. The branches which convey the blood to this plexus are named the *venæ advehentes*, and become the branches of the portal vein; while the vessels which drain the plexus into the sinus venosus are termed the *venæ revehentes*, and form the future hepatic veins (figs. 162 and 163). Ultimately the left vena revehens no longer communicates directly with the sinus venosus, but opens into the right vena revehens.

The lower part of the *portal vein* is formed from the fused vitelline veins which receive the veins from the alimentary canal; its upper part is derived from the venous rings by the persistence of the left half of the lower and the right half of the upper ring, so that the vessel forms a spiral turn round the duodenum (fig. 163).

The two umbilical veins fuse early to form a single trunk in the allantois, but remain double for some time within the embryo and pass forwards to the sinus venosus in the side walls of the body. Like the vitelline veins, their direct connection with the sinus venosus becomes interrupted by the invasion of the liver, and thus at this stage the whole of the blood from the yolk-sac and placenta passes through the substance of the liver before it reaches the heart. The right umbilical vein shrivels up and almost entirely disappears; the left, on

the other hand, becomes enlarged and opens into the upper venous ring of the vitelline veins. Finally a direct branch is established between this ring and the right hepatic vein; this branch is named the *ductus venosus*, and, enlarging rapidly, it forms a wide channel through which most of the blood, returned from the placenta, is carried direct to the heart without passing through the liver. A small proportion of the blood from the placenta is, however, conveyed from the left umbilical vein to the liver through the left vena advehens. The left umbilical vein and the ductus venosus undergo atrophy and obliteration after birth, and form respectively the ligamentum teres and ligamentum venosum of the liver (fig. 163).

The *Parietal Veins.*—The first indication of a parietal system consists in the appearance of two short transverse veins (the *ducts of Cuvier*), which open, one on either side, into the auricular portion of the heart. Each of these ducts is formed by an ascending and descending vein. The ascending veins return the blood from the parietes of the trunk and from the Wolffian bodies, and are called *cardinal* veins. The descending veins return the blood from the head, and are called *primitive jugular* veins (fig. 160). The blood from the lower limbs is collected by the right and left iliac veins, which, in the earlier stages

of development, open into the corresponding right and left cardinal veins (fig. 164); later on, a transverse branch (the left common iliac vein) connects the lower ends of the two cardinal veins, and through this the blood is carried into the right cardinal vein. The portion of the left cardinal vein above the left common iliac vein becomes atrophied as high as the level of the left renal vein, above which it persists as the superior and inferior azygos minor veins and the lower part of the left superior intercostal vein. The right cardinal vein, which now receives the blood from both lower extremities, forms a large venous trunk along the posterior abdominal wall; up to the level of the renal veins it forms the lower part of the inferior vena cava. Above the level of the renal veins the right cardinal vein persists as the vena azygos major, and receives the right intercostal veins, while the azygos minor veins are brought into communication with it by the development of transverse branches in front of the spinal column (fig. 164).

Inferior vena cava (fig. 164).—As just stated, the lower part of the inferior vena cava is formed from the post-renal part of the right cardinal vein. The upper part of the inferior vena cava arises as a small vein which lies between the two primitive kidneys and which is continuous superiorly with the conjoined ductus venosus and right hepatic vein. This small vein divides below into two

branches which anastomose with the right and left cardinal veins at the level of the renal veins. Through the anastomosis thus formed with the right cardinal vein the blood from the latter is carried into the small vein, which then becomes enlarged to form the pre-renal part of the vena cava inferior. Coincident with the atrophy of the post-renal part of the left cardinal vein, the blood from the left renal vein and its tributaries is also carried into the vena cava inferior.

In consequence of the atrophy of the Wolffian bodies the cardinal veins diminish in size; the primitive jugular veins, on the other hand, become enlarged, owing to the rapid development of the head and brain. They are further augmented by receiving the vein (*subclavian*) from the upper extremity, and so come to form the chief veins of the Cuvierian ducts; these ducts gradually assume an almost vertical position in consequence of the descent of the heart into the thorax. The right and left Cuvierian ducts are originally of the same diameter, and are frequently termed the *right* and *left superior venæ cavæ*. By the development of a transverse branch (the future *left innominate vein*) between the two primitive jugular veins, the blood is carried across from the left to the right internal jugular, which thus becomes enlarged to form the upper part of the superior vena cava of the adult; the lower part of this vessel is formed by the right Cuvierian duct. Below the origin of this transverse branch the left primitive jugular vein and left Cuvierian duct atrophy, the former constituting the upper part of the left superior intercostal vein, while the latter is represented by the vestigial fold and oblique vein of Marshall (fig. 164). Both right and left superior venæ cavæ are present in some animals, and are occasionally found in the adult human being. The oblique vein of Marshall passes downwards across the back of the left auricle to open into the coronary sinus, which, as already indicated, represents the persistent left horn of the sinus venosus.

The primitive jugular or anterior cardinal veins are situated on the ventral surface of the brain, on the mesial side of the cranial nerve-roots. A considerable portion of each of these veins disappears and is replaced by a vein which is developed on the lateral aspect of the cranial nerves from the fifth to the twelfth inclusive. This new vein (*vena capitis lateralis*) drains the blood from the mid and hind brains, and leaves the skull in company with the seventh nerve. The blood from the hind-brain is collected into a vein (the future lateral sinus) which passes through the foramen jugulare on the lateral aspect of the vagus nerve; here the two vessels join to form the internal jugular vein. On the dorsal aspect of the ear-capsule an anastomotic channel is opened up between the vena capitis lateralis and the lateral sinus; and, coincident with this, the portion of the former vein which extends from the fifth to the tenth cranial nerve becomes obliterated, and thus the whole of the blood from the brain is ultimately drained away by the lateral sinuses. The primitive jugular vein is therefore represented in the adult by the internal jugular, and not by the external jugular as is usually stated—the latter being a vessel of later formation. (Consult 'Die Entwickelung des Blutgefäss-systems,' by Hochstetter, in Hertwig's 'Entwickelungslehre;' and also an article by Mall in the 'American Journal of Anatomy,' vol. iv. December 1904.)

The fœtal circulation is described on a future page.

The pericardium.—As already pointed out (page 81), the anterior portion of the embryonic area in front of the oral plate or bucco-pharyngeal membrane is named the pericardial area. Previous to the formation of the head-fold, the mesoderm has divided into its somatic and splanchnic layers, and these two layers, together with the intervening cœlomic space, extend forwards on either side of the bucco-pharyngeal membrane into the pericardial area; the part of the cœlom contained within this area becomes the cavity of the pericardium. This is, at first, in the shape of a crescent, the lateral horns of which extend backwards on either side of the bucco-pharyngeal membrane and are continuous with the peritoneal part of the cœlomic space. The primitive blood-vessels, which, in the pericardial region, fuse to form the primitive heart, are developed in the splanchnic mesoderm of the pericardial area. By the rapid elongation of the embryo, and the formation of the head-fold, the pericardial area and its contained blood-vessels are folded backwards to form the ventral wall of the fore-gut. By means of this process the surfaces of the pericardial area are consequently reversed, its splanchnic layer being now situated on the dorsal aspect of its somatic layer, while its original anterior limit comes to form the front boundary

of the umbilicus. The vitelline veins, bringing the blood from the yolk-sac, enter the embryo through the anterior wall of the umbilicus and pass upwards and forwards to open into the tubular heart, which is, for a time, suspended along its entire length, from the ventral aspect of the fore-gut, by a dorsal mesentery (dorsal mesocardium) (fig. 183). By the absorption of the middle part of this dorsal mesocardium the great transverse sinus of the pericardium, behind the ascending aorta and pulmonary artery, is formed.

In amphibians and birds the pericardium is developed by the fusion of the lateral halves of the cœlom in the middle line beneath the fore-gut, and therefore in these animals there exists, for a period, a ventral mesocardium; but Professor Robinson has shown that the pericardial cavity in mammals is from the first a single cavity, and that there is never at any time a ventral mesocardium.

The mesoderm immediately in front of the umbilicus becomes thickened to form the septum transversum, above which are situated the lateral horns of the pericardial cavity. These assume the form of tubular passages on the sides of the fore-gut, and constitute the communications between the pericardial and peritoneal parts of the cœlom (fig. 183). The lung buds grow out behind the ducts of Cuvier into these passages, and push their way outwards and forwards into the tissue of the septum transversum. The expansion of the pleural cavities therefore takes place in the septum, which by this means is differentiated into the central part of the Diaphragm and the posterior wall of the pericardium. The anterior limit of the septum transversum is indicated by the Cuvierian ducts (superior venæ cavæ), by the growth of which the passages between the pericardium and pleuræ are closed.

Development of the Alimentary Canal.—As already indicated (page 87), the primitive alimentary canal is formed, at an early stage, by the enclosure within the embryo of a portion of the blastodermic vesicle, and is seen to consist of

FIG. 165.—Diagrammatic outline of a longitudinal vertical section of the chick on the fourth day.

ep. (From Quain's 'Anatomy,' Allen Thomson.)

three parts, viz.: (1) the *fore-gut*, within the cephalic flexure and dorsal to the heart; (2) the *mid-gut*, opening freely into the yolk-sac; and (3) the *hind-gut*, within the caudal flexure. At first the fore-gut and hind-gut end blindly (figs. 165 and 166). The anterior end of the fore-gut is separated from the stomatodœum by the pharyngeal septum; the hind-gut terminates posteriorly in the cloaca which is closed externally by the cloacal membrane. The formation of the mouth, and the subsequent communication between it and the cephalic end of the fore-gut, have already been considered; the manner in which the anus is formed will be discussed presently.

From the fore-gut are developed the pharynx, œsophagus, stomach, and greater part of the duodenum,* and further, as diverticula from the duodenum, the liver and pancreas; from the hind-gut, the rectum (except the anus) and a considerable part of the colon, and as a tubular outgrowth from it the hollow stalk of the allantois; the mid-gut gives origin to the remainder of the alimentary tube.

* The level of the opening of the common bile-duct is sometimes given as the junction of the fore-gut with the mid-gut.

The upper part of the fore-gut becomes dilated to form the pharynx (fig. 167), in relation to which the branchial arches are developed (fig. 122) (see page 101);

FIG. 166.—Diagram of a longitudinal section of a mammalian embryo. Very early. (After Quain.)

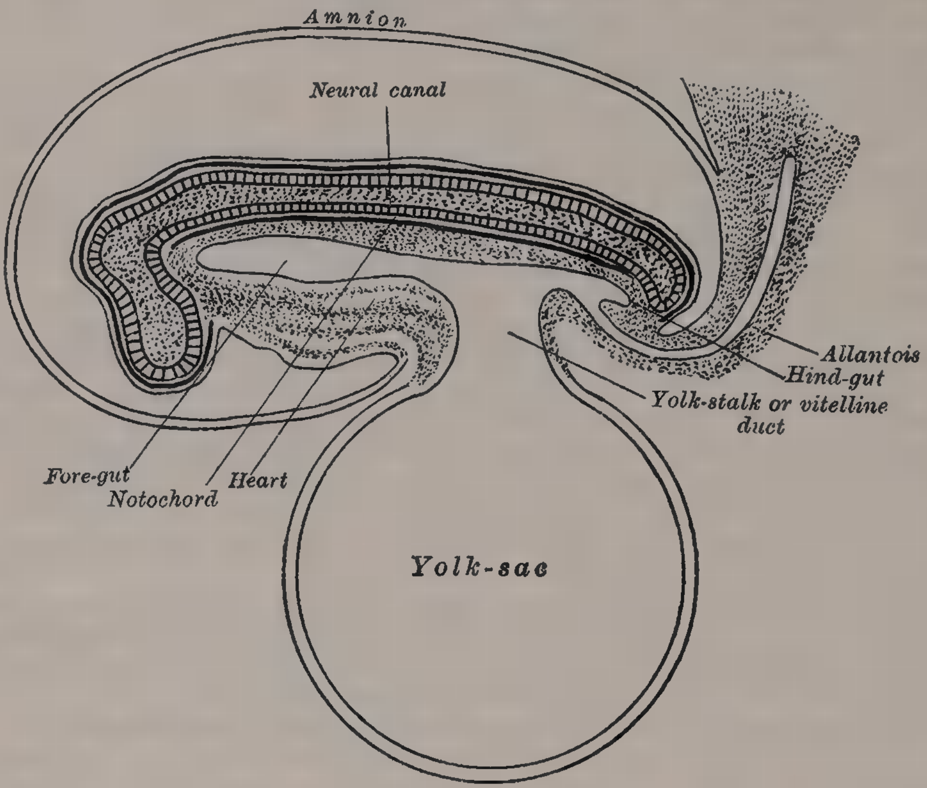

FIG. 167.—Human embryo about fifteen days old. Brain and heart represented from right side. Alimentary canal and yolk-sac in mesial section. (After His.)

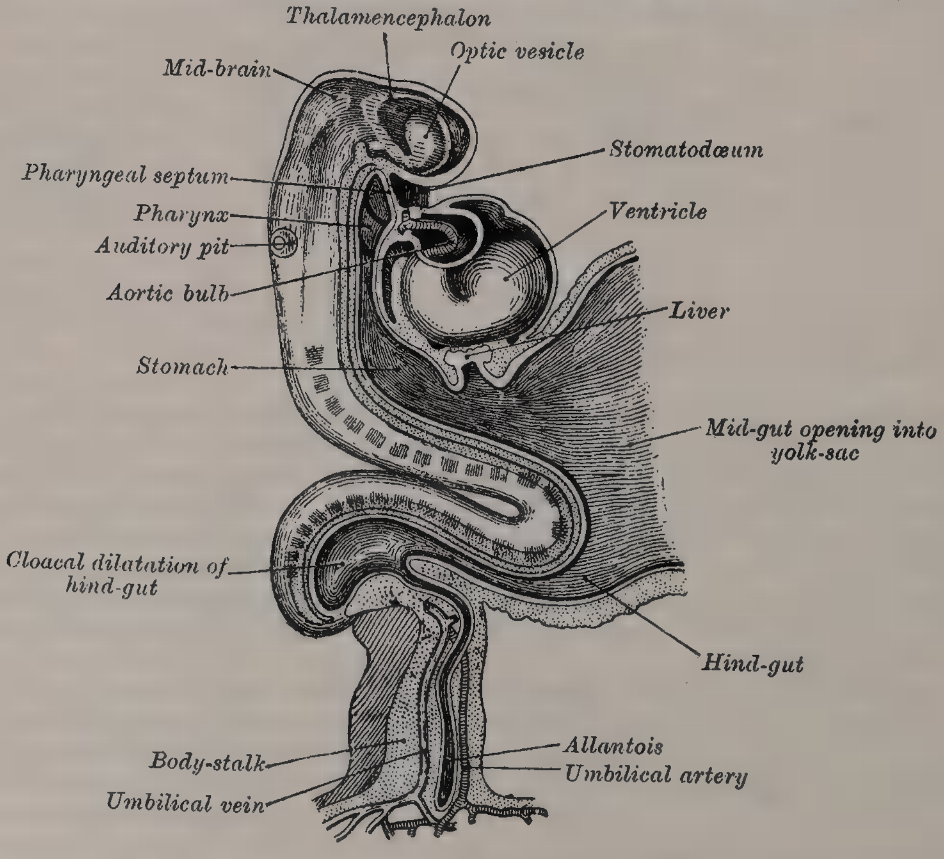
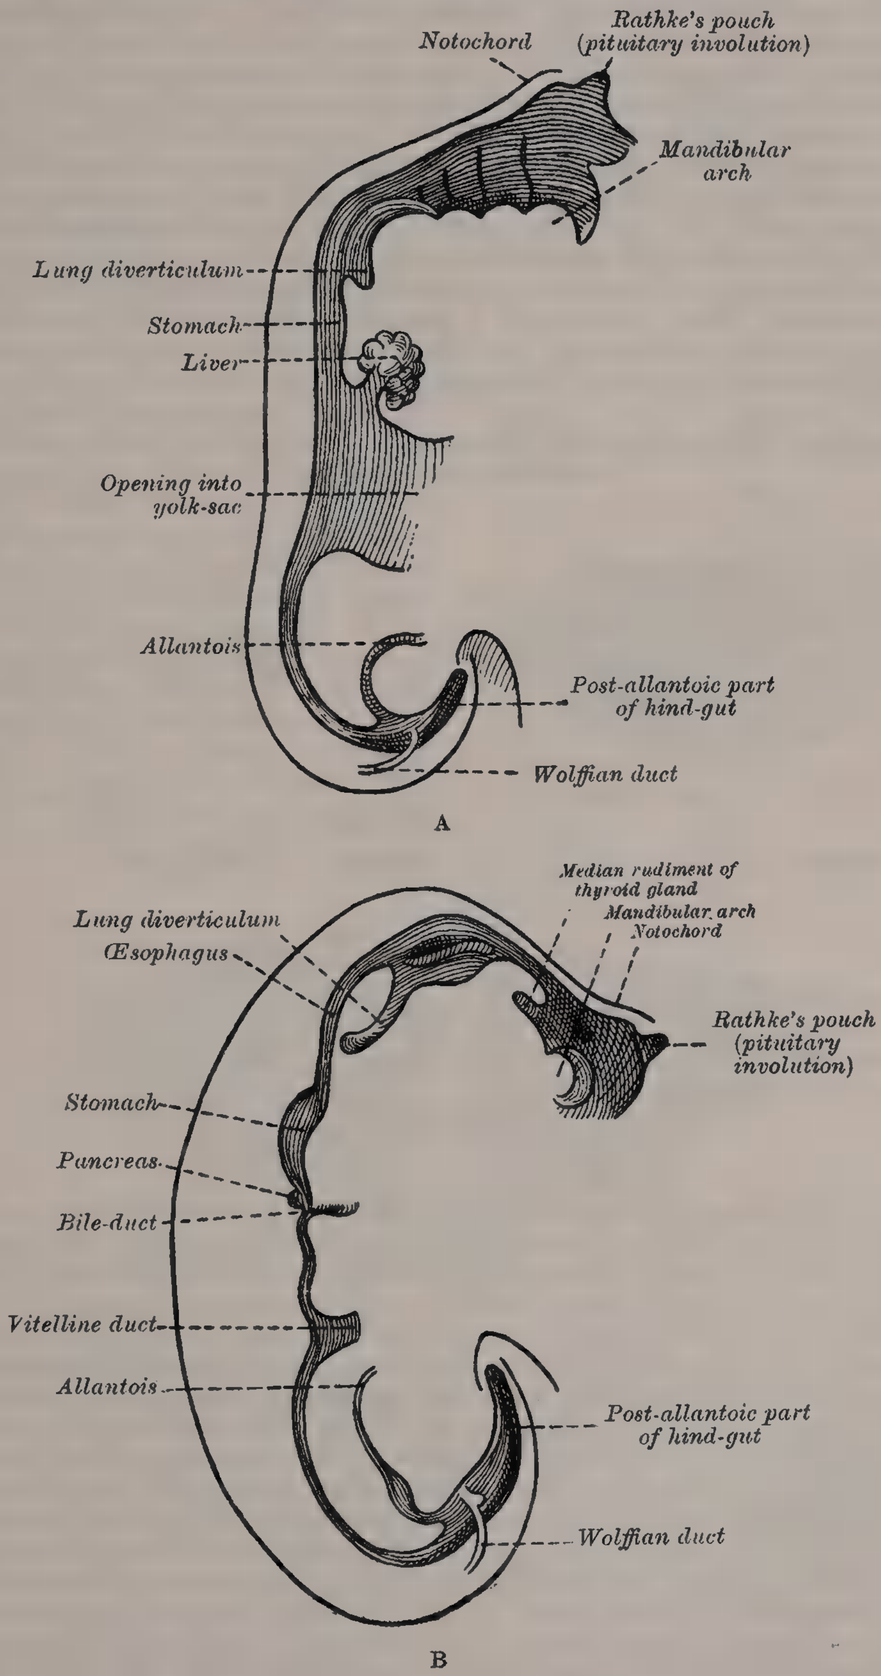


the succeeding part remains tubular, and with the descent of the stomach is elongated to form the œsophagus. About the fourth week a fusiform dilatation,

the future stomach, makes its appearance, and beyond this the mid-gut opens freely into the yolk-sac (figs. 167 and 168). The opening is at first wide, but is

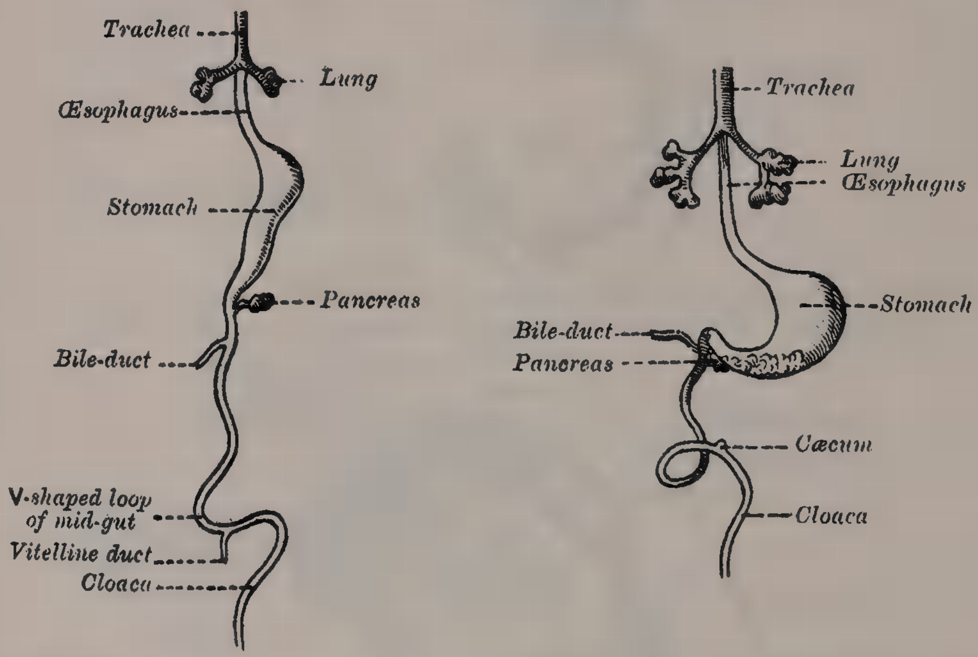
FIG. 168.—Sketches in profile of two stages in the development of the human alimentary canal. (His.) Fig. A × 30. Fig. B × 20.



gradually narrowed into a tubular stalk, the *yolk-stalk* or *vitelline duct*. The proximal part of this duct persists in a small percentage of subjects and constitutes *Meckel's diverticulum*, which is found about three or four feet above the

ileo-cæcal valve. At this stage, therefore, the alimentary canal forms a nearly straight tube in front of the notochord and primitive aortæ (fig. 166). From the stomach to the rectum it is attached to the notochord by a band of mesoderm, from which the common mesentery of the gut is subsequently developed. The stomach undergoes a further dilatation, and its two curvatures can be recognised (figs. 168, B, and 172), the greater directed towards the vertebral column and the lesser towards the anterior wall of the abdomen, while its two surfaces look to the right and left respectively. The mid-gut also undergoes great elongation, and forms a V-shaped loop which projects downwards and forwards; from the bend or angle of the loop the vitelline duct passes to the umbilicus (fig. 172). For a time a part of the loop extends beyond the abdominal cavity into the umbilical cord, but by the end of the third month this is withdrawn. With the lengthening of the tube, the mesoderm, which attaches it to the future vertebral column and which carries the blood-vessels for the supply of the gut, is thinned and drawn out to form the *posterior common mesentery*. The portion of this mesentery which is attached to the greater curvature of the stomach is named the *dorsal mesogastrium*, and the parts which suspend the colon and rectum are respectively termed the *mesocolon* and *mesorectum* (fig. 172). About

Fig. 169.—Front view of two successive stages in the development of the alimentary canal. (His.)



the sixth week a lateral diverticulum makes its appearance a short distance behind the opening of the vitelline duct, and indicates the future cæcum and appendix. The part of the loop on the distal side of the cæcal diverticulum becomes increased in diameter, and forms the future ascending and transverse portions of the large intestine. Until the third month the cæcal diverticulum has a uniform calibre, but from this time onwards its most dependent part remains rudimentary and forms the vermiform appendix, while its upper part is expanded to form the cæcum. Changes also take place in the shape and position of the stomach. Its dorsal part or greater curvature, to which the dorsal mesogastrium is attached, grows much more rapidly than its ventral part or lesser curvature. Further, the greater curvature is carried downwards and to the left, so that the right surface of the stomach is now directed backwards and the left surface forwards—a change in position which explains why the left vagus nerve is found on the front of the stomach and the right vagus on the back of it. The dorsal mesogastrium being attached to the greater curvature must necessarily follow its movements, and hence it becomes greatly elongated and drawn outwards from the vertebral column, and, like the stomach, what was originally its right surface is now directed backwards and its left forwards. In this way a pouch, the *bursa omentalis*, is formed behind the stomach; this pouch is the future lesser sac of the

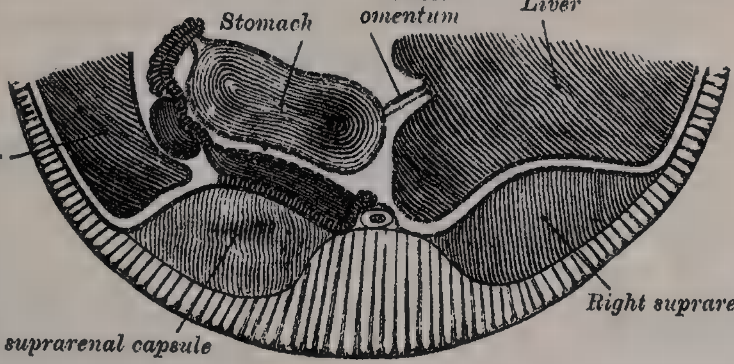
peritoneum, and it increases in size as the alimentary tube undergoes further development; the entrance to the pouch constitutes the future *foramen of Winslow* (figs. 173, 176). The duodenum is developed from that part of the tube which immediately succeeds the stomach. This undergoes little elongation, being more or less fixed in position by the liver and pancreas, which arise as diverticula from it. The duodenum is at first suspended by a mesentery, and projects forwards in the form of a loop. The loop and its mesentery are subsequently displaced by the transverse colon, so that the right surface of the duodenal mesentery is directed backwards, and, adhering to the parietal peritoneum, is lost. The remainder of the canal becomes greatly elongated, and as a consequence the tube is coiled on itself, and this elongation demands a corresponding increase in the width of the intestinal attachment of the mesentery, which becomes plaited or folded.

At this stage the small and large intestine are attached to the vertebral column by a common mesentery, the coils of the small intestine falling to the right of the middle line, while the large intestine lies on the left side.*

The gut is now rotated upon itself, so that the large intestine is carried over in front of the small intestine, and the cæcum is placed immediately below the liver; about the sixth month the cæcum descends into the right iliac fossa, and the large intestine forms an arch consisting of the ascending, transverse, and descending portions of the colon—the transverse portion crossing in front of the duodenum and lying just below the greater curvature of the stomach; within this arch the coils of the small intestine are disposed (figs. 173, 177). Sometimes the downward progress of the cæcum is arrested, so that in the adult it may be found lying immediately below the liver instead of in the right iliac region.

FIG. 170.—Schematic and enlarged cross section through the body of a human embryo in the region of the mesogastrium. Beginning of third month. (Toldt.)

FIG. 171.—Same section as in fig. 170, at end of third month. (Toldt.)



Further changes take place in the bursa omentalis and in the common mesentery, and give rise to the peritoneal relations seen in the adult. The bursa omentalis, which at first reaches only as far as the greater curvature of the stomach, grows downwards to form the great omentum, and this downward extension lies in front of the transverse colon and the coils of the small intestine. The anterior layer of the transverse mesocolon is at first quite distinct from the posterior layer of the great omentum, but ultimately the two blend, and hence the great omentum appears as if attached to the transverse colon (fig. 174). The

* Sometimes this condition persists throughout life, and it is then found that the duodenum does not cross from the right to the left side of the vertebral column, but lies entirely on the right side of the mesial plane, where it is continued into the jejunum; the arteries to the small intestine (rami intestini tenuis) also arise from the right instead of the left side of the superior mesenteric artery.

mesenteries of the ascending and descending parts of the colon disappear in the majority of cases, while that of the small intestine assumes the oblique attachment characteristic of its adult condition.

Fig. 172.—Abdominal part of alimentary canal and its attachment to the primitive or common mesentery. Human embryo of six weeks. (After Toldt.) (From Kollmann's 'Entwickelungsgeschichte.')

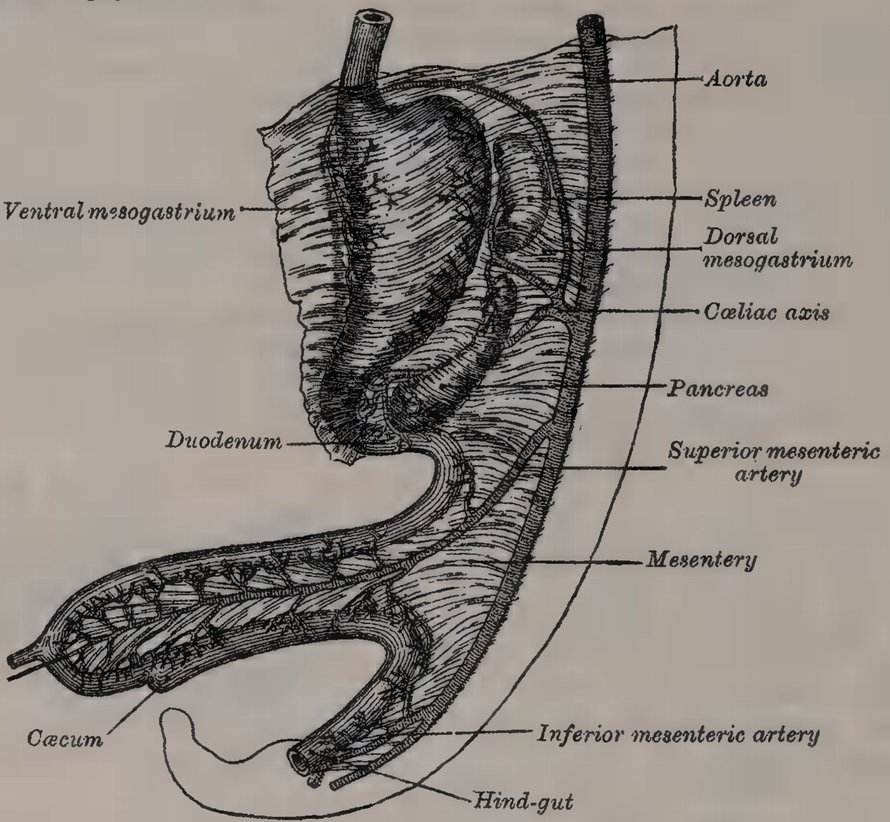


Fig. 173.—Diagrams to illustrate two stages in the development of the human alimentary canal and its mesentery. The arrow indicates the entrance to the bursa omentalis.

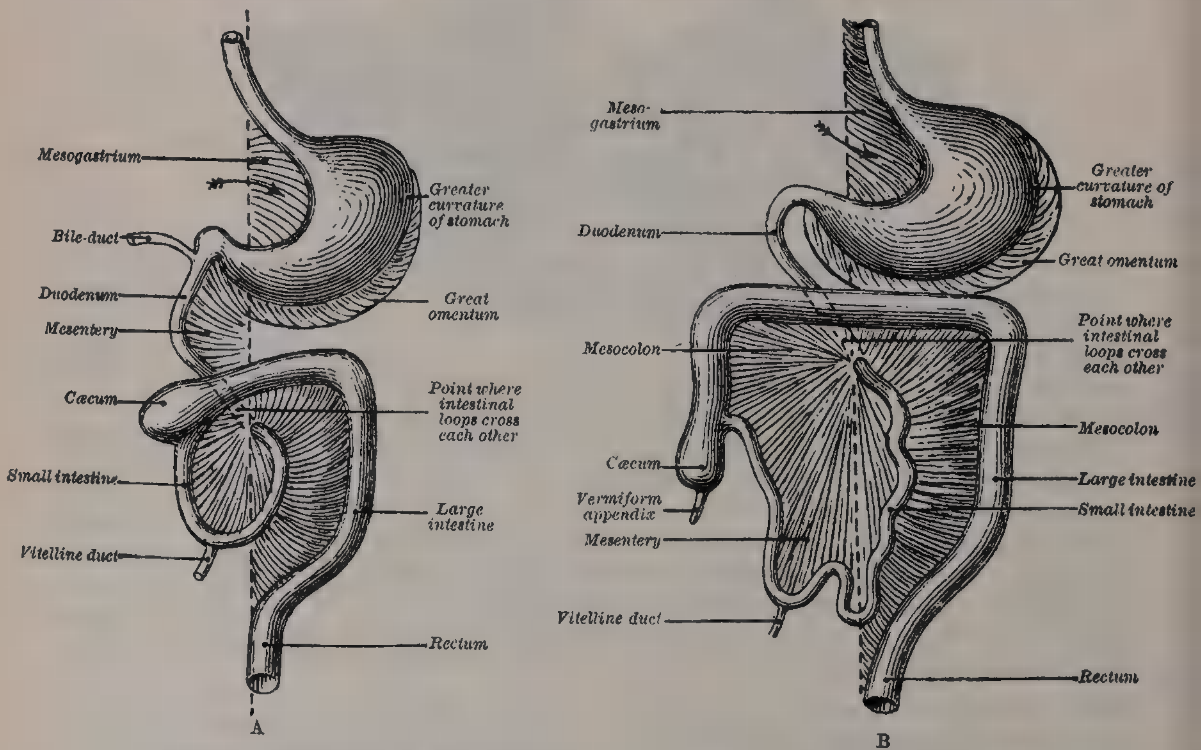
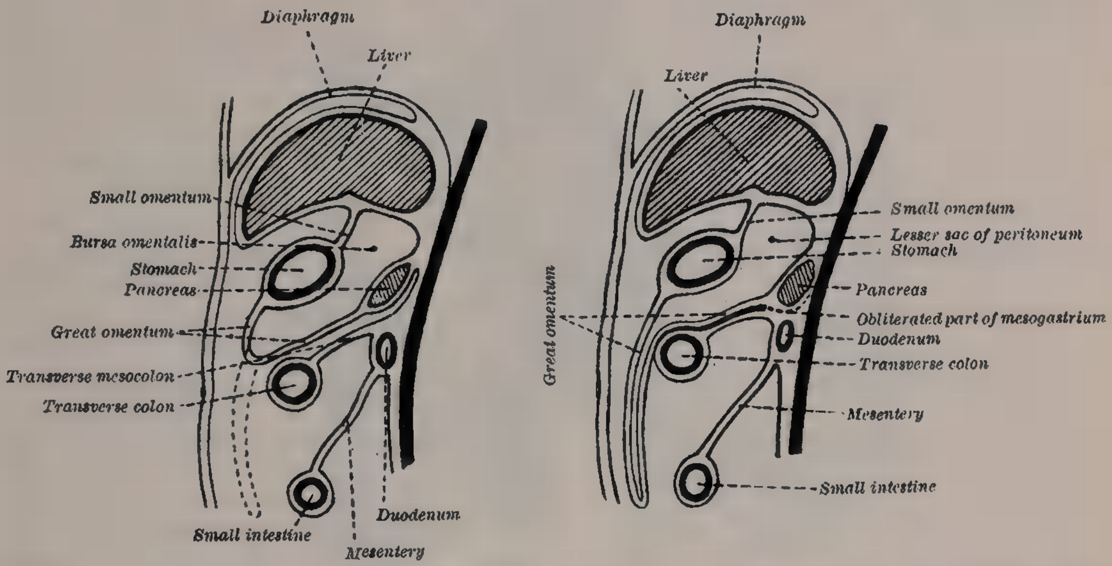


The small omentum is formed by a thinning of the mesoderm or *ventral mesogastrium*, which attaches the stomach and duodenum to the anterior

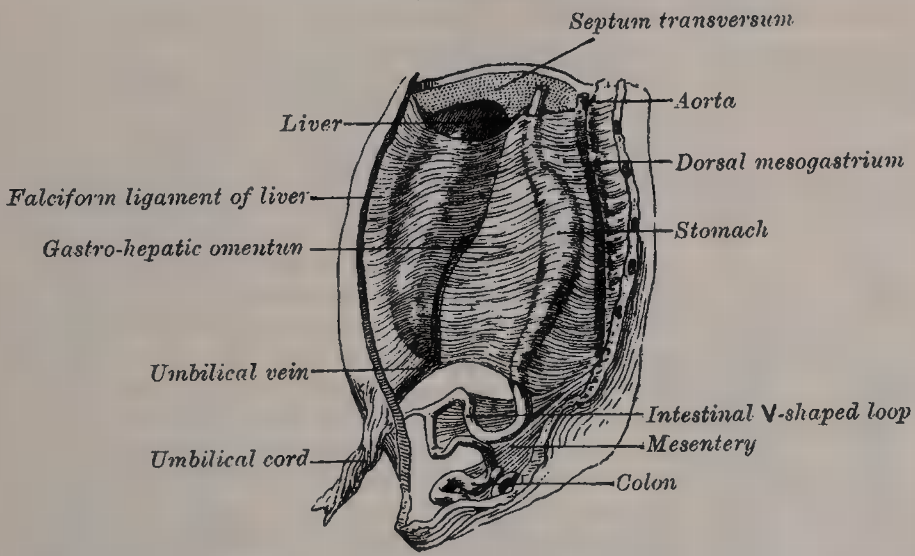
abdominal wall. By the subsequent growth of the liver this leaf of mesoderm is divided into two parts, viz.: the small omentum between the stomach and liver,

FIG. 174.—Diagrams to illustrate the development of the great omentum and transverse mesocolon.



and the falciform ligament between the liver and the abdominal wall and Diaphragm (fig. 175).

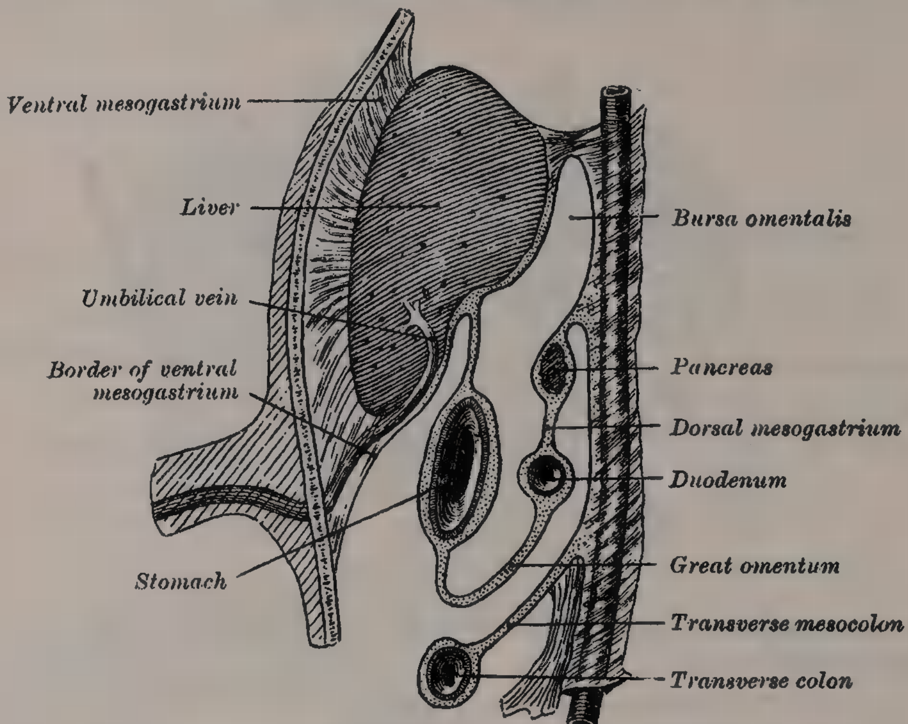
FIG. 175.—The primitive mesentery of a six weeks' human embryo, half schematic. (Kollmann.)



Formation of the rectum and anus.—The hind-gut is at first prolonged backwards into the body-stalk as the tube of the allantois; but, with the growth and flexure of the tail-end of the embryo, the body-stalk, with its contained allantoic tube, is carried forwards to the ventral aspect of the body, and consequently a bend is formed at the junction of the hind-gut and allantois. This bend becomes dilated into a pouch, which constitutes the *entodermal cloaca*; into its dorsal part the hind-gut opens, and from its ventral part the allantois passes forwards. At a later stage the Wolffian and Müllerian ducts also open into its ventral portion. The cloaca is, for a time, shut off from the exterior by a membrane, the *cloacal membrane*, formed by the apposition of the ectoderm and entoderm, and reaching, at first, as far forwards as the future umbilicus. Behind the latter, however, the mesoderm subsequently extends inwards to form the lower part of the abdominal wall and symphysis pubis. By the growth of the surrounding tissues the cloacal membrane comes to lie at the bottom of a depression which is lined by ectoderm and named the *ectodermal cloaca*.

The entodermal cloaca is divided into a dorsal and a ventral part by means of a partition consisting of two lateral septa which grow inwards and unite with

FIG. 176.—Schematic figure of the bursa omentalis, &c. Human embryo of eight weeks. (Kollmann.)



each other in the middle line—the fusion of the septa taking place from before backwards. The dorsal part forms the rectum, and the anterior part the urogenital sinus and bladder. By the rupture of the cloacal membrane the cloacal canal, opening on the exterior, is formed, thus giving rise to a condition which exists permanently in the reptile, bird, and monotreme. Into this cloacal channel the urine, the fæces, and the products of the genital organs are discharged. The communication of the rectum with the cloaca is obliterated by the inward growth of two eminences, which make their appearance one on either side of the cloaca. These join in the middle line to form the perineal septum, and also fuse with the hinder edge of the septum which separates the urogenital sinus and bladder from the rectum. The permanent anus is not developed from the cloacal opening of the hind-gut, but is formed by an invagination of the ectoderm behind the perineal septum. This invagination is termed the *proctodæum*, and it meets with the ventral aspect of the hind-gut and forms with it the *anal membrane*. By the absorption of this membrane the anus is formed. A small part of the hind-gut projects backwards beyond the anal orifice; this portion is named the post-anal gut, and usually becomes obliterated and disappears.*

F. Wood-Jones † gives a different account from

FIG. 177.—Final disposition of the intestines and their vascular relations. (Jonnesco.)

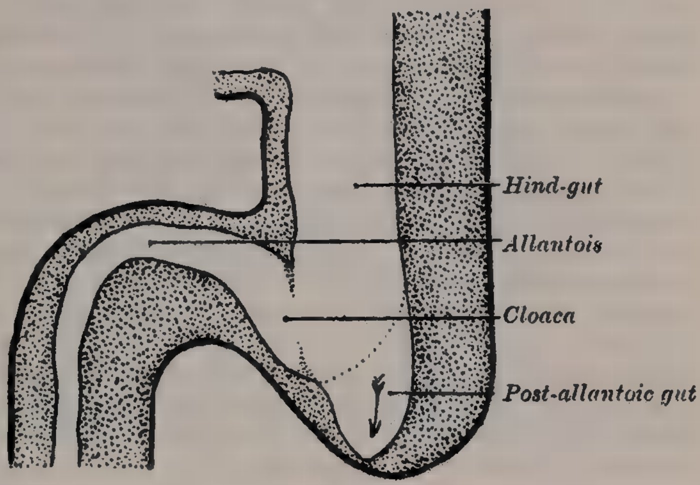
A. Aorta. *H.* Hepatic artery. *S.* Splenic artery. *M, Col.* Branches of superior mesenteric artery. *m, m'.* Branches of inferior mesenteric artery.

* Consult, in this connection, the following article: 'A Contribution to the Morphology of the Human Urino-genital Tract,' by D. Berry Hart, M.D., F.R.C.P.E. *Journal of Anatomy and Physiology*, April 1901, vol. xxxv.

† 'The Nature of the Malformations of the Rectum and Urogenital Passages,' by F. Wood-Jones, M.B., B.Sc., M.R.C.S. *British Medical Journal*, December 17, 1904.

the above as to the manner in which the rectum is separated from the cloaca. He maintains that the growth of the hind-gut keeps pace with that of the hind-end of the embryo, and 'buds backwards past its cloacal orifice, past its old termination in the allantois, and forms the portion of the hind-gut distal to the allantois'; this portion he terms the *post-allantoic gut* (figs. 178, 179, and 186). 'The cloacal opening of the hind-gut is now normally lost; originally a small opening in the embryo of 12 somites (which is about 2 mm. in total length), the rapid growth of the hind-gut, the post-allantoic gut, and of the allantois itself, together with the lateral infolding of the wall described by Keibel, serve to close the opening of the hind-gut into the cloaca.' This view, which affords a satisfactory explanation of the varieties of imperforate rectum and anus which are sometimes found, leads to the conclusion that the cloaca does not contribute to the formation of the rectum, and that the septa which have been described as fusing in the middle line to form the perinæum are non-existent.

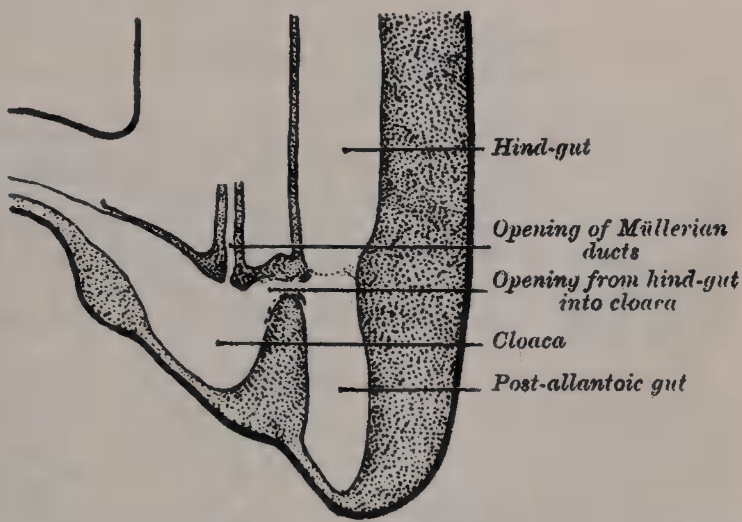
Fig. 178.—Diagram to illustrate the development of the post-allantoic gut. The hind-gut opens freely into the cloaca. (After Wood-Jones.)



The peritoneal cavity is formed by the abdominal portion of the cœlom, which becomes separated from the thoracic portion by the development of the Diaphragm.

The *liver* arises in the form of a diverticulum or hollow outgrowth from the ventral surface of the duodenum (figs. 167, 168, and 183). This diverticulum is lined by entoderm, and grows upwards and forwards into the septum transversum, and there gives off two solid buds of cells which represent the right and the left lobes of the liver. The solid buds of cells grow into columns or cylinders, termed the *hepatic cylinders*, which branch and anastomose to form a close meshwork. This network invades the vitelline and umbilical veins, and breaks up these vessels into a series of capillaries, which ramify in the meshes of the cellular network and ultimately form the venous capillaries of the liver. By the continued growth and ramification of the hepatic cylinders the mass of the liver is gradually formed. The original diverticulum from the duodenum forms the common bile-duct, and from this the cystic duct and gall-bladder arise as a hollow evagination.

Fig. 179.—Diagram to illustrate the further development of the post-allantoic gut. The hind-gut still opens into the cloaca. The opening of the Müllerian ducts is also seen. (After Wood-Jones.)

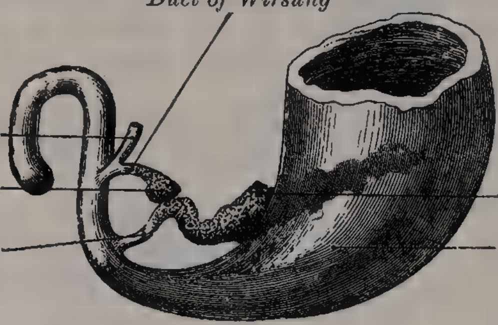


As the liver undergoes enlargement, both it and the ventral mesogastrium of the fore-gut are gradually differentiated from the septum transversum; and from the under surface of the latter the liver projects downwards into the abdominal

cavity. By the growth of the liver the ventral mesogastrium is divided into two parts, of which the anterior forms the falciform ligament, and the posterior the gastro-hepatic omentum. About the third month the liver almost fills the abdominal cavity. From this period the relative development of the liver is less active, more especially that of the left lobe, which now becomes smaller than the right; but up to the end of fœtal life the liver remains relatively larger than in the adult.

The pancreas.—During the fourth week the pancreas arises as two hollow buds, a larger dorsal and a smaller ventral bud (fig. 180). The former springs as a diverticulum from the dorsal aspect of the duodenum, a short distance above the hepatic diverticulum, and, growing upwards and backwards into the dorsal mesogastrium, forms the main part of the pancreas. The ventral part grows into the ventral mesogastrium and gives origin to the lower part of the head of the gland. It arises as an evagination from the commencement of the hepatic diverticulum, and thus, from the first, the duct of this part of the gland opens into the duodenum through an orifice common to it and the bile-duct. By the seventh week the dorsal and ventral parts have become united and their ducts communicate with each other. From this time onward the duct of the ventral part of the gland increases greatly in size, and forms the continuation of the main duct (canal of Wirsung). On the other hand, that portion of the duct of the dorsal part of the gland which extends from the point of union of the two ducts to the duodenum undergoes little enlargement, and forms the duct of Santorini, which opens about three-quarters of an inch above the orifice of the common bile-duct. The opening of the duct of Santorini into the duodenum is

Fig. 180.—The rudiments of the pancreas in a six weeks' human embryo. (After Hamburger.) (From Kollmann's 'Entwickelungsgeschichte.')



sometimes obliterated, and even if it remains patent the secretion of the dorsal part of the gland is mostly conveyed through the duct of the ventral part of the gland.

At first the pancreas is directed upwards and backwards between the two layers of the dorsal mesogastrium, which give to it a complete peritoneal investment, and its surfaces look to the right and left. With the change in the position of the stomach the dorsal mesogastrium is drawn downwards and to the left, and the right side of the pancreas is directed backwards and the left forwards. The right surface becomes applied to the posterior abdominal wall, and the peritoneum, which covered it, undergoes absorption; and thus, in the adult, the gland appears to lie behind the peritoneal cavity.

The spleen (fig. 172).—Although the spleen belongs to the group of ductless glands, its development may be conveniently referred to here. It appears in the second month as a localised thickening of the mesoderm in the dorsal mesogastrium above the tail of the pancreas. It grows towards the left side of the dorsal mesogastrium, and thus comes into contact with the right surface of the stomach. With the change in position of this viscus the spleen is carried to the left, and comes to lie behind the cardiac part of the stomach and in contact with the left kidney. The part of the dorsal mesogastrium which intervened between the spleen and the greater curvature of the stomach forms the gastro-splenic omentum.

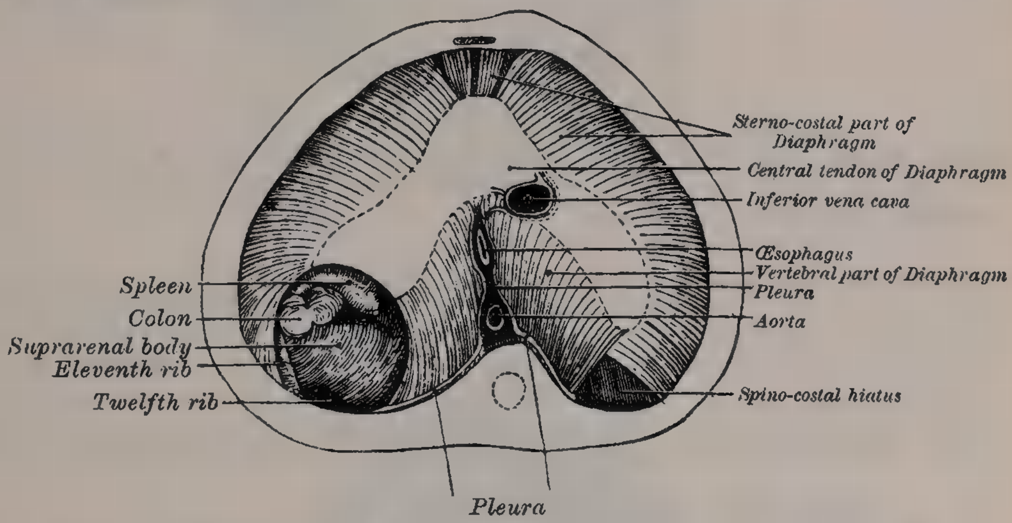
Development of the Respiratory Organs.—Towards the end of the third week a deep longitudinal furrow (figs. 126 and 127) appears in the ventral wall of the fore-gut, commencing at the level of the fourth visceral arch and reaching backwards nearly as far as the stomach. It is bounded in front by an elevation

termed the *furcula*, and laterally by two ridges. By the union of the posterior parts of the two ridges the groove is converted into a tube-like diverticulum, which is lined by entoderm and which grows backwards on the ventral aspect of the œsophagus. The upper end of this diverticulum is expanded to form the larynx; the furcula is the future epiglottis, and the upper parts of the lateral ridges constitute the aryteno-epiglottidean folds. The thyroid cartilage is developed from the cartilages of the fourth and fifth visceral arches, while that of the sixth visceral arch appears to be modified to form the cricoid and arytenoid cartilages and the cartilages of the trachea.

The lower end of the tube-like diverticulum bifurcates into a larger right and a smaller left bud, the *right* and *left lung buds*, and each of these is further subdivided—the right into three and the left into two parts; these subdivisions are the early indications of the corresponding lobes of the lungs (figs. 122 and 169). These lung buds undergo further subdivision and ramification, and ultimately end in minute expanded extremities—the infundibula of the lung. After the sixth month the air-vesicles begin to make their appearance on the infundibula in the form of minute pouches.

Development of the Diaphragm (figs. 181 and 182). The following description is based on that given by Keith.* The *central tendon* of the Diaphragm is

FIG. 181.—The thoracic aspect of the Diaphragm of a newly born child in which the communication between the peritoneum and pleura has not been closed on the left side; the position of the opening is marked on the right side by the spino-costal hiatus. (After Keith.)



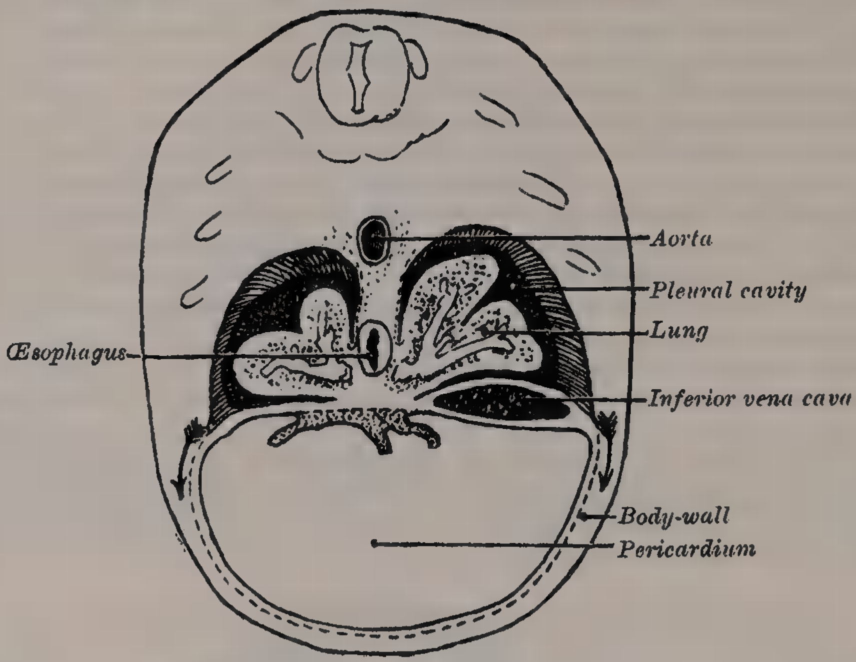
derived from the septum transversum; each half of its muscular portion is developed in two parts, viz.: (*a*) a *sterno-costal* portion, which is derived from the ventral longitudinal musculature of the embryonic neck; and (*b*) a *spinal or vertebral* portion, which arises from the bodies of the vertebræ and arcuate ligaments, and is derived from the cervical part of the transversalis muscle. The pleuro-peritoneal opening is closed by the approximation of the sterno-costal and vertebral parts; and the spino-costal fibrous hiatus, best seen on the left half of the Diaphragm, marks its position after closure. Sometimes the opening remains patent, giving rise to a congenital diaphragmatic hernia.

The formation or separation of the Diaphragm—for at first it forms part of the wall of the body-cavity—results from the development of the pleural cavities and lungs. The lung buds appear in the cervical region of the embryo, and they, together with the parts of the cœlom in which they are contained, undergo a rapid development, growing forwards and outwards into the tissue of the dorsal part of the septum transversum and of the body-wall; within that tissue the pleural cavities are excavated. The pleural cavities also develop within the body-wall towards the ventral median line, thus separating the pericardium from the thoracic wall (see arrows in fig. 182). In this manner the

* *Human Embryology and Morphology*, by Arthur Keith, M.D., F.R.C.S., 2nd edition, 1904. Consult also an article on the development of the Diaphragm, by the same author, in vol.xxxix. of the *Journal of Anatomy and Physiology*.

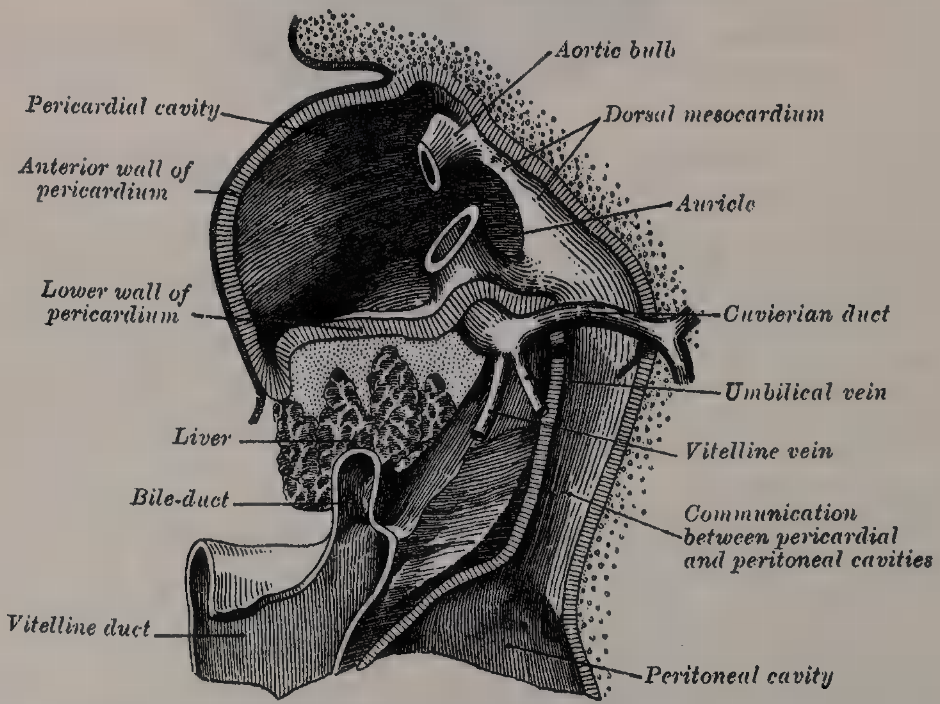
pleural cavities are excavated within the body-wall, dorsal to and on each side of the pericardium. The formation of the pleural cavities not only separates the pericardium from the body-wall, but also an inner layer from the ventro-lateral

Fig. 182.—Diagram of transverse section through rabbit embryo. (After Keith.)



aspect of the body-wall which forms the sterno-costal part of the Diaphragm, and also an inner layer from the dorsal aspect of the body-wall to form the vertebral part of the Diaphragm.

Fig. 183.—Liver with the septum transversum. Human embryo 3 mm. long. × 16. (After model and figure by His.)

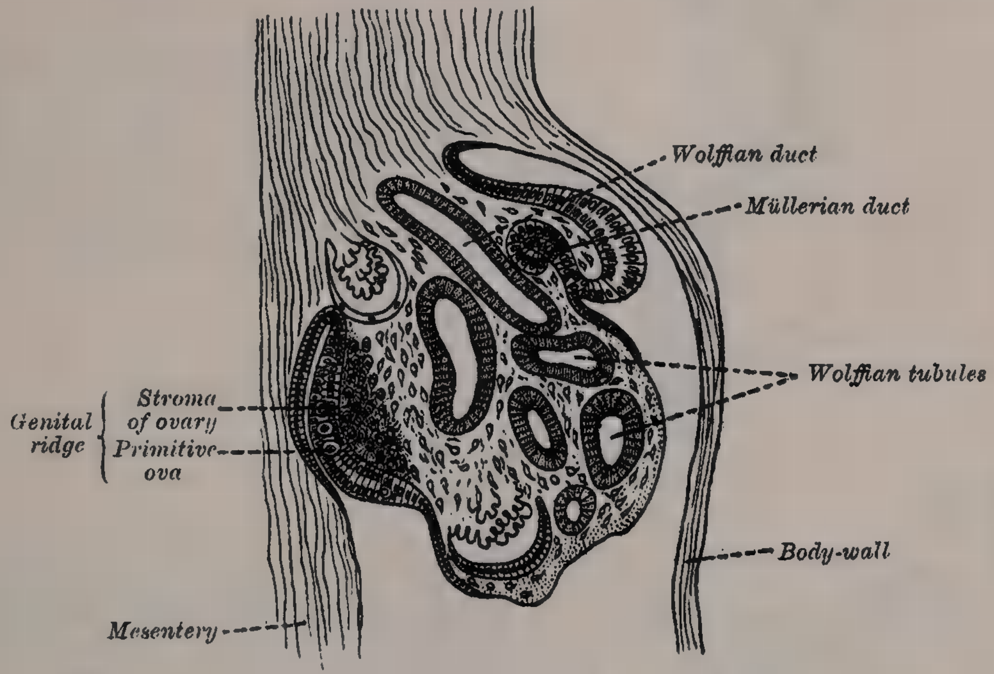


Development of the Urinary and Generative Organs.—The urinary and generative organs are developed from the intermediate cell-mass which is situated between the protovertebral somites and the lateral plates of mesoderm.

Wolffian ducts and Wolffian bodies.—In the outer part of the intermediate cell-mass, immediately under the ectoderm, a longitudinal cord of cells makes its

appearance. This cellular cord sinks into the subjacent mesoderm, and, acquiring a lumen, constitutes the *Wolffian duct*,* which passes backwards and opens into the urogenital sinus. On the inner side of this duct a series of tubules, the *Wolffian tubules*, are developed. Each tubule opens externally into the Wolffian duct, while its opposite end is invaginated by a tuft of capillary blood-vessels to form a glomerulus. These tubules increase in number, and collectively constitute

FIG. 184.—Section of the urogenital area of a chick embryo of the fourth day. (Waldeyer.)



the *Wolffian body* or *mesonephros* (fig. 185). At the beginning of the second month this body forms an elongated spindle-shaped structure, which projects into the cœlomic cavity on either side of the dorsal mesentery and reaches from the septum transversum in front to the fifth lumbar somite behind. The Wolffian body persists and forms the permanent kidney in fishes and amphibians, but in reptiles, birds, and mammals it is superseded by the *metanephros*, which forms

FIG. 185.—Enlarged view from the front of the left Wolffian body before the establishment of the distinction of sex. (From Farre, after Kobelt.)

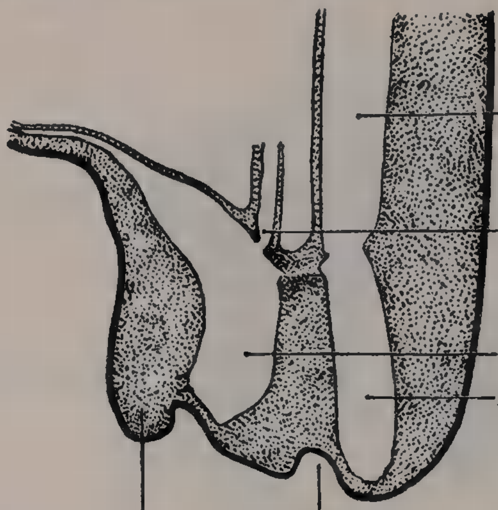
a, a, b, c, d. Tubular structure of the Wolffian body. *e.* Wolffian duct. *f.* Its upper extremity. *g.* Its termination in *x*, the urogenital sinus. *h.* The duct of Müller. *i.* Its upper, funnel-shaped extremity. *k.* Its lower end, terminating in the urogenital sinus. *l.* The genital ridge, ovary or testicle.

the permanent kidney in these animals. The anterior tubules of the Wolffian body become attached to the sexual eminence or genital ridge from which the ovary in the female, and the testicle in the male, are developed. Coincident with the development of the permanent kidneys, the Wolffian bodies atrophy, and this process proceeds to a much greater extent in the female than in the male.

* The Wolffian duct is by many embryologists regarded as being of ectodermal origin, formed by a longitudinal invagination of the ectoderm which overlies the intermediate cell-mass.

The pronephros.—In front of the Wolffian body there are developed a number of tubules which form the *pronephros* or *head-kidney*—an early embryonic structure in all vertebrates. This consists of a series of transverse tubules which open into a duct termed the *pronephric duct*; this duct is continuous posteriorly with the Wolffian duct. Each pronephric tubule communicates by means of a funnel-shaped, ciliated opening with the cœlomic cavity, and in the course of each duct

FIG. 186.—Diagram to illustrate the separation of the hind-gut from the cloaca. The hind-gut has now lost its cloacal opening. The post-allantoic gut is about to meet the proctodœal depression. (After Wood-Jones.)



a glomerulus is also developed. The pronephros undergoes rapid atrophy and practically disappears. In the female the remains of it are probably represented by the hydatids of Morgagni at the fimbriated end of the Fallopian tube; in the male, by the stalked hydatid at the upper end of the testicle.

In the male the Wolffian duct persists, and forms the tube of the epididymis, the vas deferens, and common ejaculatory duct, while the seminal vesicle arises

FIG. 187.—Diagram to illustrate the formation of the vagina, bladder, and urethra. The Müllerian ducts have lost their opening into the urogenital sinus, and the new solid vagina has grown down and later becomes canalised. (After Wood-Jones.)

as a lateral diverticulum from its hinder end. The anterior Wolffian tubules form the rete testis, vasa efferentia, and coni vasculosi of the testicle; while the posterior tubules are represented by the vasa aberrantia of the globus minor, and by the organ of Giraldès, which is sometimes found in front of the spermatic cord above the globus major (fig. 188, c).

FIG. 188.—Diagrams to show the development of male and female generative organs from a common type. (Allen Thomson.)

In the female the Wolffian bodies and ducts become atrophied. The remains of the Wolffian tubules are represented by the epoöphoron or organ of Rosenmüller, and by the paroöphoron, two small collections of rudimentary, blind tubules which are situated in the mesosalpinx. The lower part of the Wolffian duct disappears, while the upper part persists as the functionless duct of Gärtner * (figs. 188, B, and 190).

The permanent kidney, or metanephros.—The rudiments of the permanent kidneys make their appearance about the end of the first month. Each arises as a diverticulum from the hind-end of the Wolffian duct, close to where the latter opens into the urogenital sinus. This diverticulum grows upwards and forwards into the posterior part of the intermediate cell-mass, where its blind or anterior extremity becomes dilated and subsequently divides into several buds, which form the rudiments of the pelvis and calyces of the kidney. By further subdivision it gives rise to the collecting tubules of the kidney; whether the secretory tubules are developed from the renal diverticulum or from the surrounding mesoderm is not as yet determined. The mesoderm around the subdivisions of the diverticulum becomes condensed to form the connective tissue and vessels of the kidney, while the diverticulum is elongated to form the ureter, the posterior extremity of which opens at first into the hind-end of the Wolffian duct; after the sixth week, it separates from the Wolffian duct and opens independently into the part of the cloaca which ultimately becomes the bladder. The manner in which this separation is brought about is not fully known.†

The secretory tubules of the kidney become arranged into pyramidal masses or lobules, and the lobulated condition of the kidney exists for some time after birth, while traces of it may even be found in the adult. The kidney of the ox and many other animals remains lobulated throughout life.

The Müllerian ducts.—Shortly after the formation of the Wolffian ducts a second pair of ducts is developed; these are named the *Müllerian ducts*. Each arises on the outer aspect of the corresponding Wolffian body as a tubular invagination of the cells lining the cœlom (fig. 184). The orifice of the invagination remains patent, and undergoes enlargement and modification to form the abdominal ostium of the Fallopian tube. The ducts pass backwards on the outer aspects of the Wolffian bodies, but towards the posterior end of the embryo they cross to the inner side of the Wolffian ducts, and thus come to lie side by side between and behind the latter—the four ducts forming what is termed the *genital cord*.

Ultimately, the Müllerian ducts open into the urogenital sinus between the orifices of the Wolffian ducts, and terminate on an elevation named the *Müllerian eminence*. Berry Hart describes them as ending blindly on this eminence.

In the male the Müllerian ducts atrophy, but a trace of their anterior ends is represented by the sessile hydatids of the epididymis, while their terminal fused portions form the uterus masculinus or sinus pocularis in the floor of the prostatic portion of the urethra (fig. 188, C).

In the female the Müllerian ducts persist and undergo further development.

* Berry Hart (*op. cit.*) has described the Wolffian ducts as ending at the site of the future hymen in bulbous enlargements, which he has named the *Wolffian bulbs*; and states that the hymen is formed by these bulbs, 'aided by a special involution from below of the cells lining the urogenital sinus.' He further believes that 'the lower third of the vagina is due to the coalescence of the upper portion of the urogenital sinus and the lower ends of the Wolffian ducts,' and 'that the epithelial lining of the vagina is derived from the Wolffian bulbs.' He also regards the colliculus seminalis of the male urethra as being formed from the lower part of the Wolffian ducts.

† The separation of the ureter from the Wolffian duct may be brought about by the absorption of the hinder end of the latter into the genito-urinary chamber, and by the growth of the wall of this chamber between the openings. Robinson (*Proceedings of the Anatomical Society of Great Britain and Ireland*, May 1903, page lxiii) states, regarding an embryo of about seven weeks, that 'from the posterior or lower opening of the Wolffian duct a grooved ridge, the *Wolffian ledge*, runs caudally on the wall of the genito-urinary chamber and gradually disappears at the junction of the Wolffian angle with the body of the chamber. The lateral margins of the groove are continuous anteriorly with the lateral margins of the Wolffian duct, and apparently fuse together to form the ventral wall of the lower part of the duct. . . . Obviously, if the lateral margins of the groove were to fuse from before backwards, the aperture of the Wolffian duct would be carried further backward in the chamber, and its distance from the opening of the ureter increased.'

The portions which lie in the genital cord fuse to form the uterus and vagina; the parts in front of this cord remain separate, and each forms the corresponding Fallopian tube—the abdominal ostium of which is developed from the anterior extremity of the original tubular invagination from the cœlom. The fusion of the Müllerian ducts begins in the third month, and the septum formed by their fused mesial walls disappears from below upwards, and thus the cavities of the vagina and uterus are produced. About the fifth month an annular constriction marks the position of the neck of the uterus, and after the sixth month the walls of the uterus begin to thicken. The development of the vagina in the manner just described would necessitate the growth of a septum between it and the urethra; but Wood-Jones (*op. cit.*) maintains that no such septum exists, and that 'the vagina is, for a great part of fœtal life, a solid rod, and not an open canal at all' (fig. 187). He says: 'Early in the history of the embryo the Müllerian ducts open into the urogenital sinus at its upper part (fig. 186); late in its history they open at the hind-end of the vagina, and for a considerable interval they have no opening at all—the old one being lost and the new one not yet formed. No septal division is employed in this change; but as the hind-gut, when its cloacal opening is lost, re-establishes communication with the exterior by a new downgrowth, so the Müllerian ducts, when their cloacal opening becomes obliterated, tunnel a new passage to the hind-end. The active agents in this strange growth are two epithelial masses that have been described by Berry Hart as the Wolffian bulbs, but to give this name to them is to give a definite idea as to their origin, and this seems to be by no means clear.'

The urethra.—In the female the urethra is formed from the upper part of the urogenital sinus, viz. that part which lies above the openings of the Wolffian and Müllerian ducts. The portion of the sinus below these openings becomes gradually shortened, and is ultimately opened out to form the vestibule, and in this manner the urethra and vagina come to open separately on the surface. Wood-Jones regards the female urethra as 'the cloacal remnant in its simplest form,' and points out that it does not remain tubular throughout fœtal life, but is for a time 'obliterated more or less completely by the proliferation of the vaginal bulbs.' Developmentally considered, the male urethra consists of three parts: 1. The prostatic and membranous portions, which are derived from the urogenital sinus. 2. The penile portion as far as the base of the glans penis, which is formed by the fusion from behind forwards, in the middle line, of the inner genital folds. This fusion is apparently at first solid, but the epidermis extends backwards along the line of union, and by central desquamation forms the lumen of the urethra. 3. The part contained within the glans penis; this is formed by the ingrowth and subsequent central desquamation of a solid plug of epidermis which perforates the glans and meets the canal behind (Berry Hart).

The union of the inner genital folds may be arrested at any stage of their growth, giving rise to partial or complete hypospadias.

The *prostate gland* originally consists of two separate portions, each of which arises as a series of diverticular buds from the epithelial lining of the urogenital sinus, and which appear between the third and fourth months. These buds become tubular, and form the glandular substance of the two lobes, which ultimately meet and fuse behind the urethra and also extend on to its ventral aspect. The third or middle lobe is formed as an extension of the lateral lobes between the common ejaculatory ducts and the bladder. Skene's ducts in the female urethra are regarded as the analogues of the male prostatic glands.

The glands of Cowper in the male, and of Bartholin in the female, also arise as diverticula from the epithelial lining of the urogenital sinus.

The urinary bladder.—The trigone of the bladder is formed from the upper part of the urogenital sinus; the remainder of the hollow viscus being developed from the part of the cloaca which lies above the sinus. The allantois extends from the summit of the bladder to the umbilicus, and usually undergoes complete obliteration to form the fibrous cord of the urachus. In some cases, however, the allantoic canal remains patent, and urine may escape by it at the umbilicus. If the urethra is looked upon as the remnant of the cloaca, then the bladder, with the exception of the trigone, must be regarded as being developed by a dilatation of the proximal part of the allantois.

Ovaries and Testicles.—The first appearance of the ovaries and testicles is essentially the same in the two sexes, and consists in a thickening of the epithelial

layer which lines the peritoneal or body cavity on the inner side of the Wolffian ridge. Beneath this thickened epithelium an increase in the mesoblast takes place, forming a distinct projection. This is termed the *genital ridge* (fig. 184), and from it the testicle in the male, and the ovary in the female, are developed. At first the Wolffian body and genital ridge are suspended by a common mesentery, but as the embryo grows the genital ridge gradually becomes pinched off from the Wolffian body, with which it is at first continuous, though it still remains connected to the remnant of this body by a fold of peritoneum, the *mesorchium* or *mesovarium.* About the seventh week the distinction of sex in the genital ridge begins to be perceptible.

The *ovary,* thus formed from the genital ridge, consists of a central part of connective tissue covered by a layer of epithelium, the *germinal epithelium.* Between the cells of the germinal epithelium a number of larger cells, the *primitive ova,* are found, and these are carried into the subjacent stroma by budlike ingrowths of the germinal epithelium, the cells of which surround the primitive

FIG. 189.—Section of the ovary of a newly born child. (Waldeyer.)

ova; and in this manner the primitive Graafian follicles are formed. The remains of the germinal epithelium on the surface of the ovary form the permanent epithelial covering of this organ. According to Beard the primitive ova are early set apart during the segmentation of the ovum and migrate into the germinal ridge.

Waldeyer taught, and for many years his views have been accepted, that the primitive germ-cells were derived from the 'germinal epithelium' covering the genital ridge. Beard,* on the other hand, maintains that in the skate they are not derived from this epithelium, but are probably formed during the later stages of cell-cleavage, before there is any trace of an embryo; and a similar view was advanced by Nussbaum as to their origin in amphibia. Beard says: 'At the close of segmentation many of the future germ-cells lie in the segmentation cavity just beneath the site of the future embryo, and there is no doubt they subsequently wander into it.' The germ-cells, 'after they enter the resting phase, are sharply marked off from the cells of the embryo by entire absence of mitoses among them.' They can be further recognised by their irregular form and amœboid-like processes, and by the fact that their cytoplasm has no affinity for ordinary stains, but assumes a brownish tinge when treated by osmic acid. The path along which they travel into the embryo is a very definite one—viz. 'from the yolk-sac upwards between the splanchnopleure and gut in the hinder portion of the embryo.' This pathway, named by Beard the *germinal path,* 'leads them directly to the position which they ought finally to take up in the "germinal ridge" or nidus.' A considerable number apparently never reach their proper destination, since 'vagrant germ-cells are found in all sorts of places, but more particularly on the mesentery.' Some of these may possibly find their way into the germinal ridge; some probably undergo atrophy, while others may persist and become the seat of dermoid tumours.

* *Journal of Anatomy and Physiology,* vol. xxxviii.

The *testicle* is developed in a very similar way to the ovary. Like the ovary, in its earliest stages it consists of a central mass of connective tissue covered by germinal epithelium, among which larger cells, the *primitive sperm-cells*, are seen. These are carried into the subjacent stroma by tubes of germinal epithelium, which form the lining of the seminiferous tubules, while the primitive sperm-cells form the spermatogonia. The seminiferous tubules become connected with outgrowths from the Wolffian body, which, as before mentioned, form the rete testis and vasa efferentia.

The development of the other parts of the internal male and female organs has already been described.

Descent of the Testes.—The testes, at an early period of fœtal life, are placed at the back part of the abdominal cavity, behind the peritoneum and a little below the kidneys. The anterior surface and sides are invested by peritoneum. At about the third month of intra-uterine life a peculiar structure, the *gubernaculum testis*, makes its appearance. This structure is at first a slender band, extending from that part of the skin of the groin which afterwards forms the scrotum through the inguinal canal to the body and epididymis of the testicle, and is then continued upwards in front of the kidney towards the Diaphragm. As development advances, the peritoneum covering the testicle

FIG. 190.—Adult ovary, parovarium, and Fallopian tube. (From Farre, after Kobelt.)

a, a. Epoöphoron formed from the upper part of the Wolffian body. *b.* Remains of the uppermost tubes sometimes forming hydatids. *c.* Middle set of tubes. *d.* Some lower atrophied tubes. *e.* Atrophied remains of the Wolffian duct. *f.* The terminal bulb or hydatid. *h.* The Fallopian tube, originally the duct of Müller. *i.* Hydatid attached to the extremity. *l.* The ovary.

encloses it and forms a mesentery, the *mesorchium*, which also encloses the gubernaculum and forms two folds, one above the testicle and the other below it. The one above the testicle is the *plica vascularis*, and contains ultimately the spermatic vessels; the one below, the *plica gubernatrix*, contains the lower part of the gubernaculum, which has now grown into a thick cord; it terminates below at the internal ring in a tube of peritoneum, the processus vaginalis, which protrudes itself down the inguinal canal. The lower part of the gubernaculum by the fifth month has become a thick cord, while the upper part has disappeared. The lower part can now be seen to consist of a central core of unstriped muscle-fibre, and outside this of a firm layer of striped elements, connected, behind the peritoneum, with the abdominal wall. As the scrotum develops, the lower end of the gubernaculum is carried with the skin to which it is attached to the bottom of this pouch. The fold of peritoneum, constituting the processus vaginalis, projects itself downwards into the inguinal canal, and emerges at the external abdominal ring, pushing before it a part of the internal oblique muscle and the aponeurosis of the external oblique, which form respectively the cremaster muscle and the external spermatic fascia. It forms a gradually elongating depression or *cul-de-sac*, which eventually reaches the bottom of the scrotum, and into this the testicle is drawn by the growth of the body of the fœtus, for the gubernaculum does not grow commensurately with the growth of other parts, and therefore the testicle, being attached by the gubernaculum to the

bottom of the scrotum, is prevented from rising as the body grows, and is drawn first into the inguinal canal and eventually into the scrotum. It seems certain also that the gubernacular cord becomes shortened as development proceeds, and this assists in causing the testicle to reach the bottom of the scrotum. By the eighth month the testicle has reached the scrotum, preceded by the lengthened pouch of peritoneum, the processus vaginalis, which communicates by its upper extremity with the peritoneal cavity. Just before birth the upper part of the pouch usually becomes closed, and this obliteration extends gradually downwards to within a short distance of the testis. The process of peritoneum surrounding the testis, which is now entirely cut off from the general peritoneal cavity, constitutes the *tunica vaginalis*.*

In the female there is also a gubernaculum, which effects a considerable change in the position of the ovary, though not so extensive a change as that of the testicle in the male. The gubernaculum in the female, as it lies on either side in contact with the fundus of the uterus formed by the union of the Müllerian ducts, contracts adhesions to this organ, and thus the ovary is prevented from descending below this level. The remains of the gubernaculum—that is to say, the part below the attachment of the cord to the uterus to its termination in the labia majora—ultimately forms the round ligament of the uterus. A pouch of peritoneum accompanies it along the inguinal canal, analogous to the processus vaginalis in the male: it is called the *canal of Nuck*. In rare cases the gubernaculum may fail to contract adhesions to the uterus, and then the ovary descends through the inguinal canal into the labia majora, extending down the canal of Nuck, and under these circumstances resembles in position the testicle in the male.

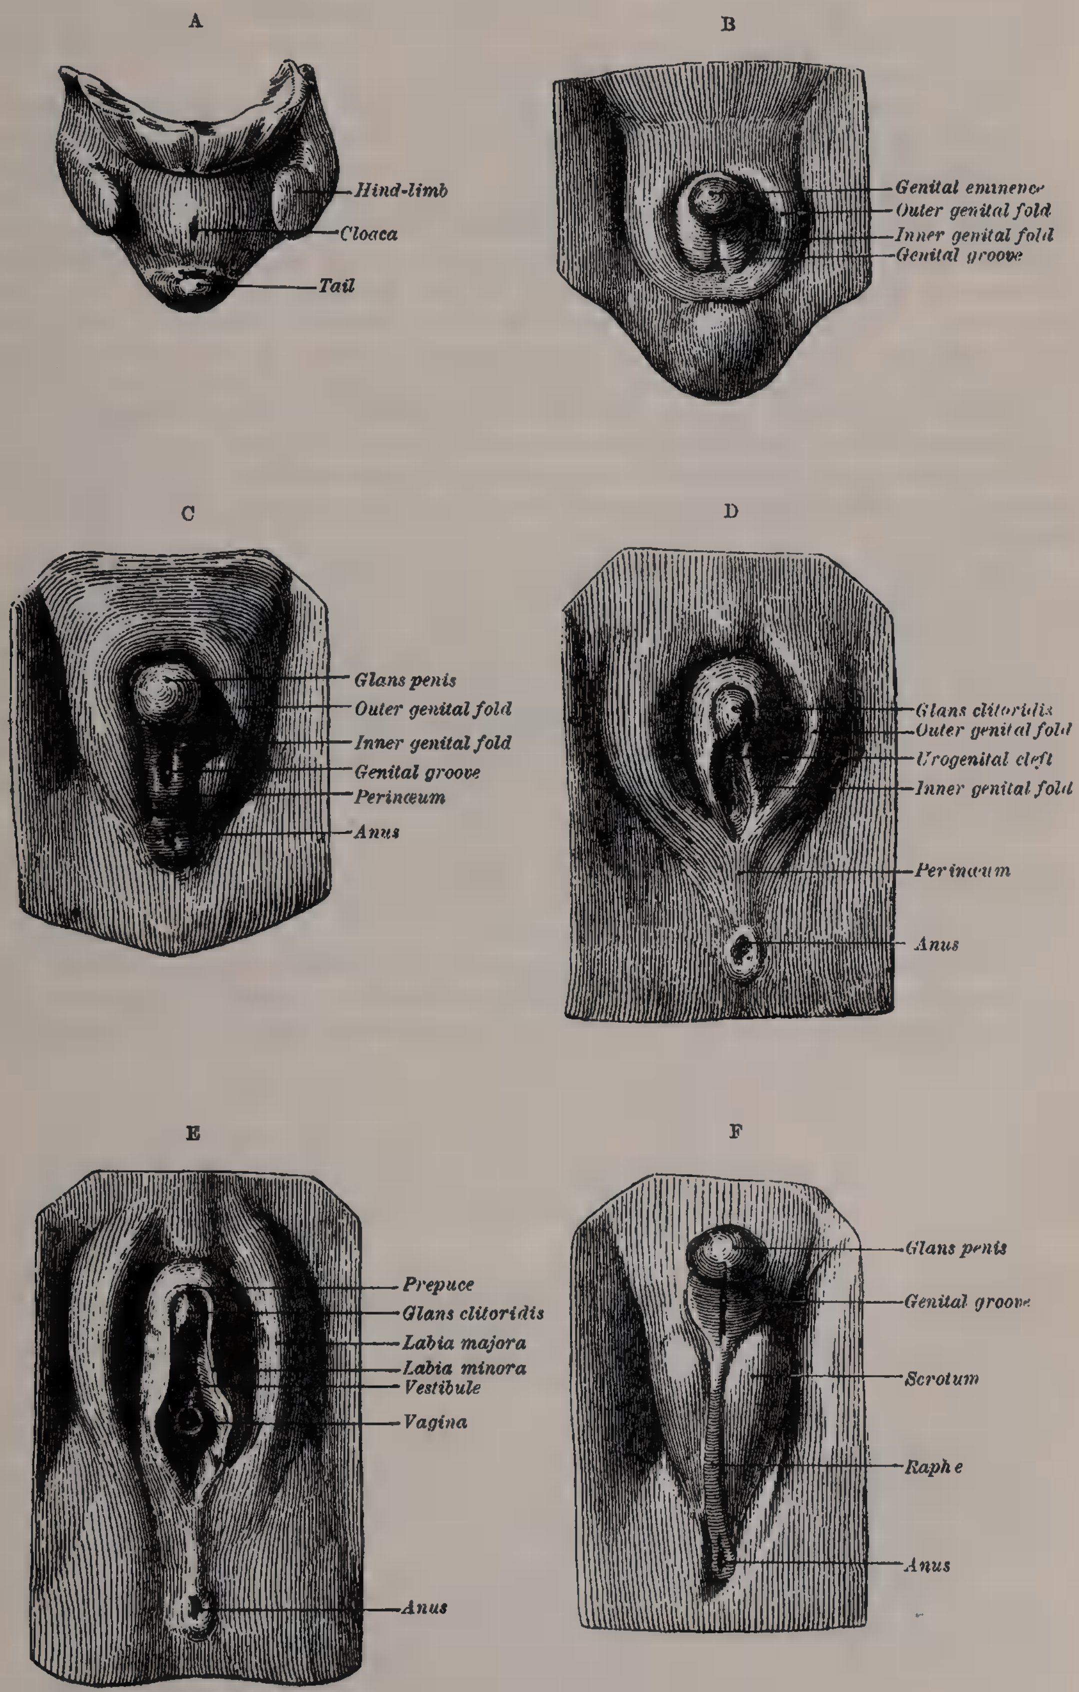
Surgical Anatomy.—Abnormalities in the formation and in the descent of the testicle may occur. The testicle may fail to be developed: or the testicle may be fully developed, and the vas deferens may be undeveloped in whole or part; or again, both testicle and vas deferens may be fully developed, but the duct may not become connected to the gland. The testicle may fail in its descent, or it may descend into some abnormal position. Thus it may be retained in the position where it was primarily developed, below the kidney; or it may descend to the internal abdominal ring, but fail to pass through this opening; it may be retained in the inguinal canal, which is perhaps the most common position; or it may pass through the external abdominal ring and remain just outside it, failing to pass to the bottom of the scrotum. On the other hand, it may get into some abnormal position: it may pass the scrotum and reach the perinæum, or it may fail to enter the inguinal canal, and may find its way through the femoral ring into the crural canal, and present itself on the thigh at the saphenous opening. There is still a third class of cases of abnormality of the testicle, where the organ has descended in due course into the scrotum, but is malplaced. The most common form of this is where the testicle is *inverted*: that is to say, the organ is rotated so that the epididymis is connected to the front of the scrotum, and the body, surrounded by the tunica vaginalis, is directed backwards. In these cases the vas deferens is to be felt in the front of the cord. The condition is of importance in connection with hydrocele and hæmatocele, and the position of the testicle should always be carefully ascertained before performing any operation for these affections. Again, more rarely, the testicle may be *reversed*. This is a condition in which the top of the testicle, indicated by the globus major of the epididymis, is at the bottom of the scrotum, and the vas deferens comes off from the summit of the organ. Cases sometimes occur, generally in the young adult, in which the spermatic cord becomes twisted. In consequence of this the circulation through it is partially or completely arrested; if the latter, the testicle becomes gangrenous; if the former, it may undergo atrophy.

The **external organs of generation** (fig. 191), like the internal, pass through a stage in which there is no distinction of sex. It is therefore necessary to describe this stage, and then follow the development of the female and male organs respectively.

In front of the cloacal membrane an elevation appears during the sixth week. This is named the *genital eminence*, and represents the rudiment of the penis or clitoris. It is bounded laterally and below by two prominent folds, termed the *external genital folds*. By the growth of the surrounding parts the ectodermal cloaca assumes the form of a cleft, the *urogenital cleft*, into which the urogenital sinus opens after the disappearance of the cloacal membrane; the

* The obliteration of the process of peritoneum which accompanies the cord, and is hence called the *funicular process*, is often incomplete. See section on Inguinal Hernia.

FIG. 191.—Stages in the development of the external sexual organs in the male and female. (Drawn from the Ecker-Ziegler models.)



margins of the cleft constitute the *inner genital folds*. On the lower aspect of the genital eminence there is seen a furrow or groove, the *genital groove*, which is continuous behind with the urogenital fissure. All these parts are well developed by the second month, yet no distinction of sex is possible.

Female Organs.—The female organs are developed by an easy transition from the above. The lower part of the urogenital sinus persists as the vestibule of the vagina and the urethra. The genital eminence forms the clitoris, the external genital folds the labia majora, and the inner genital folds the labia minora and the prepuce and frænum of the clitoris.

Male Organs.—In the male the changes are greater. The genital eminence is developed into the glans and corpora cavernosa of the penis, the glans appearing in the third month, and the corpora cavernosa in the fourth. The genital groove closes and thus forms the spongy portion of the urethra (see page 151). The bulb and corpus spongiosum of the urethra are formed by the fusion of the inner genital folds. The prepuce is generally described as growing forward from the root of the glans penis, its inner surface at first adhering to the glans and then becoming free. It is formed, however, by the epidermis passing in round the glans, so that on coronal section the epidermis presents a horse-shoe arrangement. By the breaking down of the more centrally situated cells of this epidermal invagination the prepuce becomes movable. 'Adherent prepuce is not an adhesion really, but a hindered central desquamation' (Berry Hart, *op. cit.*). The external genital folds unite in the middle line to form the scrotum, at about the same time as the genital groove closes—viz. between the third and fourth month.

The *suprarenal bodies* are developed from two different sources. The medullary part of the organ is of epiblastic origin, and is derived from the tissues forming the sympathetic ganglia of the abdomen, while the cortical portion is of mesoblastic origin, and originates as an outgrowth from the upper part of the Wolffian body. The two parts are at first quite distinct, but become combined in the process of development. The suprarenal bodies are at first larger than the kidneys; about the tenth week they equal them in size, and from that time decrease relatively to the kidney, though they remain, throughout fœtal life, proportionately much larger than in the adult.

The following table is translated from the work of Beaunis and Bouchard, with some alterations, especially in the earlier weeks. It will serve to present a *résumé* of the above facts in an easily accessible form.*

* It will be noticed that the time assigned in this table for the appearance of the first rudiment of some of the bones varies in some cases from that assigned in the description of the various bones. This is a point on which anatomists differ, and which probably varies in different cases.

CHRONOLOGICAL TABLE

OF

THE DEVELOPMENT OF THE FŒTUS

(MODIFIED FROM BEAUNIS AND BOUCHARD)

First Week.—During the early part of this period the ovum is in the Fallopian tube. Having been fertilised in the upper part of the tube, it slowly passes down, undergoing segmentation, and reaches the uterus before the end of the first week. In Peter's specimen, the age of which was probably from five to six days, the ovum was found embedded in the decidua on the posterior wall of the uterus and enveloped by a decidua reflexa, the central part of which, however, consisted merely of a layer of fibrin. The ovum was in the form of a sac, the outer wall of which consisted of a layer of trophoblast; inside this was a thin layer of mesoderm composed of round, oval, and spindle-shaped cells. Numerous villous processes—some consisting of trophoblast only, others possessing a core of mesoderm—projected from the surface of the ovum into the surrounding decidua. Inside this sac the rudiment of the embryo was found in the form of a patch of ectoderm, covered by a small but completely closed amnion. It possessed a minute yolk-sac and was surrounded by mesoderm, which was connected by a band to that lining the trophoblast.

Second Week.—By the end of this week the ovum has increased considerably in size, and the decidua reflexa forms a complete fold over it. Its villi consist of a syncytial layer, together with the layer of Langhans, and the majority of them are vascularised. The embryo has assumed a definite form : its cephalic and caudal extremities are easily distinguished and are folded towards the yolk-sac. The primitive groove and streak are evident—the former terminating anteriorly in the neurenteric canal. The neural groove and ridges have appeared, and the rudiment of the notochord is being differentiated from the entoderm. The embryo is more completely separated from the yolk-sac; the rudimentary heart has made its appearance; the allantoic diverticulum extends into the body-stalk; all three layers of the blastoderm are present, and the paraxial mesoderm is being segmented into the protovertebral somites.

Third Week.—By the end of the third week the flexures of the embryo have taken place, so that it is strongly curved. The protovertebral somites number about thirty. In the nervous system the primary divisions of the brain are visible, and the primitive ocular and auditory vesicles are already formed. The primary circulation is established. The alimentary canal presents a nearly straight tube communicating with the yolk-sac. The branchial arches are formed and the bucco-pharyngeal membrane has disappeared. The limbs have appeared as short buds. The Wolffian bodies are visible.

Fourth Week.—The umbilical vesicle has attained its full development. The caudal extremity projects. The upper and the lower limbs appear. The heart separates into a right and left heart. The special ganglia and anterior roots of the spinal nerves, the olfactory fossæ, the lungs and the pancreas can be made out. The cerebral hemispheres appear as hollow buds, and the ganglia of some of the cranial nerves are visible.

Fifth Week.—The allantois is vascular in its whole extent. The first traces of the hands and feet can be seen. The aortic bulb divides into aorta and pulmonary artery. The duct of Müller and genital gland are visible. The ossification of the clavicle and the lower jaw commences. The cartilage of Meckel occupies the first post-oral arch. The tubercles which form the rudiment of the pinna are visible. The rudiment of the penis or clitoris, in the form of the genital tubercle, is present.

Sixth Week.—The activity of the umbilical vesicle ceases. The pharyngeal clefts disappear. The vertebral column, primitive cranium, and ribs assume the cartilaginous condition. The posterior roots of the nerves, the membranes of the nervous centres, the bladder, kidney, tongue, larynx, thyroid body, and the germs of teeth are apparent.

Seventh Week.—The muscles begin to be perceptible. The points of ossification of the ribs, scapula, shaft of humerus, femur, tibia, palate, and upper jaw appear.

Eighth Week.—The distinction of arm and forearm, and of thigh and leg, is apparent, as well as the interdigital clefts. The capsule of the lens and pupillary membrane, the interventricular and commencement of the interauricular septum, the salivary glands, the spleen and suprarenal capsules are distinguishable. The larynx begins to become cartilaginous. All the vertebral bodies are cartilaginous. The points of ossification for the ulna, radius, fibula, and ilium make their appearance. The two halves of the hard palate unite. The sympathetic nerves are now for the first time to be discerned.

Ninth Week.—The corpus striatum and the pericardium are first apparent. The ovary and testicle can be distinguished from each other. The genital furrow appears. The osseous nuclei of the bodies and arches of the vertebræ, of the frontal, vomer, and malar bones, of the shafts of the metacarpal and metatarsal bones, and of the phalanges appear. The union of the hard palate is completed. The gall-bladder is seen.

Third Month.— The formation of the foetal placenta advances rapidly. The projection of the caudal extremity disappears. It is possible to distinguish the male and female organs from each other. The Cloacal aperture is divided into two parts. The cartilaginous arches on the dorsal region of the spine close. The points of ossification for the lachrymal, nasal, squamous portion of temporal and ischium appear, as well as the orbital centre of the superior maxillary. The pons Varolii and fissure of Sylvius can be made out. The eyelids, the hair, and the nails begin to form. The mammary gland, the epiglottis, and prostate are beginning to develop.The union of the testicle with the canals of the Wolffian body takes place. By the end of this month the length of the foetus is about 7 cm., but if the legs be included it is from 9 to 10 cm.

Fourth Month.—The closure of the cartilaginous arches of the spine is complete. Osseous points for the first sacral vertebra and os pubis appear. The ossification of the malleus and incus takes place. The corpus callosum, the membrana lamina spiralis, the cartilage of the Eustachian tube, and the tympanic ring are seen. Fat is first developed in the subcutaneous cellular tissue. The tonsils are seen, and the closure of the genital furrow and the formation of the scrotum and prepuce take place. By the end of the fourth month the fœtus is from 12 to 13 cm. in length, but if the legs be included it is from 16 to 20 cm.

Fifth Month.—The two layers of the decidua begin to coalesce. Osseous nuclei of the axis and odontoid process, of the lateral points of the first sacral vertebra, of the median points of the second, and of the lateral masses of the ethmoid make their appearance. Ossification of the stapes and the petrous bone, and ossification of the germs of the teeth, take place. The germs of the permanent teeth and the organ of Corti appear, The eruption of hair on the head commences. The sudoriferous glands, Brunner's glands, the follicles of the tonsil and base of the tongue, and the lymphatic glands appear at this period. The differentiation between the uterus and vagina becomes apparent. By the end of this month the total length of the fœtus, including the legs, is from 25 to 27 cm.

Sixth Month.—The points of ossification for the anterior root of the transverse process of the seventh cervical vertebra, the lateral points of the second cervical vertebra, the median points of the third, the manubrium sterni and the os calcis appear. The sacro-vertebral angle forms. The cerebral hemispheres cover the cerebellum. The papillæ of the skin, the sebaceous glands, and Peyer's patches make their appearance. The free border of the nail projects from the corium of the dermis. The walls of the uterus thicken. Measured from vertex to heels, the total length of the fœtus at the end of this month is from 30 to 32 cm.

Seventh Month.—The additional points of the first sacral vertebra, the lateral points of the third, the median point of the fourth, the first osseous point of the body of the sternum, and the osseous point for the astragalus appear. Meckel's cartilage disappears. The cerebral convolutions, the island of Reil, and the tubercula quadrigemina are apparent. The pupillary membrane atrophies. The testicle passes into the vaginal process of the peritoneum. From vertex to heels the total length at the end of the seventh month is from 35 to 36 cm., i.e. about 14 in. Its weight is a little over 3 lbs.

Eighth Month.—Additional points for the second sacral vertebra, lateral points for the fourth, and median points for the fifth sacral vertebræ can be seen. The total length, i.e. from head to heels, at the end of the eighth month is about 40 cm. (16 in.), and its weight varies between 4½ and 5½ lbs.

Ninth Month.—Additional points for the third sacral vertebra, lateral points for the fifth, osseous points for the middle turbinated bone, for the body and great cornu of the hyoid, for the second and third pieces of the body of the sternum, and for the lower end of the femur appear. Ossification of the bony lamina spiralis and axis of the cochlea takes place. The eyelids open, and the testicles are in the scrotum. At full time the fœtus weighs from 6½ to 8 lbs., and measures from head to heels about 50 cm. (20 in.).

DESCRIPTIVE AND SURGICAL

ANATOMY

OSTEOLOGY

THE SKELETON

THE term *skeleton*, in its widest application, includes the bones, cartilages, and ligaments of the body; it is, however, generally used to indicate only the bony framework.

The entire skeleton in the adult consists of 200 distinct bones. These are—

The Spine or vertebral column (sacrum and coccyx included) .	26
Cranium	8
Face	14
Hyoid bone, sternum, and ribs	26
Upper extremities	64
Lower extremities	62
	200

In this emuneration the patellæ are included as separate bones, but the smaller sesamoid bones, and the ossicula auditûs, are not reckoned. The teeth belong to the tegumentary system.

These bones are divisible into four classes: *Long*, *Short*, *Flat*, and *Irregular*.

The **Long Bones** are found in the limbs, where they form a system of levers which have to sustain the weight of the trunk, and to confer the power of locomotion. A long bone consists of a shaft and two extremities. The *shaft* is a hollow cylinder, contracted and narrowed to afford greater space for the bellies of the muscles; the walls consist of dense, compact tissue of great thickness in the middle, but becoming thinner towards the extremities; the cancellous tissue is scanty, and the bone is hollowed out in its interior to form the *medullary canal*. The *extremities* are generally somewhat expanded, for greater convenience of mutual connection, for the purposes of articulation, and to afford a broad surface for muscular attachment. Here the bone is made up of cancellous tissue with only a thin coating of compact substance. The medullary canal and the spaces in the cancellous tissue are filled with marrow. The long bones are not straight, but curved; the curve generally taking place in two directions, thus affording greater strength to the bone. The bones belonging to this class are: the *clavicle*, *humerus*, *radius*, *ulna*, *femur*, *tibia*, *fibula*, *metacarpal* and *metatarsal* bones, and the *phalanges*.

Short Bones.—Where a part of the skeleton is intended for strength and compactness, and its motion is at the same time slight and limited, it is divided into a number of small pieces united together by ligaments, and the separate bones are short and compressed, such as those of the *carpus* and *tarsus*. These bones, in their structure, are spongy throughout, excepting at their surface, where there is a thin crust of compact substance. The *patellæ*, together with the other sesamoid bones, are by some regarded as short bones.

Flat Bones.—Where the principal requirement is either extensive protection or the provision of broad surfaces for muscular attachment, the osseous structure

is expanded into broad, flat plates, as in the bones of the skull and the shoulder-blade. These bones are composed of two thin layers of compact tissue enclosing between them a variable quantity of cancellous tissue. In the cranial bones, these layers of compact tissue are familiarly known as the *tables* of the skull; the outer one is thick and tough; the inner one thinner, denser, and more brittle, and hence termed the *vitreous table*. The intervening cancellous tissue is called the *diploë*, and this, in certain regions of the skull, becomes absorbed so as to leave spaces filled with air (*air-sinuses*) between the two tables. The flat bones are: the *occipital, parietal, frontal, nasal, lachrymal, vomer, scapula, os innominatum, sternum, ribs*, and, according to some, the *patella*.

The **Irregular** or **Mixed Bones** are such as, from their peculiar form, cannot be grouped under either of the preceding heads. Their structure is similar to that of other bones, consisting of a layer of compact tissue externally, and of cancellous tissue within. The irregular bones are: the *vertebræ, sacrum, coccyx, temporal, sphenoid, ethmoid, malar, superior maxillary, inferior maxillary, palate, inferior turbinated*, and *hyoid*.

Surfaces of Bones.—If the surface of any bone is examined, certain eminences and depressions are seen, to which descriptive anatomists have given the following names.

These eminences and depressions are of two kinds: *articular* and *non-articular*. Well-marked examples of articular eminences are found in the heads of the humerus and femur; and of articular depressions, in the glenoid cavity of the scapula, and the acetabulum. Non-articular eminences are designated according to their form. Thus, a broad, rough, uneven elevation is called a *tuberosity, protuberance*, or *process*; a small, rough prominence, a *tubercle*; a sharp, slender, pointed eminence, a *spine*; a narrow, rough elevation, running some way along the surface, a *ridge, crest*, or *line*.

The non-articular depressions are also of very variable form, and are described as *fossæ, pits, depressions, grooves, furrows, fissures, notches*, &c. These non-articular eminences and depressions serve to increase the extent of surface for the attachment of ligaments and muscles, and are usually well marked in proportion to the muscularity of the subject.

A prominent process projecting from the surface of a bone, which it has never been separate from or movable upon, is termed an *apophysis* (from ἀπόφυσις, *an excrescence*); but if such process is developed as a separate piece from the rest of the bone, to which it is afterwards joined, it is termed an *epiphysis* (from ἐπίφυσις, *an accretion*). The main part of the bone, or shaft, which is formed from the primary centre of ossification, is termed the *diaphysis*, and is separated, during growth, from the epiphysis by a layer of cartilage, at which growth in length of the bone takes place.

Bones are often traversed by canals or foramina, not only for the entrance of nutrient vessels into their interior, but also for the transmission of vessels and nerves from one part to another.

In describing the various surfaces or aspects of a bone, or indeed of any other structure, the body is supposed to be in the erect position. Any surface, extremity, or other part directed upwards towards the head is termed *superior*, while those directed downwards towards the feet are termed *inferior*. Surfaces directed forwards towards the front of the body are termed *anterior* or *ventral*, while those directed backwards are *posterior* or *dorsal*. Those surfaces which are directed towards a median, antero-posterior, vertical plane are termed *internal* or *mesial*, while those directed away from this plane are *external* or *lateral*.

The minute structure, growth, and composition of bone are described on pages 25 and 28.

THE SPINE

The **Spine** is a flexuous and flexible column, formed of a series of bones called *vertebræ* (from *vertere*, to turn).

The **Vertebræ** are thirty-three in number, and have received the names *cervical, thoracic* or *dorsal, lumbar, sacral*, and *coccygeal*, according to the position which they occupy; seven being found in the cervical region, twelve in the thoracic, five in the lumbar, five in the sacral, and four in the coccygeal.

This number is sometimes increased by an additional vertebra in one region,

or the number may be diminished in one region, the deficiency being supplied by an additional vertebra in another. These observations do not apply to the cervical portion of the spine, the number of bones forming which is seldom increased or diminished.

The Vertebræ in the upper three regions of the spine are separate throughout the whole of life; but those found in the sacral and coccygeal regions are in the adult firmly united, so as to form two bones—five entering into the formation of the upper bone or *sacrum*, and four into the terminal bone of the spine or *coccyx*.

General Characters of a Vertebra

Each **vertebra** consists of two essential parts—an anterior solid segment, the *body* or *centrum*, and a posterior segment, the *neural arch*. The arch is formed of two *pedicles*, and two *laminæ*, which with the body form the *vertebral foramen*; they support seven *processes*—viz. four *articular*, two *transverse*, and one *spinous*.

The bodies of the vertebræ are piled one upon the other, forming a strong pillar, for the support of the cranium and trunk; the arches form a hollow cylinder behind the bodies for the protection of the spinal cord. The different vertebræ are connected together by means of the articular processes and the intervertebral fibro-cartilages; while the transverse and spinous processes serve as levers for the attachment of muscles which move the different parts of the spine. Lastly, between each pair of vertebræ apertures exist through which the spinal nerves pass from the cord. Each of these constituent parts must now be separately examined.

The **Body** or **centrum** is the largest part of a vertebra. It forms a segment of a solid column for the support of the trunk. Above and below, it is flattened; its upper and lower surfaces are rough, for the attachment of the intervertebral fibro-cartilages, and present a rim around their circumference. In front, it is convex from side to side, concave from above downwards. Behind, it is flat from above downwards and slightly concave from side to side. Its anterior surface is perforated by a few small apertures, for the passage of nutrient vessels; while on the posterior surface is a single large, irregular aperture, or occasionally more than one, for the exit of veins from the body of the vertebra—the *venæ basis vertebræ*.

The **Pedicles** are two short, thick processes of bone, which project backwards, one on each side, from the upper part of the body of the vertebra, at the line of junction of its posterior and lateral surfaces. The concavities above and below the pedicles are the *intervertebral notches*; they are four in number, two on each side, the inferior ones being generally the deeper. When the vertebræ are articulated, the notches of each contiguous pair of bones form the *intervertebral foramina*, which communicate with the spinal canal and transmit the spinal nerves and blood-vessels.

The **Laminæ** are two broad plates of bone which are connected to the body by the pedicles. They fuse in the middle line posteriorly, and so complete the vertebral foramen, which serves for the lodgment and protection of the spinal cord. Their upper borders and the lower part of their anterior surfaces are rough for the attachment of the ligamenta subflava.

The **Spinous Process** projects backwards from the junction of the two laminæ, and serves for the attachment of muscles and ligaments.

The **Articular Processes**, four in number, two on each side, spring from the junction of the pedicles with the laminæ. The two superior project upwards, their articular surfaces being directed more or less backwards; the two inferior project downwards, their articular surfaces looking more or less forwards.*

The **Transverse Processes**, two in number, project one at each side from the point where the lamina joins the pedicle, between the superior and inferior articular processes. They serve for the attachment of muscles and ligaments.

Characters of the Cervical Vertebræ (fig. 192)

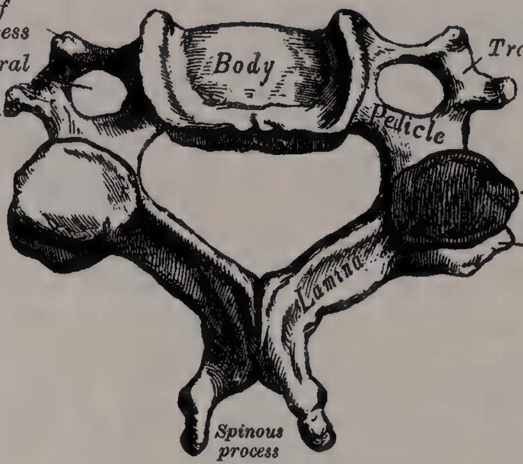
The **Cervical Vertebræ** are smaller than those in the other regions of the spine, and may readily be distinguished by a foramen in the transverse process,

* It may, perhaps, be as well to remind the reader that the direction of a surface is determined by that of a line drawn at right angles to it.

which does not exist in the transverse process of either the dorsal or lumbar vertebræ.

The **Body** is small, comparatively dense, and broader from side to side than from before backwards. The anterior and posterior surfaces are flattened and of equal depth; the former is placed on a lower level than the latter, and its inferior border is prolonged downwards, so as to overlap the upper and fore part of the vertebra below. Its upper surface is concave transversely, and presents a projecting lip on each side; its lower surface is convex from side to side, concave from before backwards, and presents laterally a shallow concavity, which receives the corresponding projecting lip of the adjacent vertebra. The *pedicles* are directed outwards and backwards, and are attached to the body midway between the upper and lower borders, so that the superior intervertebral notch is as deep as the inferior, but it is, at the same time, narrower. The *laminæ* are narrow, long, thinner above than below; they enclose the spinal foramen, which is large, and of a triangular form. The *spinous process* is short, and bifid at the extremity to afford greater extent of surface for the attachment of muscles, the two divisions being often of unequal size. They increase in length from the fourth to the seventh. The *articular processes* are flat, oblique, and of an oval form: the superior are directed backwards and upwards; the inferior forwards and downwards. The *transverse processes* are short, directed obliquely outwards and forwards, bifid at their extremity, and marked by a groove along their

FIG. 192.—A cervical vertebra.



upper surface, which runs downwards and outwards from the superior intervertebral notch, and serves for the transmission of one of the cervical nerves. They are situated in front of the articular processes and on the outer side of the pedicles, and are pierced at their base by a foramen, the *foramen transversarium* or *vertebrarterial foramen*, for the transmission of the vertebral artery, vein, and plexus of nerves. Each process is formed by two roots: the anterior root, sometimes called the *costal process*, arises from the side of the body, and is the homologue of the rib in the dorsal region of the spine; the posterior root springs from the junction of the pedicle with the lamina, and corresponds with the transverse process in the dorsal region. It is by the junction of the two that the foramen for the vertebral vessels is formed. The extremity of each of these roots forms the *anterior* and *posterior tubercles* of the transverse processes.*

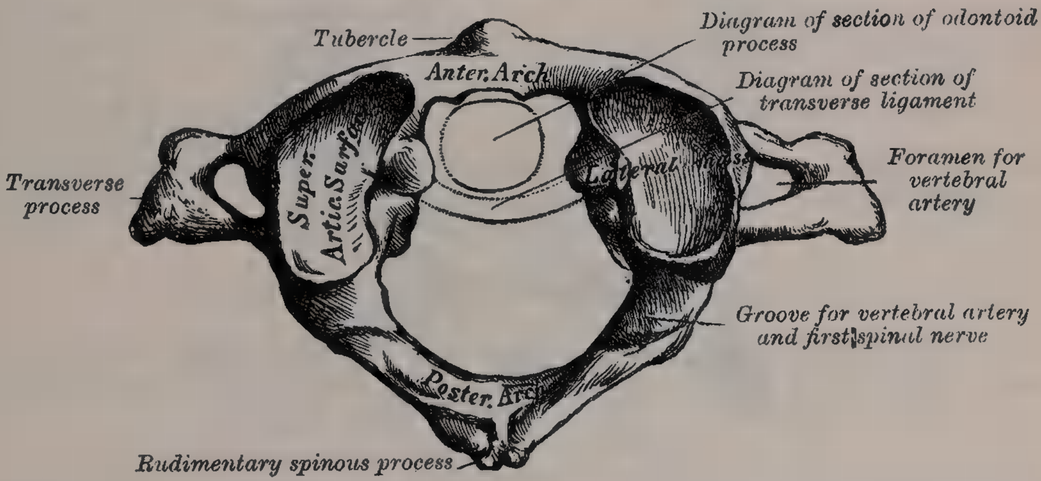
The peculiar vertebræ in the cervical region are the first, or *Atlas*; the second, or *Axis*; and the seventh, or *Vertebra prominens*. The great modifications in the form of the atlas and axis are designed to admit of the nodding and rotatory movements of the head.

The **Atlas** (fig. 193) is so named because it supports the globe of the head. The chief peculiarities of this bone are that it has neither body nor spinous

* The anterior tubercle of the transverse process of the sixth cervical vertebra is of large size, and is sometimes known as 'Chassaignac's' or the 'carotid tubercle.' It is in close relation with the carotid artery, which lies in front and a little external to it; so that, as was first pointed out by Chassaignac, the vessel can with ease be compressed against it.

process. The body is detached from the rest of the bone, and forms the odontoid process of the second vertebra. The atlas is ring-like, and consists of an anterior arch, a posterior arch, and two lateral masses. The *anterior* arch forms about one-fifth of the ring: its anterior surface is convex, and presents about its centre a *tubercle*, for the attachment of the Longus colli muscle; posteriorly it is concave, and marked by a smooth, oval or circular facet, for articulation with the odontoid process of the axis. The upper and lower borders respectively give attachment to the anterior occipito-atlantal and the anterior atlanto-axial ligaments; the former connects it with the occipital bone above and the latter with the axis below. The *posterior* arch forms about two-fifths of the circumference of the bone: it terminates behind in a *tubercle*, which is the rudiment of a spinous process, and gives origin to the Rectus capitis posticus minor. The diminutive size of this process prevents any interference in the movements between the atlas and the cranium. The posterior part of the arch presents above and behind a rounded edge for the attachment of the posterior occipito-atlantal ligament, while in front, immediately behind each superior articular process, is a groove, sometimes converted into a foramen by a delicate bony spiculum which arches backwards from the posterior extremity of the superior articular process. These grooves represent the superior intervertebral notches, and are peculiar from being situated behind the articular processes, instead of in front of them. They serve for the transmission of the vertebral artery, which,

FIG. 193.—First cervical vertebra, or Atlas.

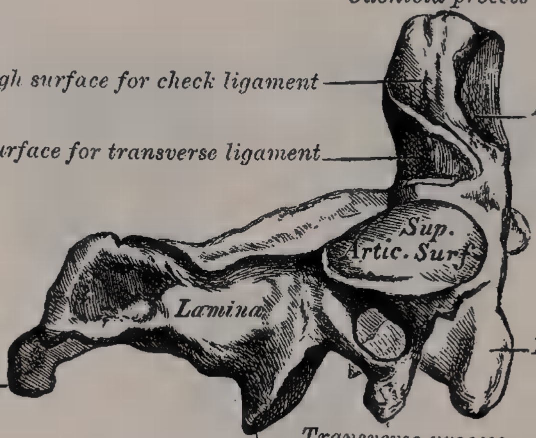


ascending through the foramen in the transverse process, winds round the lateral mass in a direction backwards and inwards. They also transmit the suboccipital (first spinal) nerve. On the under surface of the posterior arch, in the same situation, are two other grooves, placed behind the lateral masses, and representing the inferior intervertebral notches of other vertebræ. They are much less marked than the superior. The lower border gives attachment to the posterior atlanto-axial ligament, which connects it with the axis. The *lateral masses* are the most bulky and solid parts of the atlas, in order to support the weight of the head: they present two articulating processes above, and two below. The two superior are of large size, oval, concave, and approach each other in front, but diverge behind: they are directed upwards, inwards, and a little backwards, each forming a kind of cup for the corresponding condyle of the occipital bone, and are admirably adapted to the nodding movements of the head. Not infrequently they are partially subdivided by a more or less deep indentation which encroaches upon each lateral margin. The inferior articular processes are circular in form, flattened or slightly concave and directed downwards and inwards, articulating with the axis, and permitting the rotatory movements of the head. Just below the inner margin of each superior articular surface is a small tubercle, for the attachment of the transverse ligament which, stretching across the ring of the atlas, divides it into two unequal parts—the anterior or smaller segment receiving the odontoid process of the axis, the posterior allowing the transmission of the spinal cord and its membranes. This part of the spinal canal is of considerable size, to afford space for the spinal cord; and hence lateral displacement of the

atlas may occur without compression of this structure. The *transverse processes* are of large size, project directly outwards and downwards from the lateral masses, and serve for the attachment of special muscles which assist in rotating the head. They are long, and do not present an anterior and posterior tubercle, which have become fused into one mass; they are perforated at their base by a foramen for the vertebral artery, which is directed from below, upwards and backwards.

The **Axis** (fig. 194) is so named from forming the pivot upon which the first vertebra, carrying the head, rotates. The most distinctive character of this bone is the strong, prominent process, tooth-like in form (hence the name *odontoid*), which rises perpendicularly from the upper surface of the body. The *body* is deeper in front than behind, and prolonged downwards anteriorly so as to overlap the upper and fore part of the next vertebra. It presents in front a median longitudinal ridge, separating two lateral depressions for the attachment of the Longus colli muscle of either side. The *odontoid process* presents two articulating surfaces: one in front, of an oval form, for articulation with the atlas; another behind for the transverse ligament—the latter frequently encroaching on the sides of the process. The apex is pointed, and gives attachment to the middle odontoid or check ligament. Below the apex, the process is somewhat enlarged and presents on either side a rough impression for the attachment of the lateral

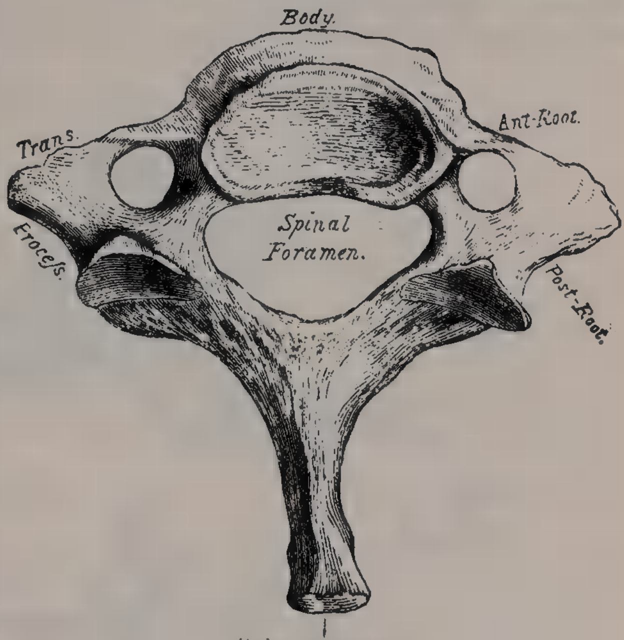
Fig. 194.—Second cervical vertebra, or Axis.



odontoid or check ligaments, which connect it to the occipital bone; the base of the process, where it is attached to the body, is constricted, so as to prevent displacement from the transverse ligament, which binds it in this situation to the anterior arch of the atlas. Sometimes, however, this process does become displaced, especially in children, in whom the ligaments are more relaxed: instant death is the result of this accident. The internal structure of the odontoid process is more compact than that of the body. The *pedicles* are broad and strong, especially their anterior extremities, which coalesce with the sides of the body and the root of the odontoid process. They are covered above by the superior articulating surfaces. The *laminæ* are thick and strong, and the spinal foramen large, but smaller than that of the atlas. The *transverse processes* are very small, not bifid, but terminating in a single tubercle; they are perforated by the foramen for the vertebral artery, which is directed obliquely upwards and outwards. The *superior articular surfaces* are round, slightly convex, directed upwards and outwards, and are peculiar in being supported on the body, pedicles, and transverse processes. The *inferior articular surfaces* have the same direction as those of the other cervical vertebræ. The *superior intervertebral notches* are very shallow, and lie behind the articular processes; the *inferior* in front of them, as in the other cervical vertebræ. The *spinous process* is of large size, very strong, deeply channelled on its under surface, and presents a bifid, tubercular extremity for the attachment of muscles which serve to rotate the head upon the spine.

Seventh Cervical (fig. 195).—The most distinctive character of this vertebra is the existence of a long and prominent spinous process; hence the name 'vertebra prominens.' This process is thick, nearly horizontal in direction, not bifurcated, but terminating in a tubercle, which has attached to it the lower end of the ligamentum nuchæ. The *transverse process* is of considerable size, its posterior tubercles are large and prominent, while the anterior are small and faintly marked; its upper surface has usually a shallow groove, and it seldom presents more than a trace of bifurcation at its extremity. The foramen in the transverse process is sometimes as large as in the other cervical vertebræ, but is generally smaller on one or both sides, and sometimes wanting. On the left side it occasionally gives passage to the vertebral artery; more frequently the vertebral vein traverses it on both sides; but the usual arrangement is for both artery and vein to pass in front of the transverse process, and not through the foramen. Sometimes the anterior root of the transverse process exists as a separate bone, and attains a large size. It is then known as a 'cervical rib.'

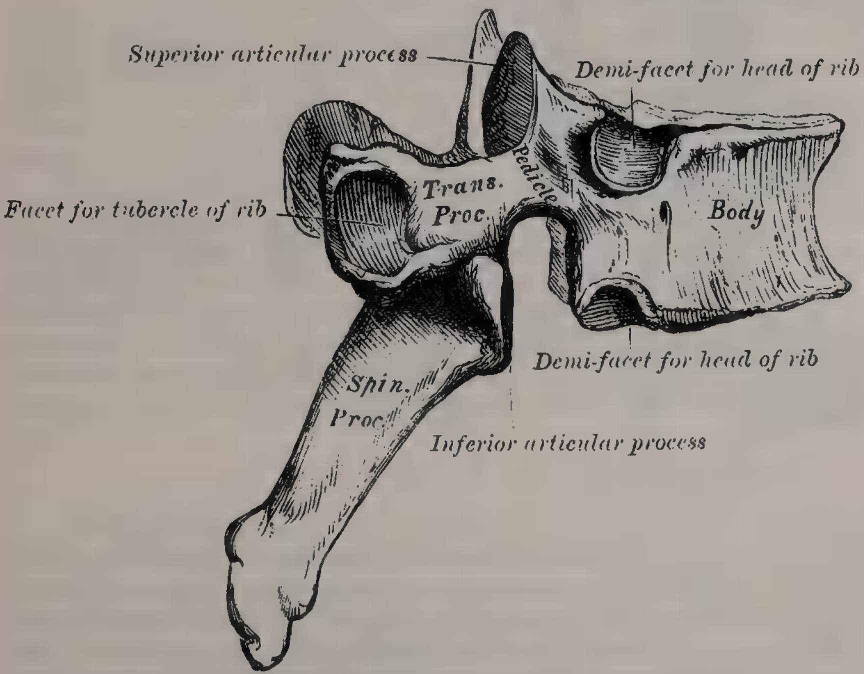
Fig. 195.—Seventh cervical vertebra, or vertebra prominens.



Characters of the Thoracic or Dorsal Vertebræ

The **Dorsal Vertebræ** (fig. 196) are intermediate in size between those in the cervical and those in the lumbar region, and increase in size from above

Fig. 196.—A dorsal vertebra.

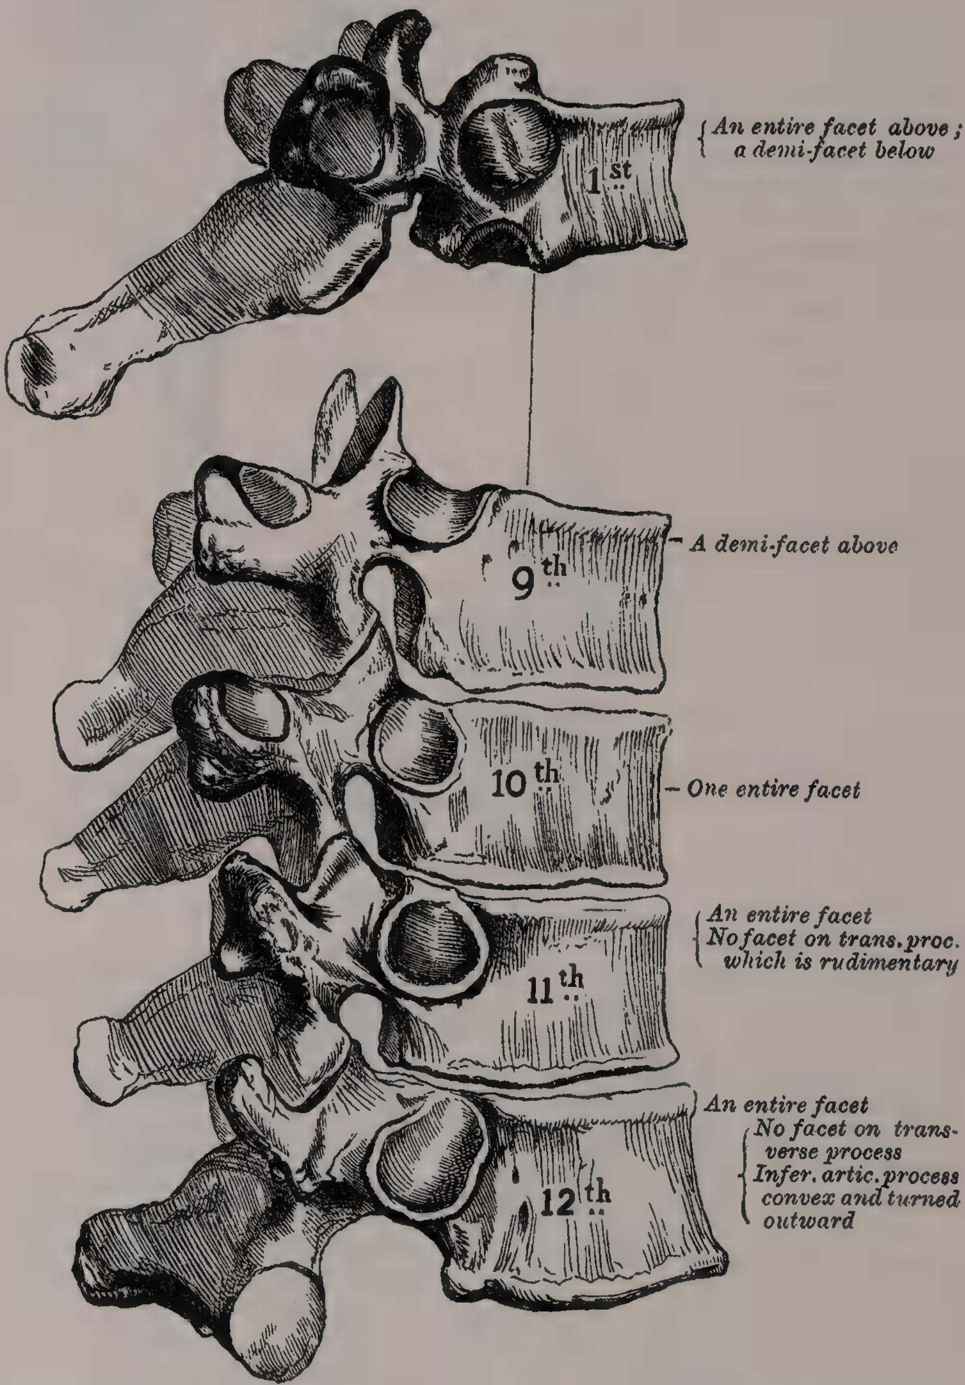


downwards, the upper vertebræ being much smaller than those in the lower part of the region. The dorsal vertebræ may be at once recognised by the presence

of one or more facets or half-facets on the sides of the body for the heads of the ribs.

The **bodies** of the dorsal vertebræ resemble those in the cervical and lumbar regions at the respective ends of this portion of the spine; but in the middle of the dorsal region their form is very characteristic, being heart-shaped, and as broad in the antero-posterior as in the lateral direction. They are slightly thicker behind than in front, flat above and below, convex and prominent in front, deeply

FIG. 197.—Peculiar dorsal vertebræ.



concave behind, slightly constricted laterally and in front, and marked on each side, near the root of the pedicle, by two demi-facets, one above, the other below. These are covered with cartilage in the recent state, and, when the vertebræ are articulated with one another, form, with the intervening fibro-cartilages, oval surfaces for the reception of the heads of the corresponding ribs. The *pedicles* are directed backwards and slightly upwards, and the inferior intervertebral notches are of large size, and deeper than in any other region of the spine. The *laminæ*

are broad, thick, and imbricated—that is to say, they overlap one another like tiles on a roof. The spinal foramen is small, and of a circular form. The *spinous process* is long, triangular on transverse section, directed obliquely downwards, and terminates in a tubercular extremity. These processes overlap one another from the fifth to the eighth, but are less oblique in direction above and below. The *articular processes* are flat, nearly vertical in direction, and project from the upper and lower parts of the pedicles; the superior being directed backwards and a little outwards and upwards, the inferior forwards and a little inwards and downwards. The *transverse processes* arise from the same parts of the arch as the posterior roots of the transverse processes in the neck, and are situated behind the articular processes and pedicles; they are thick, strong, and of considerable length, directed obliquely backwards and outwards, and present a clubbed extremity, which is tipped on its anterior part by a small, concave surface, for articulation with the tubercle of a rib. Besides the articular facet for the rib, three indistinct tubercles may be seen rising from the transverse processes of the lower three or four dorsal vertebræ, one at the upper border, one at the lower border, and one externally. In man, they are comparatively small in size, and serve only for the attachment of muscles. But in some animals they attain considerable magnitude, either for the purpose of more closely connecting the segments of this portion of the spine, or for muscular and ligamentous attachment.

The peculiar dorsal vertebræ are the *first, ninth, tenth, eleventh,* and *twelfth* (fig. 197).

The **First Dorsal Vertebra** presents, on each side of the *body*, a single entire articular facet for the head of the first rib, and a half-facet for the upper half of the second. The body is like that of a cervical vertebra, being broad transversely; its upper surface is concave, and lipped on each side. The *superior articular surfaces* are oblique, directed upwards and backwards, but not outwards; the *spinous process* thick, long, and almost horizontal. The *transverse processes* are long, and the upper intervertebral notch deeper than in the other vertebræ of this series.

The **Ninth Dorsal** has no demi-facet below. In some subjects, however, the ninth has two demi-facets on each side; when this occurs the tenth has only a demi-facet at the upper part.

The **Tenth Dorsal** has (except in the cases just mentioned) an entire articular facet on each side above, which is partly placed on the outer surface of the pedicle. It has no demi-facet below.

In the **Eleventh Dorsal**, the body approaches in its form and size to the lumbar. The articular facets for the heads of the ribs, one on each side, are of large size, and placed chiefly on the pedicles, which are thicker and stronger in this and the next vertebra than in any other part of the dorsal region. The *spinous process* is short, and nearly horizontal in direction. The *transverse processes* are very short, tubercular at their extremities, and have no articular facets for the tubercles of the ribs.

The **Twelfth Dorsal** has the same general characters as the eleventh, but may be distinguished from it by the inferior articular processes being convex and turned outwards, like those of the lumbar vertebræ; by the general form of the body, laminæ, and spinous process, approaching to that of the lumbar vertebræ; and by the transverse processes being subdivided into three elevations, the superior, inferior, and external tubercles, which correspond to the mammillary, accessory, and transverse processes of the lumbar vertebræ. Traces of similar elevations are found on the tenth and eleventh dorsal vertebræ (*vide ut supra*).

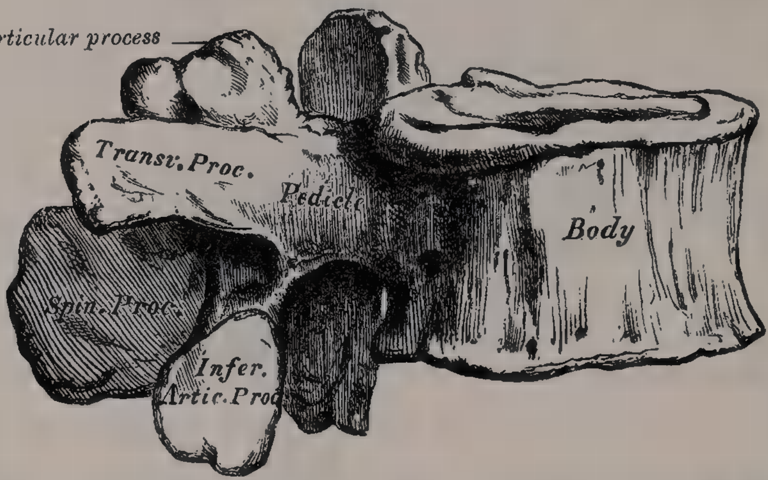
Characters of the Lumbar Vertebræ

The **Lumbar Vertebræ** (fig. 198) are the largest segments of the movable part of the vertebral column, and can at once be distinguished by the absence of the foramen in the transverse process, the characteristic feature of the cervical vertebræ, and by their not having any articulating facet on the side of the body, the distinguishing mark of the dorsal vertebræ.

The **body** is large, and has a greater diameter from side to side than from before backwards, a little thicker in front than behind, flattened or slightly concave above and below, concave behind, and deeply constricted in front and at the

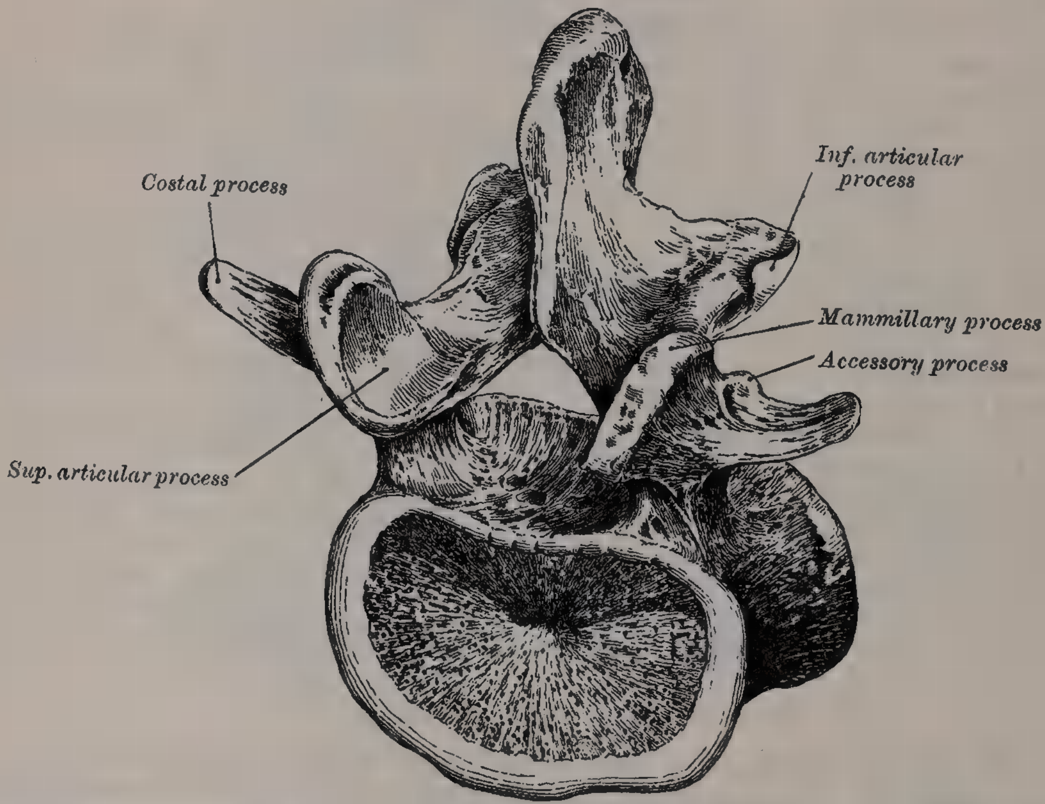
sides, presenting prominent margins, which afford a broad basis for the support of the superincumbent weight. The *pedicles* are very strong, directed backwards from the upper part of the bodies; consequently, the inferior intervertebral notches are of considerable depth. The *laminæ* are broad, short, and strong; and the spinal foramen triangular, larger than in the dorsal, but smaller than in the

FIG. 198.—Lumbar vertebra.



cervical, region. The *spinous process* is thick and broad, somewhat quadrilateral, projecting backwards, thicker below than above, and terminating in a rough, uneven border. The *superior articular processes* are concave, and look backwards and inwards; the *inferior*, convex, look forwards and outwards; the former are separated by a much wider interval than the latter, and embrace the lower

FIG. 199.—Lumbar vertebra.



articulating processes of the vertebra above. The *transverse processes* are long, slender, directed transversely outwards in the upper three lumbar vertebræ, slanting a little upwards in the lower two. In the upper vertebræ of the series they arise from the junction of the pedicle and the lamina, but as they descend they appear to advance and arise from the pedicle and posterior part of the body of the vertebra. They are situated in front of the articular processes instead

of behind them as in the dorsal vertebræ, and are homologous with the ribs. Of the three tubercles noticed in connection with the transverse processes of the lower dorsal vertebræ, the *superior* one becomes connected in this region with the back part of the superior articular process, and has received the name of *mammillary* process; the *inferior* is represented by a small process pointing downwards, situated at the back part of the base of the transverse process, and called the *accessory* process—this is the true transverse process, which is rudimental in this region of the spine; the *external* one, the so-called transverse process, is the homologue of the rib, and hence is sometimes called the *costal* process (fig. 199). Although in man these are comparatively small, in some animals they attain considerable size, and serve to lock the vertebræ more closely together.

The **Fifth Lumbar** vertebra is characterised by having the body much thicker in front than behind, which accords with the prominence of the sacro-vertebral articulation; by the smaller size of its spinous process; by the wide interval between the inferior articulating processes; and by the greater size and thickness of its transverse processes, which spring from the body as well as from the pedicles.

Structure of the Vertebræ.—The body is composed of light, spongy, cancellous tissue, having a thin coating of compact tissue on its external surface perforated by numerous orifices, some of large size, for the passage of vessels; its interior is traversed by one or two large canals, for the reception of veins, which converge towards a single large, irregular aperture, or several small apertures, at the posterior part of the body of each bone. The arch and processes projecting from it have, on the contrary, a thick covering of compact tissue.

Development.—Each vertebra is formed of four primary centres of ossification (fig. 200), one for each lamina and its processes, and two for the body.* Ossification commences in the laminæ of the upper cervical vertebræ about the sixth week of fœtal life, the date becoming gradually later as one passes down the column. The ossific granules first appear in the situation where the transverse processes afterwards project, and spread backwards to the spine, forwards into the pedicles, and outwards into the transverse and articular processes. Ossification in the body commences in the centre of the cartilage about the eighth week in the mid-dorsal region, and from there subsequently extends upwards and downwards along the column. The ossific granules form two closely approximated centres, which speedily coalesce to form one ossific point. At birth these three pieces are perfectly separate. It is important to note that a portion of the postero-lateral aspect of the body is formed from the centre of the neural arch, and the line of junction of the body and arch (*neuro-central synchondrosis*) encroaches on the former. It therefore follows that, in the dorsal region, the facets for the heads of the ribs lie behind the neuro-central synchondrosis and are ossified from the centres for the neural arch. During the first year the laminæ become united behind, the union taking place first in the lumbar region and then extending upwards through the dorsal and lower cervical regions. About the third year the bodies of the upper cervical vertebræ become joined to the arch on each side, and the junction takes place from above downwards, but is not completed in the lower lumbar vertebræ until the sixth year. Before puberty, no other changes occur, excepting a gradual increase in the growth of these primary centres; the upper and under surfaces of the bodies, and the ends of the transverse and spinous processes, being tipped with cartilage, in which ossific granules are not as yet deposited. About the sixteenth year (fig. 201), five secondary centres appear, one for the tip of each transverse process, one for the extremity of the spinous process; and two epiphysial plates, one for the upper and the other for the lower surface of the body (fig. 202). These fuse with the rest of the bone about the age of five-and-twenty.

Exceptions to this mode of development occur in the first, second, and seventh cervical vertebræ, and in those of the lumbar region.

* By many observers it is asserted that the bodies of the vertebræ are developed from a single centre which speedily becomes bilobed, so as to give the appearance of two nuclei; but that there are two centres, at all events sometimes, is evidenced by the fact that the two halves of the body of the vertebra may remain distinct throughout life, and be separated by a fissure through which a protrusion of the spinal membranes may take place, constituting an anterior spina bifida.

The Atlas (fig. 203).—The atlas is usually ossified from three centres. Two of these are destined for the lateral masses, the ossification of which commences about the seventh week of fœtal life near the articular processes, and extends backwards; at birth, these portions of bone are separated from one another behind by a narrow interval filled with cartilage. Between the third and fourth years they unite either directly or through the medium of a separate centre, developed in the cartilage in the middle line. The anterior arch, at birth, is altogether cartilaginous and consists of the hypochordal brace or bar (see page 96), which persists in the case of the atlas; in this a separate nucleus appears about the end of the first year after birth, and joins the lateral masses from the sixth to the eighth year after birth—their line of union extending across the anterior portions of the superior articular facets. Sometimes there are two nuclei developed in the cartilage, one on either side of the median line, which join to form a single mass. Occasionally there is no separate centre, the anterior arch being formed by the gradual extension forwards and ultimate junction of the two lateral masses.

The **Axis** (fig. 204) is developed by *five* primary and *two* secondary centres. The body and arch of this bone are formed in the same manner as the corresponding parts in the other vertebræ; one centre (or two, which speedily coalesce) for the lower part of the body, and one for each lamina. The centres for the laminæ appear about the seventh or eighth week, that for the body about the fourth month. The odontoid process consists originally of an extension upwards of the cartilaginous mass, in which the lower part of the body is formed. At about the sixth month of fœtal life, two osseous nuclei make their appearance in the base of this process: they are placed laterally, and join before birth to form a conical bilobed mass deeply cleft above; the interval between the cleft and the summit of the process is formed by a wedge-shaped piece of cartilage. The base of the process is separated from the body by a cartilaginous interval, which gradually becomes ossified at its circumference, but remains cartilaginous in its centre until advanced age.* In this cartilage,

rudiments of the lower epiphysial lamella of the atlas and the upper epiphysial lamella of the axis may sometimes be found. Finally, as Humphry has demonstrated, the apex of the odontoid process has a separate nucleus, which appears in the second year and joins about the twelfth year. This is the upper epiphysial lamella of the atlas. In addition to these there is a secondary centre for a thin epiphysial plate on the under surface of the body of the bone.

The Seventh Cervical.—The anterior or costal part of the transverse process of the seventh cervical is sometimes developed from a separate osseous centre at about the sixth month of fœtal life, and joins the body and posterior division of the transverse process between the fifth and sixth years. Occasionally this process continues as a separate piece, and, becoming lengthened outwards and forwards, constitutes what is known as a cervical rib. This separate ossific centre for the costal process has also been found in the fourth, fifth, and sixth cervical vertebræ.

The **Lumbar Vertebræ** (fig. 205) have *two additional centres* for the mammillary tubercles, which project from the back part of the superior articular processes. The transverse process of the first lumbar is sometimes developed as a separate piece, which may remain permanently unconnected with the rest of the bone, thus forming a lumbar rib—a peculiarity which is rarely met with.

Progress of Ossification in the Spine generally.—Ossification of the laminæ of the vertebræ commences in the cervical region of the spine, and proceeds gradually downwards. Ossification of the bodies, on the other hand, commences about the mid-dorsal region, and extends both upwards and downwards Although, however, the ossific nuclei for the bodies first make their appearance in the dorsal vertebræ, the lumbar and first sacral are those in which these nuclei are largest at birth.

Attachment of Muscles.—To the *Atlas* are attached nine pairs: the Longus colli, Rectus capitis anticus minor, Rectus lateralis, Obliquus capitis superior and inferior, Splenius colli, Levator anguli scapulæ, First Intertransverse, and Rectus capitis posticus minor.

To the *Axis* are attached eleven pairs: the Longus colli, Levator anguli scapulæ, Splenius colli, Scalenus medius, Transversalis cervicis, Intertransversales, Obliquus capitis inferior, Rectus capitis posticus major, Semispinalis colli, Multifidus spinæ, Interspinales.

To the remaining vertebræ, generally, are attached thirty-five pairs and a single muscle: *anteriorly*, the Rectus capitis anticus major, Longus colli, Scalenus anticus, medius, and posticus, Psoas magnus and parvus, Quadratus lumborum, Diaphragm, Obliquus abdominis internus, and Transversalis abdominis; *posteriorly*, the Trapezius, Latissimus dorsi, Levator anguli scapulæ, Rhomboideus major and minor, Serratus posticus superior and inferior, Splenius, Erector spinæ, Ilio-costalis, Longissimus dorsi, Spinalis dorsi, Cervicalis ascendens, Transversalis colli, Trachelo-mastoid, Complexus, Biventer cervicis, Semispinalis dorsi et colli, Multifidus spinæ, Rotatores spinæ, Interspinales, Supraspinales, Intertransversales, Levatores costarum.

Sacral and Coccygeal Vertebræ

The **Sacral** and **Coccygeal Vertebræ** consist at an early period of life of nine separate pieces which are united in the adult, so as to form two bones, five entering into the formation of the sacrum, four into that of the coccyx. Occasionally, the coccyx consists of five bones.*

The Sacrum

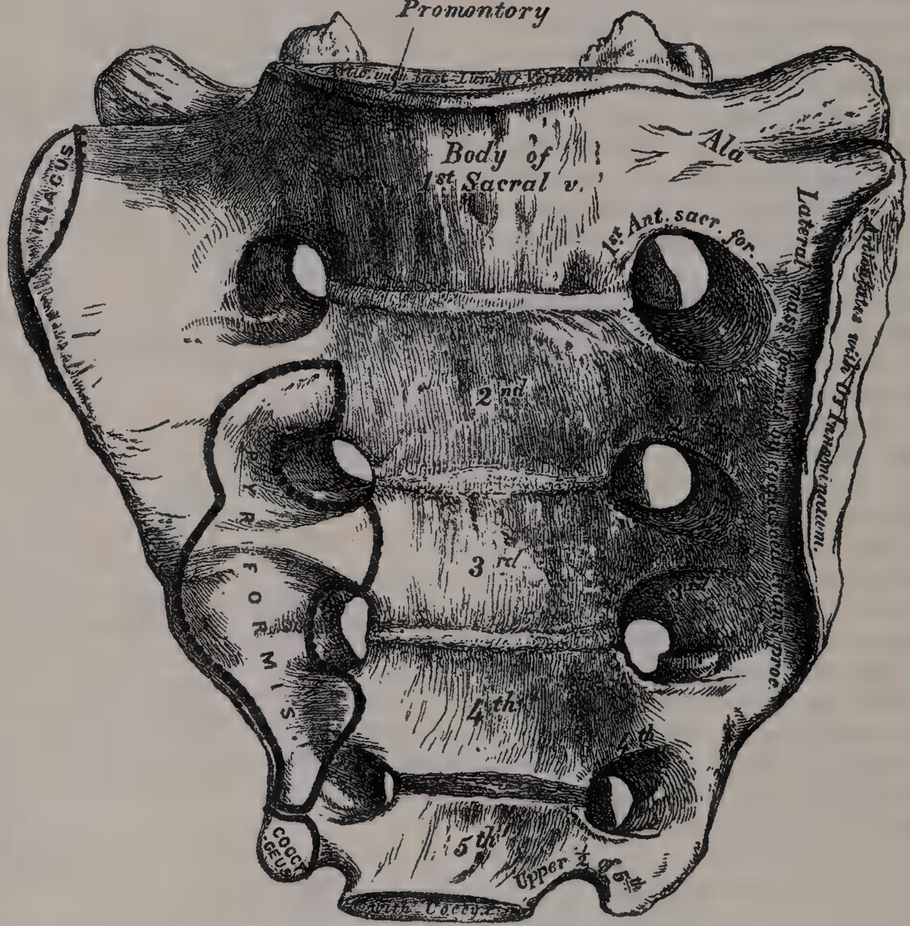
The **Sacrum** (sacer, *sacred*) is a large, triangular bone (fig. 206), situated at the lower part of the vertebral column, and at the upper and back part of the pelvic cavity, where it is inserted like a wedge between the two innominate bones; its upper part or base articulates with the last lumbar vertebra, its apex with the coccyx. The sacrum is curved upon itself, and placed very obliquely, its upper extremity projecting forwards, and forming, with the last lumbar

* Sir George Humphry describes this as the usual composition of the coccyx.—*On the Skeleton*, p. 456.

vertebra, a very prominent angle, called the *promontory* or *sacro-vertebral angle*; while its central part is projected backwards, so as to give increased capacity to the pelvic cavity. It presents for examination an anterior and posterior surface, two lateral surfaces, a base, an apex, and a central canal.

The **Anterior Surface** is concave from above downwards, and slightly so from side to side. In the middle are seen four transverse ridges, indicating the original division of the bone into five separate pieces. The portions of bone intervening between the ridges correspond to the bodies of the vertebræ. The body of the first segment is of large size, and in form resembles that of a lumbar vertebra; the succeeding ones diminish in size from above downwards, are flattened from before backwards, and curved so as to accommodate themselves to the form of the sacrum, being concave in front, convex behind. At each end of the ridges above mentioned are seen the *anterior sacral foramina*, analogous to the intervertebral foramina, four in number on each side, somewhat rounded in

Fig. 206.—Sacrum, anterior surface.



form, diminishing in size from above downwards, and directed outwards and forwards: they give exit to the anterior divisions of the sacral nerves and entrance to the lateral sacral arteries. External to these foramina is the *lateral mass*, consisting, at an early period of life, of separate segments; in the adult, these become blended with the bodies and with each other. Each lateral mass is traversed by four broad, shallow grooves, which lodge the anterior divisions of the sacral nerves as they pass outwards, the grooves being separated by prominent ridges of bone which give attachment to the slips of the Pyriformis muscle.

If a vertical section is made through the centre of the sacrum (fig. 207), the bodies are seen to be united at their circumference by bone, a wide interval being left centrally, which, in the recent state, is filled by intervertebral substance. In some bones, this union is more complete between the lower segments than between the upper ones.

The **Posterior Surface** (fig. 208) is convex and much narrower than the anterior. In the middle line are three or four tubercles, which represent the rudimentary

spinous processes of the sacral vertebræ. Of these tubercles, the first is generally prominent, and distinct from the rest; the second and third are either separate or united into a tubercular ridge, which diminishes in size from above downwards; the fourth usually, and the fifth always remaining undeveloped. External to the spinous processes on each side are the *laminæ*, broad and well marked in the first three pieces; sometimes the fourth, and generally the fifth, are only partially developed and fail to meet in the middle line. These partially developed laminæ are prolonged downwards, as rounded processes, the *sacral cornua*, and are connected to the cornua of the coccyx. Between them the bony wall of the lower end of the sacral canal is imperfect, and is liable to be opened in the sloughing of bed-sores. External to the laminæ is a linear series of indistinct tubercles representing the *articular processes*; the upper pair are large, well developed, and correspond in shape and direction to the superior articulating processes of a lumbar vertebra; the second and third are small; the fourth and fifth (usually blended together) are situated on each side of the sacral canal and assist in forming the sacral cornua. External to the articular processes are the four *posterior sacral foramina*; they are smaller in size and less regular in form than the anterior, and transmit the posterior divisions of the sacral nerves. On the outer side of the posterior sacral foramina is a series of tubercles, the rudimentary *transverse processes* of the sacral vertebræ. The first pair of transverse tubercles are of large size, very distinct, and correspond with each superior angle of the bone; they, together with the second pair, which are of small size, give attachment to the horizontal part of the sacro-iliac ligament; the third give attachment to the oblique fasciculi of the posterior sacro-iliac ligaments; and the fourth and fifth to the great sacro-sciatic ligaments. The interspace between the spinous and transverse processes on the back of the sacrum presents a wide, shallow concavity, called the *sacral groove*; it is continuous above with the vertebral groove, and lodges the origin of the Multifidus spinæ.

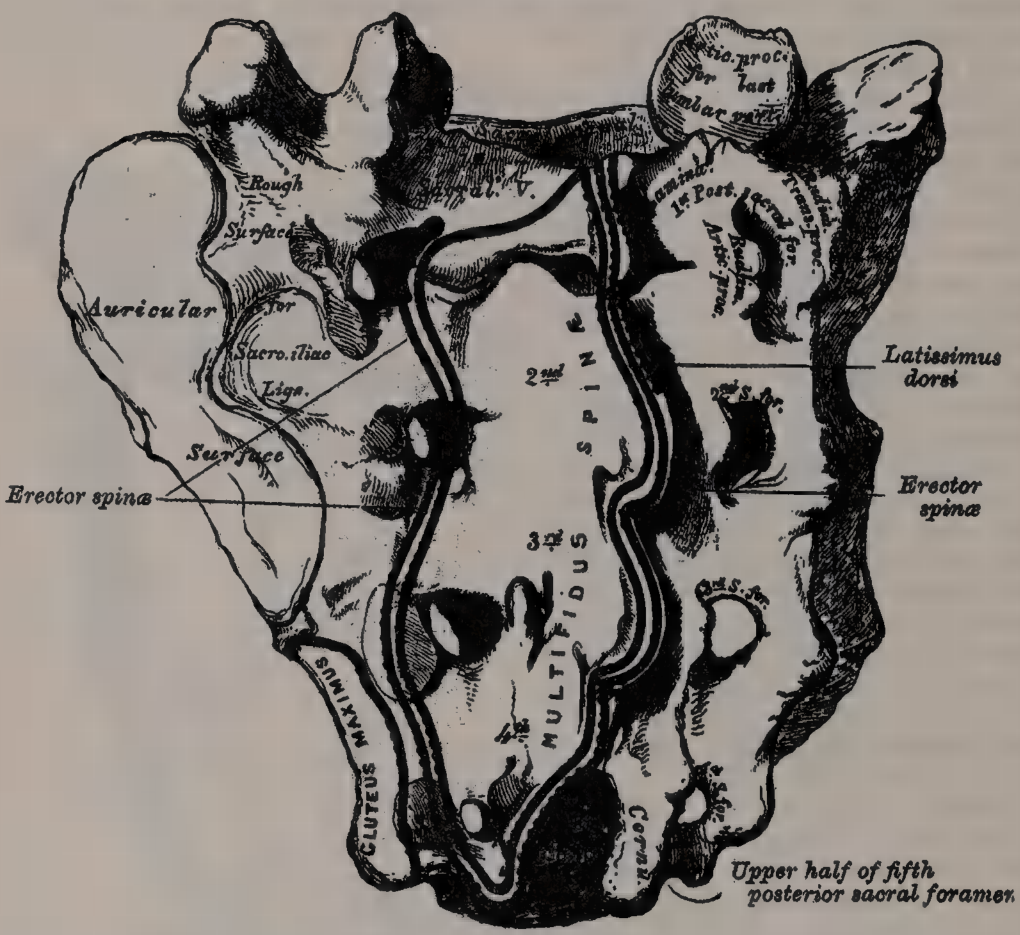
Fig. 207.—Vertical section of the sacrum.

The **Lateral Surface**, broad above, becomes narrowed into a thin edge below. Its upper half presents in front a broad, ear-shaped surface for articulation with the ilium. This is called the *auricular* surface, and in the fresh state is coated with fibro-cartilage. It is bounded posteriorly by deep and uneven impressions, for the attachment of the posterior sacro-iliac ligaments. The lower half is thin and sharp, and terminates in a projection called the *inferior lateral angle*; below this angle is a notch, which is converted into a foramen by articulation with the transverse process of the upper piece of the coccyx, and transmits the anterior division of the fifth sacral nerve. This lower, sharp border gives attachment to the greater and lesser sacro-sciatic ligaments, and to some fibres of the Gluteus maximus posteriorly, and to the Coccygeus in front.

The **Base** of the sacrum, which is broad and expanded, is directed upwards and forwards. In the middle is seen a large oval articular surface, the upper aspect of the body of the first sacral vertebra, which is connected with the under surface of the body of the last lumbar vertebra by a fibro-cartilaginous disc. It

is bounded behind by the large, triangular orifice of the sacral canal. The orifice is formed behind by the laminæ and spinous process of the first sacral vertebra: the superior articular processes project from it on each side; they are oval, concave, directed backwards and inwards, like the superior articular processes of a lumbar vertebra; and in front of each articular process is an intervertebral notch, which forms the lower part of the foramen between the last lumbar and first sacral vertebra. Lastly, on each side of the large oval articular plate is a broad and flat triangular surface of bone, which extends outwards, supports the Psoas magnus muscle and lumbo-sacral cord, and is continuous on each side with the iliac fossa. This is called the *ala* of the sacrum, and gives attachment to a few

Fig. 208.—Sacrum, posterior surface.



of the fibres of the Iliacus muscle. The posterior part of the ala represents the transverse process, and its anterior part the costal process of the first sacral segment.

The **Apex**, directed downwards and slightly forwards, presents a small, oval, concave surface for articulation with the coccyx.

The **Spinal Canal** (fig. 207) runs throughout the greater part of the bone; it is large and triangular in form above; small and flattened, from before backwards, below. In this situation its posterior wall is incomplete, from the non-development of the laminæ and spinous processes. It lodges the sacral nerves, and is perforated by the anterior and posterior sacral foramina, through which these pass out.

Structure.—It consists of much loose, spongy tissue within, invested externally by a thin layer of compact tissue.

Differences in the Sacrum of the Male and Female.—The sacrum in the female is shorter and wider than in the male; the lower half forms a greater angle with the upper; the upper half of the bone being nearly straight, the lower half presenting the greatest amount of curvature. The bone is also directed more obliquely backwards, which increases the size of the pelvic cavity and renders the sacro-vertebral angle more projecting. In the male the curvature is

more evenly distributed over the whole length of the bone, and is altogether greater than in the female.

Peculiarities of the Sacrum.—This bone, in some cases, consists of six pieces; occasionally, the number is reduced to four. Occasionally the bodies of the first and second segments are not joined, or the laminæ and spinous processes have not coalesced. Sometimes the upper pair of transverse tubercles are not joined to the rest of the bone on one or both sides; and, lastly, the sacral canal may be open for nearly the lower half of the bone, in consequence of the imperfect development of the laminæ and spinous processes. The sacrum, also, varies considerably with respect to its degree of curvature.

Development (figs. 209, 210, 211).—The sacrum, formed by the union of five vertebræ, has usually *thirty-five* centres of ossification, but this number may be increased.

The *bodies* of the sacral vertebræ have each three ossific centres: one for the central part, one for the epiphysial plate on its upper and another for that on its under surface. Occasionally the primary centres for the bodies of the first and second piece of the sacrum are double.

The arch of each sacral vertebra is developed by two centres, one for each lamina. These unite with each other behind, and subsequently join the body.

The *lateral masses* have six additional centres, two for each of the first three vertebræ.* These centres make their appearance above and to the outer side of the anterior sacral foramina (fig. 209), and are developed into separate segments (fig. 210); they are subsequently blended with each other, and with the bodies and transverse processes, to form the lateral masses.

Lastly, each *lateral surface* of the sacrum is developed by two epiphysial plates (fig. 211): one for the auricular surface, and one for the remaining part of the thin lateral edge of the bone.

At 25th year

Period of Development.—At about the eighth or ninth week of fœtal life, ossification of the central part of the body of the first sacral vertebra commences and is rapidly followed by deposit of ossific matter in the second and third; but ossification does not commence in the lower two segments until between the fifth and eighth months of fœtal life. Between the sixth and eighth months ossification of the laminæ takes place; and about the same time, the centres for the lateral masses of the first three sacral vertebræ make their appearance. The period at which the arch becomes completed by the junction of the laminæ with the bodies in front, and with each other behind, varies in different segments. The junction between the laminæ and the bodies takes place first in the lower vertebræ as early as the second year, but is not effected in the uppermost until the fifth or sixth year. About the sixteenth year the epiphysial plates for the upper and under surfaces of the bodies are formed; and between the eighteenth and twentieth years, those for each lateral surface of the sacrum make their appearance. The

* Occasionally the fourth vertebra has also these two additional centres.

bodies of the sacral vertebræ are, during early life, separated from each other by intervertebral discs. But about the eighteenth year the two lowest segments become joined together by bone. This process gradually extends upwards until all the segments become united; and the bone is completely formed from the twenty-fifth to the thirtieth year of life.

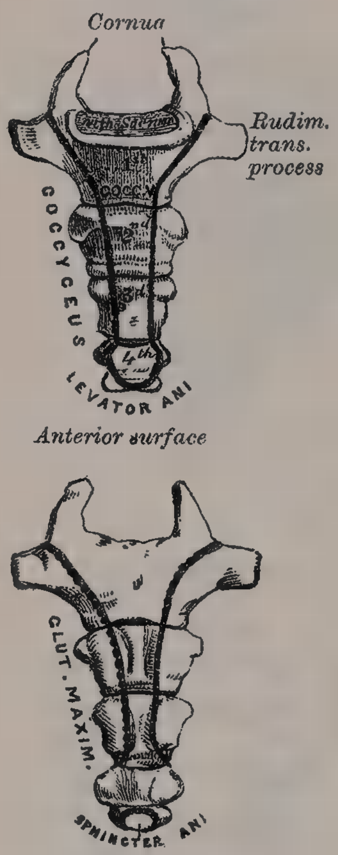
Articulations.—With four bones: the last lumbar vertebra, coccyx, and the two innominate bones.

Attachment of Muscles.—To eight pairs: in front, the Pyriformis and Coccygeus, and a portion of the Iliacus to the base of the bone; behind, the Gluteus maximus, Latissimus dorsi, Multifidus spinæ, and Erector spinæ, and sometimes the Extensor coccygis.

The Coccyx

The **Coccyx** (*κόκκυξ, cuckoo*), so called from having been compared to a cuckoo's beak (fig. 212), is usually formed of four small segments of bone, and is the most rudimentary part of the vertebral column. In each of the first three segments may be traced a rudimentary body, articular and transverse processes; the last piece (sometimes the third) is a mere nodule of bone, without distinct processes. All the segments are destitute of pedicles, laminæ, and spinous processes; and, consequently, of intervertebral foramina and spinal canal. The first segment is the largest; it resembles the lowermost sacral vertebra, and often exists as a separate piece; the last three, diminishing in size from above downwards, are usually blended together so as to form a single bone. The gradual diminution in the size of the pieces gives this bone a triangular form, the base of the triangle joining the end of the sacrum. It presents for examination an anterior and posterior surface, two borders, a base, and an apex. The *anterior surface* is slightly concave, and marked with three transverse grooves, indicating the points of junction of the different pieces. It has attached to it the anterior sacro-coccygeal ligament and Levator ani muscle, and supports the lower end of the rectum. The *posterior surface* is convex, marked by transverse grooves similar to those on the anterior surface; and presents on each side a lineal row of tubercles, the rudimentary articular processes of the coccygeal vertebræ. Of these, the superior pair are large, and are called the *cornua of the coccyx*: they project upwards, and articulate with the cornua of the sacrum, the junction between these two bones completing the fifth posterior sacral foramen for the transmission of the fifth sacral nerve. The *lateral borders* are thin, and present a series of small eminences, which represent the transverse processes of the coccygeal vertebræ. Of these, the first on each side is the largest, flattened from before backwards, and often ascends to join the lower part of the thin lateral edge of the sacrum, thus completing the fifth anterior sacral foramen for the transmission of the anterior division of the fifth sacral nerve; the others diminish in size from above downwards, and are often wanting. The *borders* of the coccyx are narrow, and give attachment on each side to the sacro-sciatic ligaments, to the Coccygeus muscle in front of the ligaments, and to the Gluteus maximus behind them. The *base* presents an oval surface for articulation with the sacrum. The *apex* is rounded, and has attached to it the tendon of the external Sphincter muscle of the anus. It may be bifid, and is sometimes deflected to one or other side.

Fig. 212.—Coccyx.



Anterior surface

Posterior surface

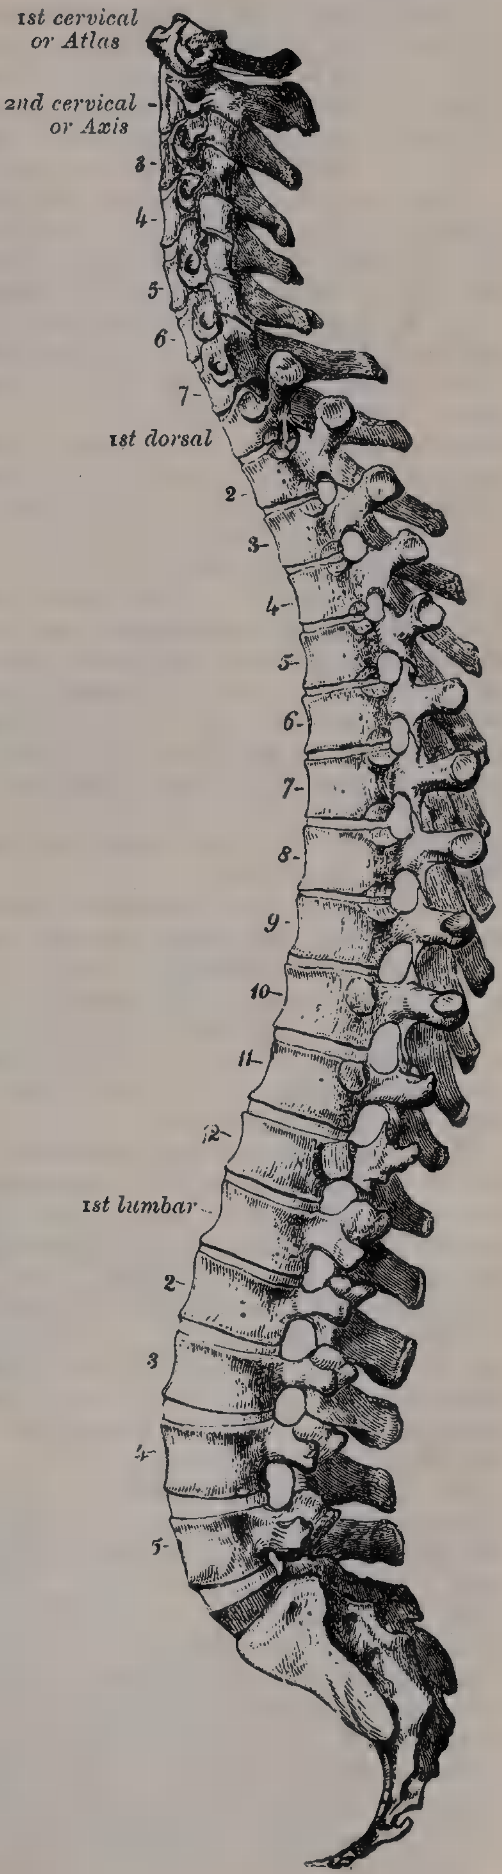
Development.—The coccyx is developed by *four* centres, one for each piece. Occasionally one of the first three pieces of this bone is developed by two centres,

placed side by side. The ossific nuclei make their appearance in the following order: in the first segment, shortly after birth; in the second piece, at from five to ten years; in the third, from ten to fifteen years; in the fourth, from fifteen to twenty years. As age advances, these various segments become united with each other from below upwards, the union between the first and second segments being frequently delayed until after the age of twenty-five or thirty. At a late period of life, especially in females, the coccyx often becomes joined to the end of the sacrum.

Articulation.—With the sacrum.

Attachment of Muscles. — To four pairs and one single muscle: on either side, the Coccygeus; behind, the Gluteus maximus and Extensor coccygis, when present; at the apex, the Sphincter ani; and in front, the Levator ani.

Fig. 213.—Lateral view of the spine.



Of the Spine in general

The **Spinal Column,** formed by the junction of the vertebræ, is situated in the median line, at the posterior part of the trunk; its average length in the male is about two feet four inches. Of this length the cervical part measures about five inches, the dorsal about eleven, the lumbar about seven, and the sacrum and coccyx about five. The female spine is about two feet in length.

Viewed from in front, the width of the bodies of the vertebræ will be found to increase from the second cervical to the first dorsal; there is then a slight diminution in the next three vertebræ; below this there is again a gradual and progressive increase in width as low as the sacro-vertebral angle. From this point there is a rapid diminution, terminating below at the apex of the coccyx.

Viewed laterally (fig. 213), the spinal column presents several curves, which correspond to the different regions of the column, and are called *cervical, dorsal, lumbar*, and *pelvic*. The *cervical* curve commences at the apex of the odontoid process, and terminates at the middle of the second dorsal vertebra; it is convex in front, and is the least marked of all the curves. The *dorsal* curve, which is concave forwards, commences at the middle of the second and terminates at the middle of the twelfth dorsal vertebra. Its most prominent point behind corresponds to the spine of the seventh dorsal. The *lumbar* curve is more marked in the female than in the male;

it commences at the middle of the last dorsal vertebra, and terminates at the sacro-vertebral angle. It is convex anteriorly; the convexity of the lower three vertebræ being much greater than that of the upper two. The *pelvic* curve commences at the sacro-vertebral articulation, and terminates at the point of the coccyx. It is concave anteriorly. The dorsal and pelvic curves are the primary curves, and begin to be formed about the fourth month of fœtal life. The cervical and lumbar curves are compensatory or secondary, and are developed after birth in order to maintain the erect position.

If a body is enveloped in plaster of Paris and a vertical section in the median line is made, it will be found, as pointed out by Humphry, that a plumb-line dropped from the middle of the odontoid process of the axis will pass through the middle of the body of the second dorsal vertebra, through the middle of the body of the last dorsal, through the middle and anterior-inferior edge of the last lumbar, and bisects a line drawn transversely through the heads of the thigh bones. It is known from experiment that the line of gravity of the head passes through the middle of the odontoid process; it therefore follows that the line of gravity of the head passes through the points of confluence of the three superior curves of the spine and through the heads of the thigh bones, so that the weight of the skull and its contents is directly transmitted to the pelvis and lower extremities when the body is in the erect position.

The spine has also a slight *lateral* curvature, the convexity of which is directed towards the right side. This may be produced, as Bichat first explained, chiefly by muscular action; most persons using the right arm in preference to the left, especially in making long-continued efforts, when the body is curved to the right side. In support of this explanation, it has been found, by Béclard, that in one or two individuals who were left-handed, the lateral curvature was directed to the left side. Others regard this curvature as being produced by the aortic arch and upper part of the thoracic aorta—a view which is supported by the fact that in cases where the viscera are transposed and the aorta is on the right side, the convexity of the lateral curvature is directed to the left side.

The movable part of the spinal column presents for examination an anterior, a posterior, and two lateral surfaces: a base, summit, and spinal canal.

The **anterior surface** presents the bodies of the vertebræ joined to each other in the recent state by the intervertebral discs. The bodies are broad in the cervical region, narrow in the upper part of the dorsal, and broadest in the lumbar region. The whole of this surface is convex transversely, concave from above downwards in the dorsal region, and convex in the same direction in the cervical and lumbar regions.

The **posterior surface** presents in the median line the spinous processes. In the cervical region these are short, horizontal, with bifid extremities. In the dorsal region, they are directed obliquely above, assume almost a vertical direction in the middle, and are horizontal, with a slight inclination downwards, below, as are also the spines of the lumbar vertebræ. They are separated by considerable intervals in the loins, by narrower intervals in the neck, and are closely approximated in the middle of the dorsal region. Occasionally one of these processes deviates a little from the median line—a fact to be remembered in practice, as irregularities of this sort are attendant also on fractures or displacements of the spine. On either side of the spinous processes, extending the whole length of the column, is the *vertebral groove* formed by the laminæ in the cervical and lumbar regions, where it is shallow, and by the laminæ and transverse processes in the dorsal region, where it is deep and broad. In the recent state, these grooves lodge the deep muscles of the back. External to the vertebral grooves are the articular processes, and still more externally the transverse processes. In the dorsal region, the latter processes stand backwards, on a plane considerably posterior to the same processes in the cervical and lumbar regions. In the cervical region, the transverse processes are placed in front of the articular processes, and on the outer side of the pedicles, between the intervertebral foramina. In the dorsal region they are posterior to the pedicles, intervertebral foramina, and articular processes. In the lumbar, they are placed in front of the articular processes, but behind the intervertebral foramina.

The **lateral surfaces** are separated from the posterior by the articular processes

in the cervical and lumbar regions, and by the transverse processes in the dorsal. These surfaces present in front the sides of the bodies of the vertebræ, marked in the dorsal region by the facets for articulation with the heads of the ribs. More posteriorly are the intervertebral foramina, formed by the juxtaposition of the intervertebral notches, oval in shape, smallest in the cervical and upper part of the dorsal regions, and gradually increasing in size to the last lumbar. They are situated between the transverse processes in the neck, and in front of them in the thoracic and lumbar regions, and transmit the spinal nerves.

The **base** of that portion of the vertebral column which is formed by the twenty-four movable vertebræ consists of the under surface of the body of the fifth lumbar vertebra; and the **summit**, of the upper surface of the atlas.

The **vertebral** or **spinal canal** follows the different curves of the spine; it is largest in those regions in which the spine enjoys the greatest freedom of movement, as in the neck and loins, where it is wide and triangular; and narrow and rounded in the thoracic region, where motion is more limited.

Surface Form.—The only parts of the vertebral column which lie closely under the skin, and so directly influence surface form, are the apices of the spinous processes. These are always distinguishable at the bottom of a furrow, which, more or less evident, runs down the mesial line of the back from the external occipital protuberance above to the middle of the sacrum below. In the neck the furrow is broad, and terminates in a conspicuous projection, which is caused by the spinous processes of the seventh cervical vertebra (vertebra prominens) and the first dorsal, the latter being the more prominent of the two. Above this the spinous process of the sixth cervical vertebra may sometimes be seen to form a projection; the other cervical spines are sunken, and are not visible, though the spine of the axis can be felt, and generally also the spines of the third, fourth, and fifth cervical vertebræ. In the dorsal region, the furrow is shallow, and during stooping disappears, and then the spinous processes become more or less visible. The markings produced by these spines are small and close together. In the lumbar region the furrow is deep, and the situation of the lumbar spines is frequently indicated by little pits or depressions, especially if the muscles in the loins are well developed and the spine incurved. They are much larger and farther apart than in the dorsal region. In the sacral region the furrow is shallower, presenting a flattened area which terminates below at the most prominent part of the posterior surface of the sacrum, formed by the spinous process of the third sacral vertebra. At the bottom of the furrow may be felt the irregular posterior surface of the bone. Below this, in the deep groove leading to the anus, the coccyx may be felt. In order to identify any particular spine it is customary to count from the prominence caused by the seventh cervical and first dorsal spines; of these two, the spine of the first dorsal is the more prominent. It is useful, however, to bear in mind that the root of the spine of the scapula is on a level with the interval between the spines of the third and fourth dorsal vertebræ; the apex or inferior angle of the scapula is on a level with the interval between the spines of the seventh and eighth dorsal; the highest point of the crest of the ilium corresponds to the fourth lumbar spine, and the posterior superior spine of the ilium corresponds to the second sacral spine. The only other portions of the vertebral column which can be felt from the surface are the transverse processes of three of the cervical vertebræ—viz. the first, the sixth, and the seventh. The transverse process of the atlas can be felt as a rounded nodule of bone just below and in front of the apex of the mastoid process, along the anterior border of the Sterno-mastoid. The transverse process of the sixth cervical vertebra is of surgical importance. If deep pressure be made in the neck, in the course of the carotid artery, opposite the cricoid cartilage, the prominent anterior tubercle of the transverse process of the sixth cervical vertebra can be felt. This has been named *Chassaignac's tubercle*, and against it the carotid artery may be most conveniently compressed by the finger. The transverse process of the seventh cervical vertebra can also be often felt. Sometimes the anterior root, or costal process, is large and segmented off, forming a cervical rib.

Surgical Anatomy.—Occasionally the coalescence of the laminæ is not completed, and consequently a cleft is left in the arches of the vertebræ, through which a protrusion of the spinal membranes (dura mater and arachnoid), and generally of the spinal cord itself, takes place, constituting the malformation known as *spina bifida*. This condition is most common in the lumbo-sacral region, but it may occur in the dorsal or cervical region, or the arches throughout the whole length of the canal may remain unapproximated. In some rare cases, in consequence of the non-coalescence of the two primary centres from which the body is formed, a similar condition may occur in front of the canal, the bodies of the vertebræ being found cleft and the tumour projecting into the thorax, abdomen, or pelvis, between the lateral halves of the bodies affected.

The construction of the spinal column of a number of pieces, securely connected together and enjoying only a slight degree of movement between any two individual pieces, but permitting of a very considerable range of movement as a whole, allows a sufficient degree

of mobility without any material diminution of strength. The many joints of which the spine is composed, together with the very varied movements to which it is subjected, render it liable to sprains; but so closely are the individual vertebræ articulated that these sprains are rarely or ever severe, and an amount of violence sufficiently great to produce tearing of the ligaments would tend rather to cause a dislocation or fracture. The further safety of the column and its slight liability to injury is provided for by its disposition in curves, instead of in one straight line. For it is an elastic column, and must first bend before it breaks; under these circumstances, being made up of three curves, it represents three columns, and greater force is required to produce bending of a short column, than of a longer one that is equal to it in breadth and material. Again, the safety of the column is provided for by the interposition of the intervertebral discs between the bodies of the vertebræ, which act as admirable buffers in counteracting the effects of violent jars or shocks. Fracture-dislocation of the spine may be caused by direct or indirect violence or by a combination of the two, as when a person, falling from a height, strikes against some prominence and is doubled over it. The fractures from indirect violence are the more common, and here the bodies of the vertebræ are compressed, while the arches are torn asunder; in fracture from direct violence, on the other hand, the arches are compressed and the bodies of the vertebræ separated from each other. It will therefore be seen that in both classes of injury the spinal marrow is the part least likely to be injured, and may escape damage even where there has been considerable lesion of the bony framework. For, as Mr. Jacobson states, 'being lodged in the centre of the column, it occupies neutral ground in respect to forces which might cause fracture. For it is a law in mechanics that when a beam, as of timber, is exposed to breakage and the force does not exceed the limits of the strength of the material, one division resists compression, another laceration of the particles, while the third, between the two, is in a negative condition.'* Applying this principle to the spine, it will be seen that, whether the fracture-dislocation be produced by direct or indirect violence, one segment, either the anterior or posterior, will be exposed to compression, the other to laceration, and the intermediate part, where the cord is situated, will be in a neutral state. When a fracture-dislocation is produced by indirect violence, the displacement is almost always the same; the upper segment being driven forwards on the lower, so that the cord is compressed between the body of the vertebra below and the arch of the vertebra above.

The parts of the spine most liable to be injured are: (1) the junction of the dorsal with the lumbar region, including the last two dorsal and the upper two lumbar vertebræ, for this part is near the middle of the column and there is therefore a greater amount of leverage, and moreover the portion above is comparatively fixed, and the vertebræ which form this portion of the column, though smaller than those below, have nevertheless to bear almost as great a weight; (2) the cervico-dorsal region, because here the flexible cervical portion of the spine joins the more fixed dorsal region; and (3) the atlanto-axial region, because it enjoys an extensive range of movement, and, being near the skull, is influenced by violence applied to the head.

In fracture-dislocation it has been proposed to cut down and expose the injured bones, in order to facilitate replacement and remove pressure from the spinal cord; and much controversy has arisen as to the value of this operation. The rule for the guidance of the surgeon in these cases appears to be as follows: If there is evidence of complete destruction or division of the spinal cord at the seat of lesion, the operation is practically useless; but if there seems to be any probability that a portion of the cord has escaped, an operation is indicated, on the chance that when pressure has been removed, a sufficient quantity of the substance of the cord may remain intact to allow of its carrying on its functions to a certain extent. Laminectomy is also performed in other classes of cases: (1) where the laminæ have been driven in by direct violence; (2) where paraplegia supervenes after an appreciable interval since the injury, and is therefore probably due to the effusion of blood or inflammatory exudation; (3) where paraplegia occurs in cases of spinal caries, if the paraplegic symptoms persist for a long period, or threaten life from intractable cystitis or bed-sores.

THE SKULL

The **Skull** or **Cranium** (*κράνος, a helmet*) is supported on the summit of the vertebral column, and is of an oval shape, wider behind than in front. It is composed of a series of flattened or irregular bones which, with one exception (the lower jaw), are immovably jointed together. It consists of two parts: (1) the Brain-case (cranium cerebrale), which encloses and protects the brain; and (2) the skeleton of the Face (cranium viscerale). The Brain-case is composed of *eight* bones—viz. the *occipital*, two *parietal*, *frontal*, two *temporal*, *sphenoid*, and *ethmoid*. The Face is composed of *fourteen* bones—viz. the two *nasal*, two *superior maxillary*, two *lachrymal*, two *malar*, two *palate*, two *inferior turbinated*, *vomer*,

* Holmes's *System of Surgery*, vol. i. p. 529. 1883.

and *inferior maxillary.* The *ossicula auditûs*, the *teeth*, and *Wormian bones* are not included in this enumeration.

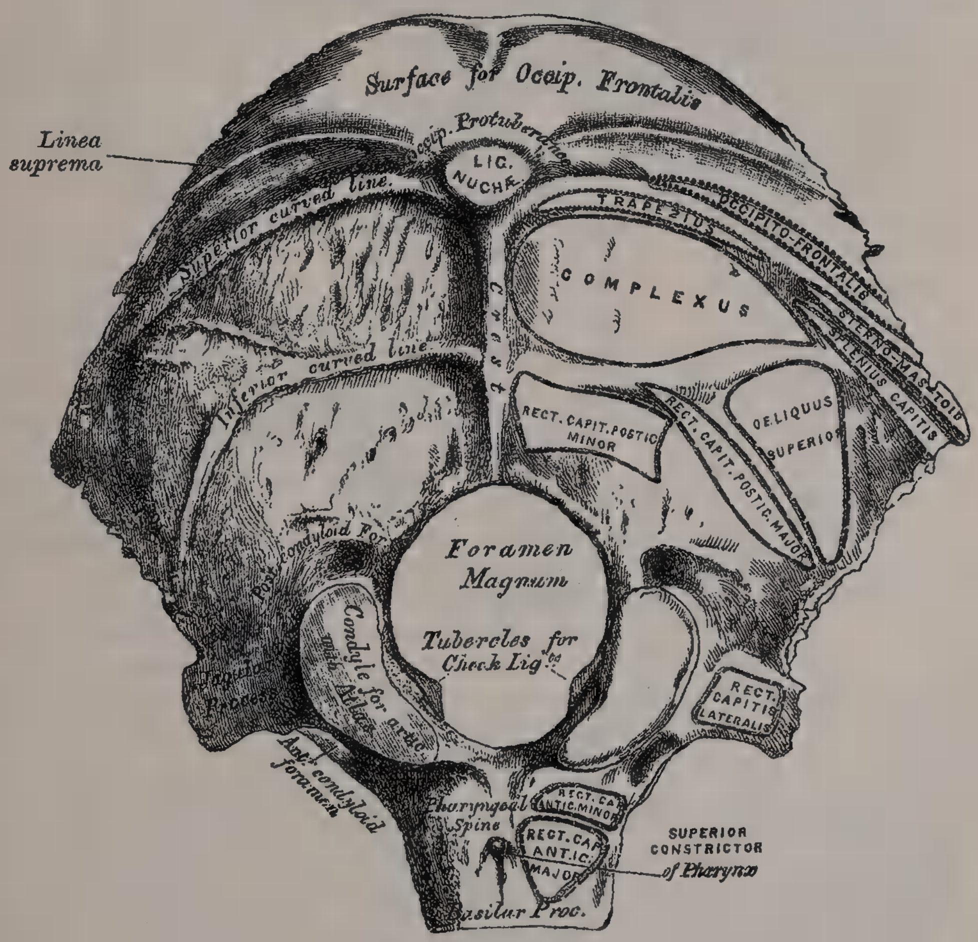
Skull, 22 bones
- *Brain-case, 8 bones*
  - Occipital.
  - Two Parietal.
  - Frontal.
  - Two Temporal.
  - Sphenoid.
  - Ethmoid.
- *Face, 14 bones*
  - Two Nasal.
  - Two Superior Maxillary.
  - Two Lachrymal.
  - Two Malar.
  - Two Palate.
  - Two Inferior Turbinated.
  - Vomer.
  - Inferior Maxillary.

The Hyoid bone, situated at the root of the tongue and attached to the base of the skull by ligaments, has also to be considered in this section.

The Occipital Bone

The **Occipital Bone** (ob, caput, *against the head*) is situated at the back part and base of the cranium. It is trapezoid in shape and is much curved on itself (fig. 214). It presents at its front and lower part a large oval aperture, the

Fig. 214.—Occipital bone. Outer surface.



foramen magnum, by which the cranial cavity communicates with the spinal canal. The portion of bone behind this opening is curved and expanded and forms the *tabula*; the portion in front is a thick, elongated mass of bone, the *basilar process*; while on either side of the foramen are situated the *lateral* or

condylic portions, bearing the condyles, by which the bone articulates with the atlas. It presents for examination two surfaces, four borders, and four angles.

The **external surface** is convex. Midway between the summit of the bone and the posterior margin of the foramen magnum is a prominent tubercle, the *inion* or *external occipital protuberance*, and descending from it as far as the foramen, a vertical ridge, the *external occipital crest*. This protuberance and crest give attachment to the Ligamentum nuchæ, and vary in prominence in different skulls. Passing outwards from the occipital protuberance is a semicircular ridge on each side, the *superior curved line*. Above this line there is often a second less distinctly marked ridge, called the *highest curved line* (*linea suprema*), to which the epicranial aponeurosis is attached. The bone between these two lines is smoother and denser than the rest of the surface. Running parallel with these from the middle of the crest is another semicircular ridge on each side, the *inferior curved line*. The surface of the bone above the linea suprema is rough and porous, and, in the recent state, is covered by the Occipito-frontalis muscle, while the superior and inferior curved lines, together with the surfaces of bone between and below them, serve for the attachment of several muscles. The superior curved line gives attachment internally to the Trapezius, externally to the muscular origin of the Occipito-frontalis, and to the Sterno-cleido-mastoid to the extent shown in fig. 214; the depressions between the curved lines to the Complexus internally, the Splenius capitis and Obliquus capitis superior externally. The inferior curved line, and the depressions below it, afford insertion to the Rectus capitis posticus, major and minor.

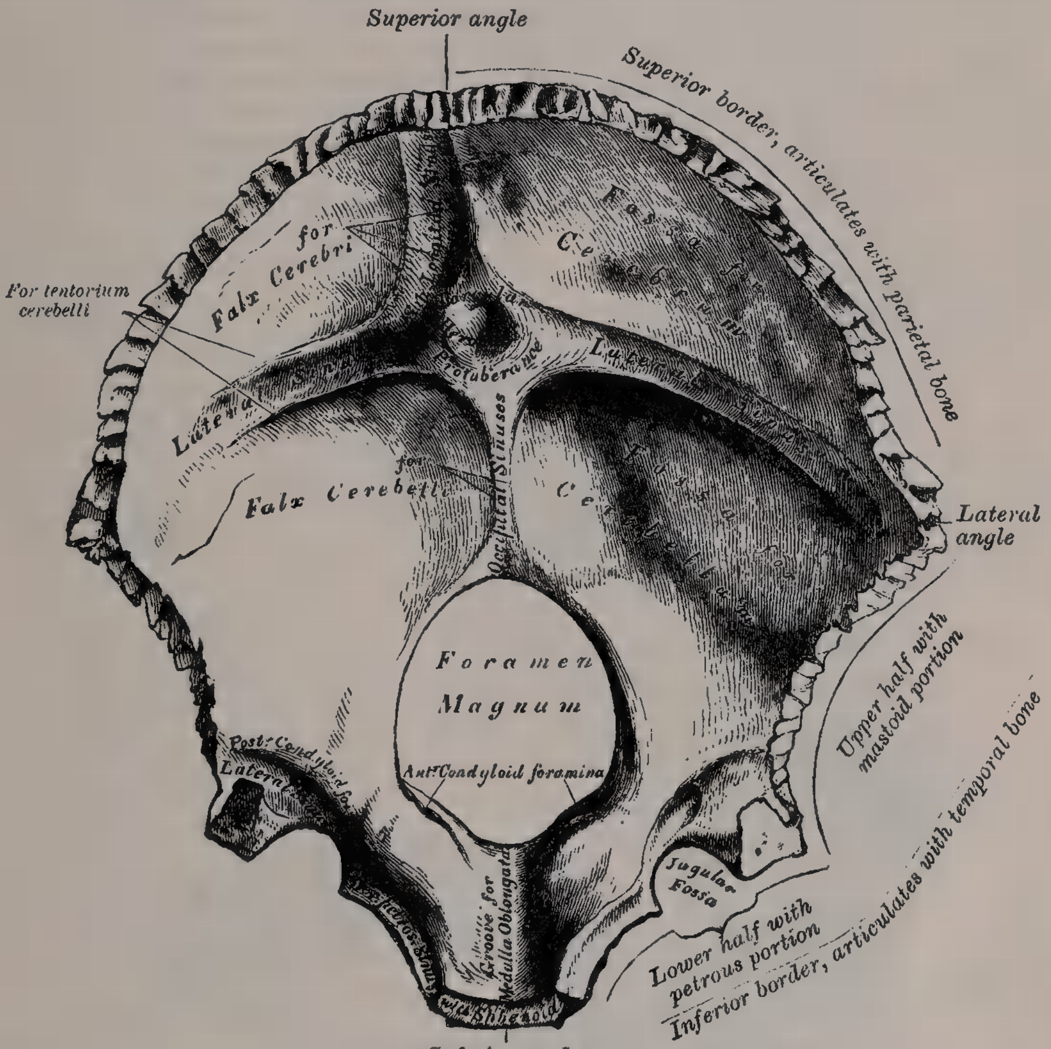
The **foramen magnum** is a large, oval aperture, its long diameter extending from before backwards. It transmits the medulla oblongata and its membranes, the spinal accessory nerves, the vertebral arteries, the anterior and posterior spinal arteries, and the occipito-axial ligaments. Its back part is wide for the transmission of the medulla, and the corresponding margin rough for the attachment of the dura mater enclosing it; the fore part is narrower, being encroached upon by the condyles; it has projecting towards it, from below, the odontoid process, and its margins are smooth and bevelled internally to support the medulla oblongata. The point corresponding with the middle of its anterior margin is termed the *basion*; that corresponding with the middle of its posterior margin is named the *opisthion*. On each side of the foramen magnum are the *condyles*, for articulation with the atlas; they are convex, oval or reniform in shape, and directed downwards and outwards; they converge in front, and encroach slightly upon the anterior segment of the foramen. On the inner border of each condyle is a rough tubercle for the attachment of the check ligaments which connect this bone with the odontoid process of the axis; while external to them is a rough tubercular prominence, the *jugular process*, channelled in front by a deep notch, which forms part of the jugular foramen, or foramen lacerum posterius. This notch is frequently bisected by a projection of bone, the *intrajugular process*, which curves outwards from the margin of the notch. The under surface of this process presents an eminence, which represents the *paramastoid process* of some mammals. This eminence is occasionally large, and extends as low as the transverse process of the atlas. This surface affords attachment to the Rectus capitis lateralis muscle and to the lateral occipito-atlantal ligament; its upper or cerebral surface presents a deep groove which lodges part of the lateral sinus, while its external surface is marked by a quadrilateral rough facet, covered with cartilage in the fresh state, and articulating with a similar surface on the petrous portion of the temporal bone. On the outer side of each condyle, near its fore part, is a foramen, the *anterior condyloid*; it is directed downwards, outwards, and forwards, and transmits the hypoglossal nerve, and occasionally a meningeal branch of the ascending pharyngeal artery. This foramen is sometimes double. Behind each condyle is a fossa,* occasionally perforated at the bottom by a foramen, the *posterior condyloid*, for the transmission of a vein to the lateral sinus. In front of the foramen magnum is a strong quadrilateral plate of bone, the *basilar process*, wider behind than in front; its under surface, which is rough, presenting in the median line

* This fossa presents many variations in size. It is usually shallow, and the foramen small; occasionally wanting on one or both sides. Sometimes both fossa and foramen are large, but confined to one side only; more rarely, the fossa and foramen are very large on both sides.

a tubercular ridge, the *pharyngeal spine*, for the attachment of the tendinous raphe and Superior constrictor of the pharynx; and on each side of it, rough depressions for the attachment of the Rectus capitis anticus, major and minor.

The **Internal** or **Cerebral Surface** (fig. 215) is deeply concave. The posterior part or tabula is divided by a crucial ridge into four fossæ. The two superior fossæ receive the occipital lobes of the cerebrum, and present slight depressions corresponding to their convolutions. The two inferior, which receive the hemispheres of the cerebellum, are larger than the former, and comparatively smooth; both are marked by slight grooves for the lodgment of arteries. At the point of meeting of the four divisions of the crucial ridge is an eminence, the *internal occipital protuberance*. It nearly corresponds to that on the outer surface, and is perforated by one or more large vascular foramina. From this eminence, the

FIG. 215.—Occipital bone. Inner surface.



superior division of the crucial ridge runs upwards to the superior angle of the bone; on one side, generally the right, it presents a deep groove for the superior longitudinal sinus, the margins of which give attachment to the falx cerebri. The inferior division, the *internal occipital crest*, runs to the posterior margin of the foramen magnum, on the edge of which it becomes gradually lost; this ridge, which is bifurcated below, serves for the attachment of the falx cerebelli. It is usually marked by a single groove, which commences at the back part of the foramen magnum and lodges the occipital sinus. Occasionally two sinuses exist, and the groove is then double. The transverse grooves pass outwards to the lateral angles; they are deeply channelled, for the lodgment of the lateral sinuses, their prominent margins affording attachment to the tentorium cerebelli.* At

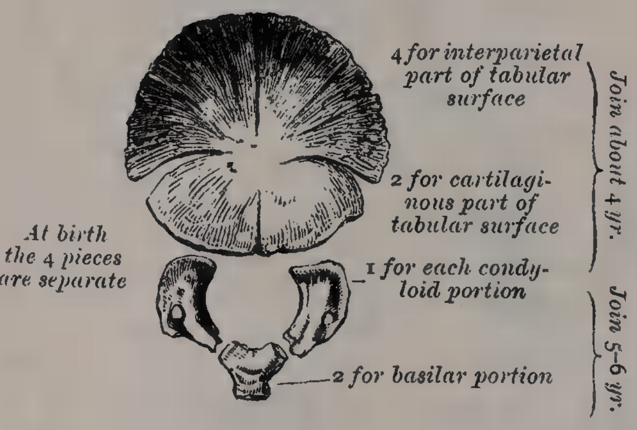
* Usually one of the transverse grooves is deeper and broader than the other: occasionally, both grooves are of equal depth and breadth, or both equally indistinct. The

the point of meeting of these grooves is a depression, the *torcular Herophili*,* placed a little to one or the other side of the internal occipital protuberance. More anteriorly is the foramen magnum, and on each side of it, but nearer its anterior than its posterior part, the internal opening of the anterior condyloid foramen; the internal openings of the posterior condyloid foramina are a little external and posterior, protected by a small arch of bone. At this part of the internal surface there is a very deep groove, in which the posterior condyloid foramen, when it exists, has its termination. This groove is continuous, in the complete skull, with the transverse groove on the posterior part of the bone, and lodges the end of the same sinus, the lateral. In front of the foramen magnum is the basilar process, presenting a shallow depression, the *basilar groove*, which slopes from behind, upwards and forwards, and supports the medulla oblongata and part of the pons Varolii, and on each side of the basilar process is a narrow channel, which, when united with a similar channel on the petrous portion of the temporal bone, forms a groove, which lodges the inferior petrosal sinus.

Angles.—The *superior* angle is received into the interval between the posterior superior angles of the two parietal bones: it corresponds with that part of the skull in the fœtus which is called the *posterior fontanelle*. The *inferior* angle is represented by the square-shaped surface of the basilar process. At an early period of life, a layer of cartilage separates this part of the bone from the sphenoid; but in the adult, the union between them is osseous. The *lateral* angles correspond to the outer ends of the transverse grooves, and are received into the interval between the posterior inferior angles of the parietal and the mastoid portion of the temporal.

Borders.—The *superior* border extends on each side from the superior to the lateral angle, is deeply serrated for articulation with the parietal bone, and forms, by this union, the lambdoid suture; the *inferior* border extends from the lateral to the inferior angle; its upper half is rough, and articulates with the mastoid portion of the temporal, forming the masto-occipital suture; the lower half articulates with the petrous portion of the temporal, forming the petro-occipital suture; these two portions are separated from one another by the jugular process. In front of this process is a deep notch, which, with a similar one on the petrous portion of the temporal, forms the *foramen lacerum posterius* or *jugular foramen*.

Fig. 216.—Development of occipital bone. Usually by seven centres.



Structure.—The occipital bone consists of two compact laminæ, called the *outer* and *inner tables*, having between them the diploic tissue; this bone is especially thick at the ridges, protuberances, condyles, and anterior part of the basilar process; while at the bottom of the fossæ, especially the inferior, it is thin, semi-transparent, and destitute of diploë.

Development (fig. 216).—At birth the bone consists of four distinct parts: a *tabular* or expanded portion, which lies behind the foramen magnum; two *condylar* parts, which form the sides of the foramen; and a *basilar* part, which lies in front of the foramen. The upper portion of the tabular surface—that is to say, the portion above the level of the external occipital protuberance—is developed from membrane, and may remain separated from the rest of the bone throughout life when it constitutes the *interparietal* bone; the rest of the bone is developed from cartilage. The number of nuclei for the interparietal part of the tabular portion, which is developed from membrane, varies from two to four. They appear about the thirteenth week and coalesce about the fifteenth. The

broader of the two transverse grooves is nearly always continuous with the vertical groove for the superior longitudinal sinus.

* The columns of blood coming in different directions were supposed to be *pressed* together at this point (*torcular*, a wine-press).

cartilaginous portion of the tabular part begins to ossify from two centres, which appear about the seventh week of fœtal life and soon unite to form a single piece. Union of the upper and lower portions takes place about the third or fourth month. Each of the condylar parts begins to ossify from a single centre about the end of the eighth week. The basilar portion is ossified from two centres, one placed in front of the other. These appear about the sixth week and rapidly coalesce, so that the ossification from one centre is frequently described. About the fourth year, the tabular and the two condyloid pieces join; and about the sixth year, the bone consists of a single piece. At a later period, between the eighteenth and twenty-fifth years, the occipital and sphenoid become united, forming a single bone.

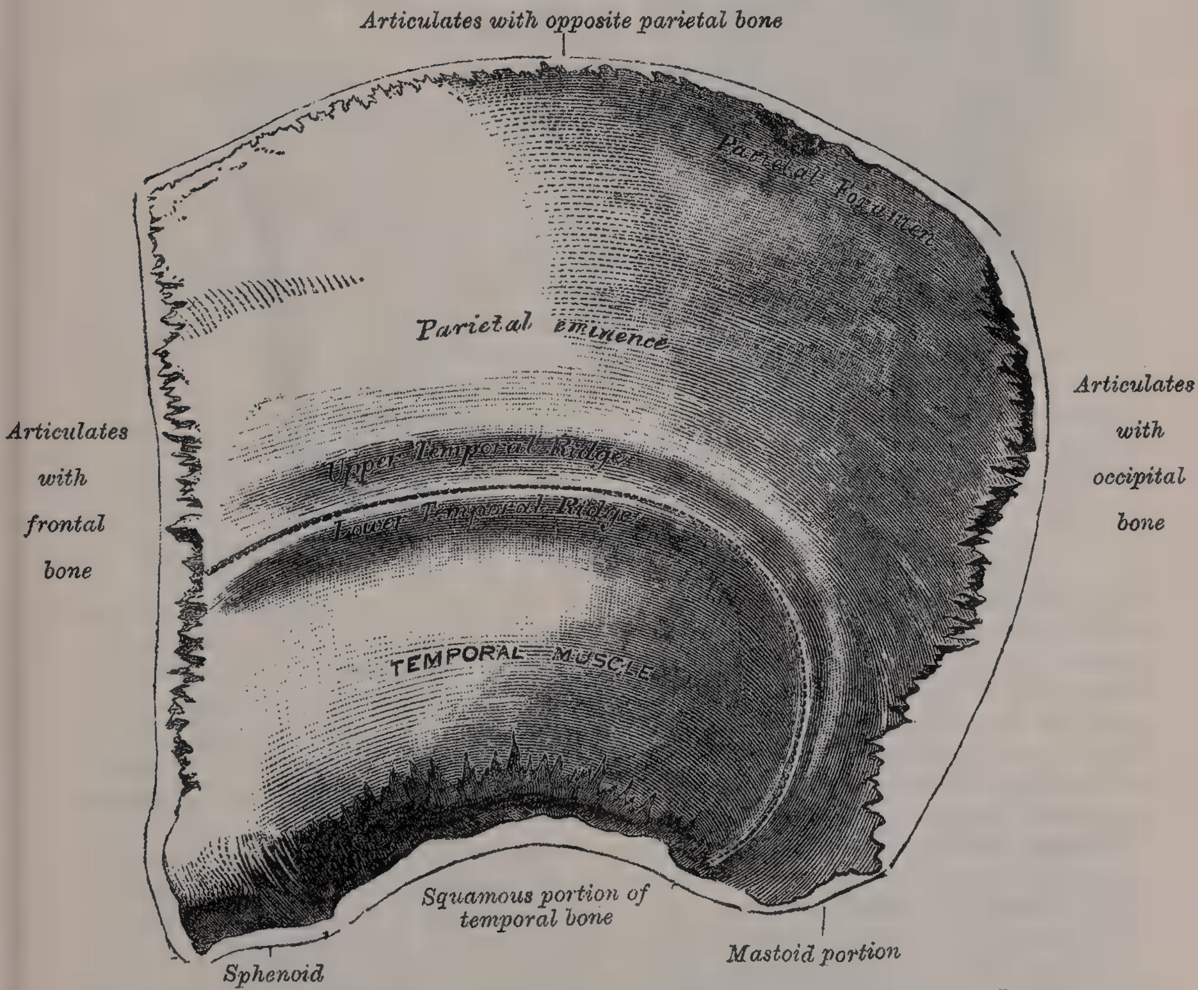
Articulations.—With six bones: two parietal, two temporal, sphenoid, and atlas.

Attachment of Muscles.—To twelve pairs; to the superior curved line are attached the Occipito-frontalis, Trapezius, and Sterno-cleido-mastoid. To the space between the curved lines, the Complexus,* Splenius capitis, and Obliquus capitis superior; to the inferior curved line, and the space between it and the foramen magnum, the Rectus capitis posticus, major and minor; to the transverse process, the Rectus capitis lateralis; and to the basilar process, the Rectus capitis anticus, major and minor, and the Superior constrictor of the pharynx.

The Parietal Bones

The **Parietal Bones** (paries, *a wall*) form, by their union, the sides and roof of the skull. Each bone is of an irregular quadrilateral form, and presents for examination two surfaces, four borders, and four angles.

Fig. 217.—Left parietal bone. External surface.



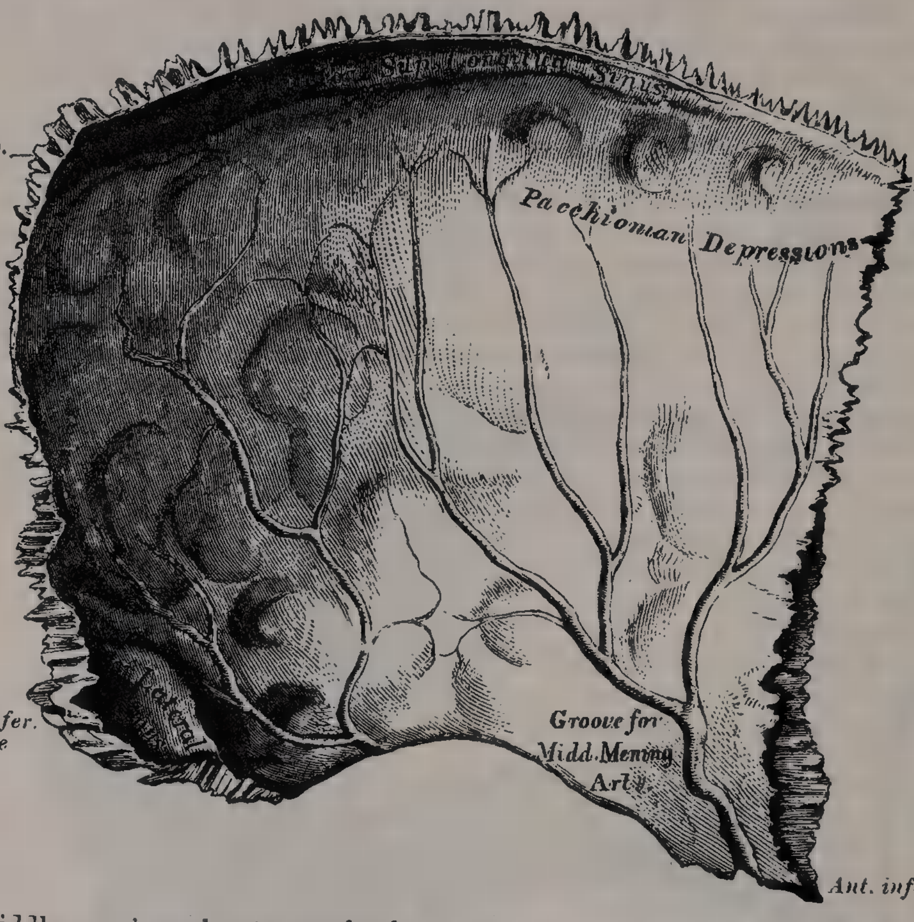
Surfaces.—The *external surface* (fig. 217) is convex, smooth, and marked about its centre by an eminence, called the *parietal eminence*, which indicates the

* To these the Biventer cervicis should be added, if it is regarded as a separate muscle.

point where ossification commenced. Crossing the middle of the bone in an arched direction are two well-marked curved lines or ridges, the *upper* and *lower temporal ridges*; the former gives attachment to the temporal fascia, while the latter indicates the upper limit of the origin of the temporal muscle. Above these ridges, the surface of the bone is rough and porous, and covered by the aponeurosis of the Occipito-frontalis; between them the bone is smoother and more polished than the rest; below them the bone forms part of the temporal fossa, and affords attachment to the Temporal muscle. At the back part of the superior border, close to the sagittal suture, is a small foramen, the *parietal foramen*, which transmits a vein to the superior longitudinal sinus, and sometimes a small branch of the occipital artery. Its existence is not constant, and its size varies considerably.

The **internal surface** (fig. 218) is concave; it presents depressions for lodging the convolutions of the cerebrum, and numerous furrows for the ramifications of

FIG. 218.—Left parietal bone. Internal surface.



the middle meningeal artery; the latter run upwards and backwards from the anterior inferior angle, and from the central and posterior part of the lower border of the bone. Along the upper margin is part of a shallow groove, which, when joined to the opposite parietal, forms a channel for the superior longitudinal sinus, the elevated edges of which afford attachment to the falx cerebri. Near the groove are seen several depressions, especially in the skulls of old persons; they lodge the Pacchionian bodies. The internal opening of the parietal foramen is also seen when that aperture exists.

Borders.—The *superior*, the longest and thickest, is dentated to articulate with its fellow of the opposite side, forming the sagittal suture. The *inferior* is divided into three parts: of these, the anterior is thin and pointed, bevelled at the expense of the outer surface, and overlapped by the tip of the great wing of the sphenoid; the middle portion is arched, bevelled at the expense of the outer surface, and overlapped by the squamous portion of the temporal; the posterior portion is thick and serrated for articulation with the mastoid portion of the temporal. The *anterior* border, deeply serrated, is bevelled at the expense of the outer surface above and of the inner below; it articulates with the frontal bone,

forming the *coronal suture*. The *posterior* border, deeply denticulated, articulates with the occipital, forming the *lambdoid suture*.

Angles.—The *anterior superior* angle, thin and pointed, corresponds with the union of the sagittal and coronal sutures; this point is named the *bregma*. This region in the fœtal skull is membranous, and is called the *anterior fontanelle*. The *anterior inferior* angle is thin and lengthened, being received in the interval between the great wing of the sphenoid and the frontal. Its inner surface is marked by a deep groove, sometimes a canal, for the anterior branch of the middle meningeal artery. The *posterior superior* angle corresponds with the point of junction of the sagittal and lambdoid sutures—a point which is termed the *lambda*. In the fœtus this part of the skull is membranous, and is called the *posterior fontanelle*. The *posterior inferior* angle articulates with the mastoid portion of the temporal bone, and generally presents on its inner surface a broad, shallow groove which lodges part of the lateral sinus. The point of union of the posterior inferior angle of the parietal with the occipital and mastoid part of the temporal is named the *asterion*.

Development.—The parietal bone is formed in membrane, being developed by one centre, which appears at the parietal eminence about the seventh or eighth week of fœtal life. Ossification gradually extends from the centre to the circumference of the bone: the angles are consequently the parts last formed, and it is here that the fontanelles exist previous to the completion of the growth of the bone. Occasionally the parietal bone is divided into two parts, upper and lower, by an antero-posterior suture.

Articulations.—With five bones: the opposite parietal, the occipital, frontal, temporal, and sphenoid.

Attachment of Muscles.—One only, the Temporal.

The Frontal Bone

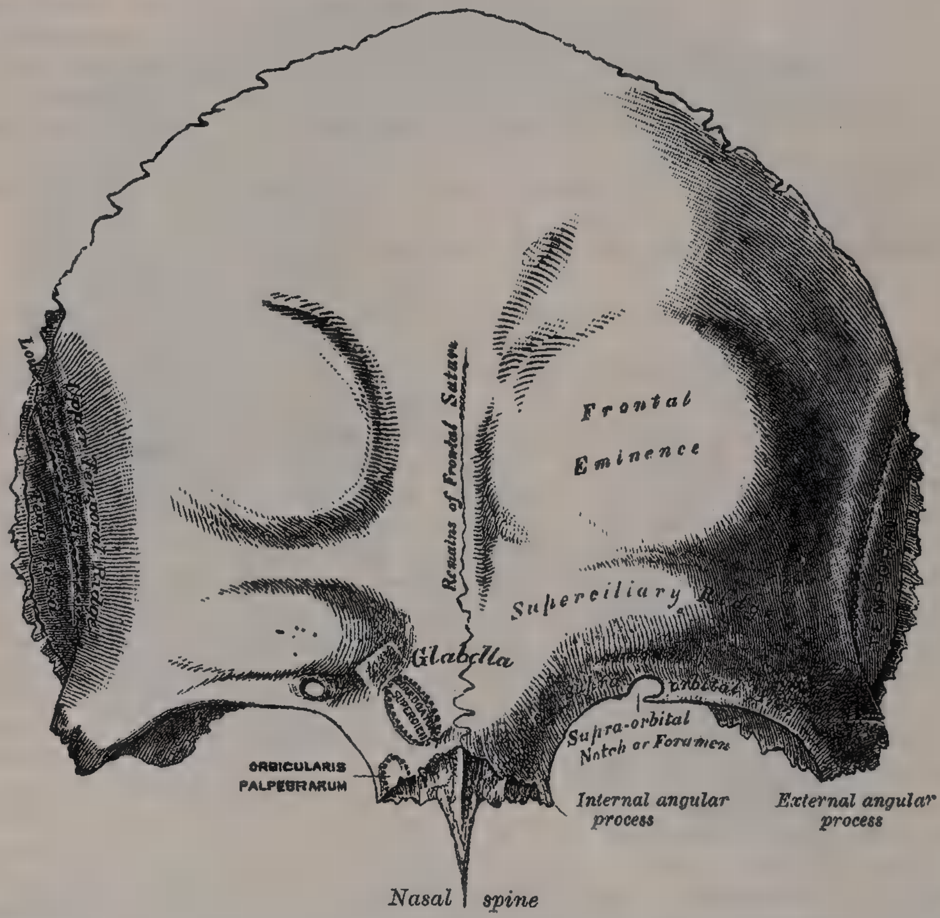
The **Frontal Bone** (frons, *the forehead*) resembles a cockle-shell in form, and consists of two portions—a *vertical* or *frontal* portion situated at the anterior part of the cranium, forming the forehead; and a *horizontal* or *orbito-nasal* portion which enters into the formation of the roof of the orbits and nasal fossæ.

Vertical Portion.—*External Surface* (fig. 219).—In the median line, traversing the lower part of the bone, may occasionally be seen the remains of the suture which represents the line of union of the two parts of which the bone consists at an early period of life. This is well marked in young subjects, but usually becomes obliterated in adult life, except at the lower part, where traces of it may sometimes remain. It is termed the *frontal* (metopic) suture. On either side of this suture, a little below the centre of the bone, is a rounded eminence, the *frontal eminence*. These eminences vary in size in different individuals, are occasionally unsymmetrical, and are especially prominent in cases of well-marked cerebral development. The whole surface of the bone above this part is smooth, and covered by the aponeurosis of the Occipito-frontalis muscle. Below the frontal eminence, and separated from it by a shallow groove, is the *superciliary ridge*, broad internally, where it is continuous with the nasal eminence, but less distinct as it arches outwards. These ridges are, in most cases, caused by the projection outwards of the frontal air sinuses,* are usually larger and more rounded in the male than the female, and give attachment to the Orbicularis palpebrarum and Corrugator supercilii. The degree of prominence of the superciliary ridges is not necessarily an index of the size of the frontal air sinuses, since in some cases the latter are large where the former are faintly marked. On the other hand, the ridges may be prominent, and the sinuses rudimentary or absent, as in the skull of the Maori. Between the two superciliary ridges is a smooth surface, the *glabella* or *nasal eminence*. Beneath the superciliary ridge is the *supra-orbital*

* Some confusion is occasioned to students commencing the study of anatomy by the name 'sinus' having been given to two perfectly different kinds of space connected with the skull. It may be as well, therefore, to state here, at the outset, that the 'sinuses' in the interior of the cranium which produce the grooves on the inner surface of the bones are venous channels along which the blood runs in its passage back from the brain, while the 'sinuses' external to the cranial cavity (the frontal, sphenoidal, ethmoidal, and maxillary) are hollow spaces in the bones themselves which communicate with the nostrils, and contain air.

arch, a curved and prominent margin, which forms the upper boundary of the orbit, and separates the vertical from the horizontal portion of the bone. The outer part of the arch is sharp and prominent, affording to the eye, in that situation, considerable protection from injury; the inner part is less prominent. At the junction of the internal and middle thirds of this arch is a notch, sometimes converted into a foramen, and called the *supra-orbital notch* or *foramen* It transmits the supra-orbital artery, vein, and nerve. A small aperture is seen in the upper part of the notch, which transmits a vein from the diploë to join the supra-orbital vein. The supra-orbital arch terminates externally in the *external angular process*, and internally in the *internal angular process.* The external angular process is strong, prominent, and articulates with the malar bone; running upwards and backwards from it are two well-marked lines, which, commencing together at the external angular process, soon diverge from each other and run in a curved direction across the bone. These are the *upper* and *lower temporal ridges*; the upper gives attachment to the temporal fascia, the

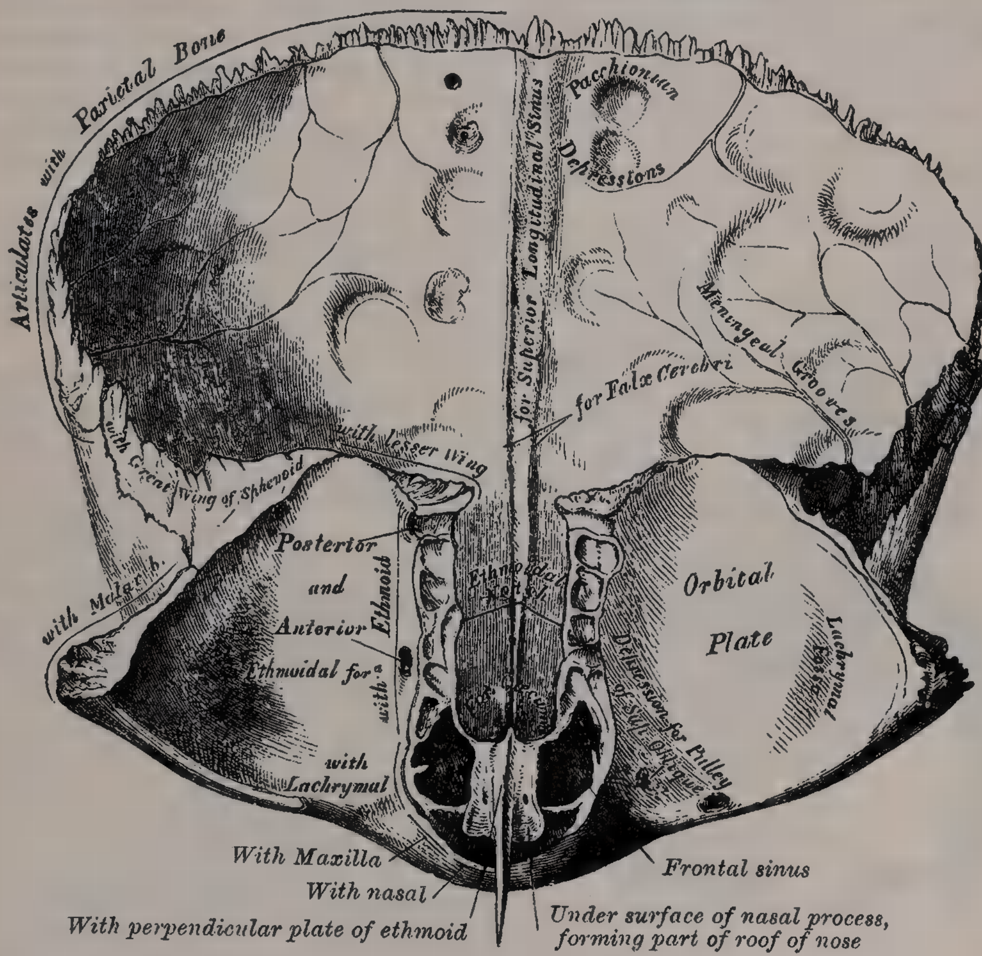
FIG. 219.—Frontal bone. Outer surface.



lower to the temporal muscle. Beneath them is a slight concavity, which forms the anterior part of the temporal fossa, and gives origin to the Temporal muscle. The internal angular processes are less marked than the external, but descend to a lower level, and articulate with the lachrymal bones. Between the internal angular processes is a rough, uneven interval, the *nasal notch*, which articulates in the middle line with the nasal bones, and on either side with the nasal process of the superior maxillary bone. The term *nasion* is applied to the middle of the fronto-nasal suture. From the centre of this notch projects a process, the *nasal process*, which extends beneath the nasal bones and nasal processes of the superior maxillary bones, and supports the bridge of the nose. The nasal process terminates below in a long pointed process, the *nasal spine*, and on either side of this is a small grooved surface which enters into the formation of the roof of the nasal fossa. The nasal spine forms part of the septum of the nose, articulating in front with the nasal bones and behind with the perpendicular plate of the ethmoid.

Internal Surface (fig. 220).—Along the middle line in the upper part of the bone is a vertical groove, the edges of which unite below to form a ridge, the *frontal crest*; the groove lodges the superior longitudinal sinus, while its margins and the crest afford attachment to the falx cerebri. The crest terminates below in a small notch which is converted into a foramen by articulation with the ethmoid. It is called the *foramen cæcum*, and varies in size in different subjects; it is sometimes impervious, and lodges a process of the falx cerebri; when open, it transmits a vein from the lining membrane of the nose to the superior longitudinal sinus. On either side of the groove the bone is deeply concave, presenting depressions for the convolutions of the brain, and numerous small furrows for lodging the ramifications of the anterior branches of the middle meningeal arteries. Several small, irregular fossæ are also seen on either side of the groove, for the reception of the Pacchionian bodies.

FIG. 220.—Frontal bone. Inner surface.



Horizontal Portion.—This portion of the bone consists of two thin plates, the *orbital plates*, which form the vaults of the orbits, and are separated from one another by a median gap, the *ethmoidal notch*.

The *external surface* of each orbital plate consists of a smooth, concave, triangular lamina of bone, marked at its anterior and external part (immediately beneath the external angular process) by a shallow depression, the *lachrymal fossa*, for lodging the lachrymal gland; and at its anterior and internal part, by a depression (sometimes a small tubercle), the *trochlear fossa*, for the attachment of the cartilaginous pulley of the Superior oblique muscle of the eyeball. The ethmoidal notch separates the two orbital plates; it is quadrilateral, and filled up, in the articulated skull, by the cribriform plate of the ethmoid. The margins of this notch present several half-cells, which, when united with corresponding half-cells on the upper surface of the ethmoid, complete the ethmoidal cells; two grooves are also seen crossing these edges transversely; they are converted into canals by articulation with the ethmoid, and are called the *anterior* and *posterior ethmoidal*

canals: they open on the inner wall of the orbit. The anterior one transmits the nasal nerve and anterior ethmoidal vessels, the posterior one the posterior ethmoidal vessels. In front of the ethmoidal notch, on either side of the nasal spine, are the openings of the frontal air sinuses. These are two irregular cavities, which extend backwards, upwards and outwards, a variable distance, between the two tables of the skull, and are separated from one another by a thin, bony septum, which is often displaced to one side. Absent at birth, they are usually fairly well developed between the ninth and twelfth years. These cavities vary in size in different persons, are larger in men than in women, and are frequently of unequal size on the two sides, the right being commonly the larger.* They are lined by mucous membrane, and communicate with the nose by the infundibulum. They rarely communicate with each other.

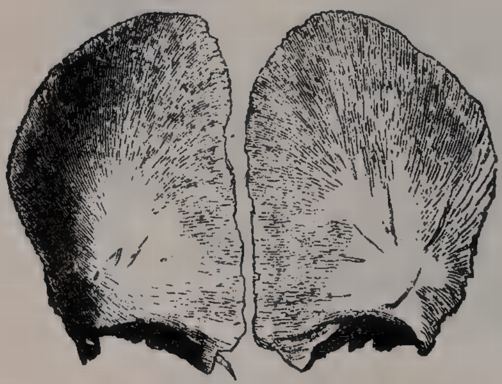
The *internal surface* presents the convex upper surfaces of the orbital plates, separated from each other in the middle line by the ethmoidal notch, and marked by depressions for the convolutions of the frontal lobes of the brain, and faint grooves for meningeal arteries derived from the ophthalmic.

Borders.—The border of the vertical portion is thick, strongly serrated, bevelled at the expense of the internal table above, where it rests upon the parietal bones, and at the expense of the external table at each side, where it receives the lateral pressure of those bones; this border is continued below into a triangular, rough surface, which articulates with the great wing of the sphenoid. The border of the horizontal portion is thin, serrated, and articulates with the lesser wing of the sphenoid.

Structure.—The vertical portion and external angular processes are very thick, consisting of diploic tissue and the frontal air sinuses contained between two compact laminæ. The horizontal portion is thin, translucent, and composed entirely of compact tissue; hence the facility with which instruments can penetrate the cranium through this part of the orbit.

Development (fig. 221).—The frontal bone is formed in membrane, being developed by *two* centres, one for each lateral half, which make their appearance about the seventh or eighth week, above the orbital arches. From this point ossification extends, in a radiating manner, upwards into the forehead, and backwards over the orbit. At birth the bone consists of two pieces, which afterwards become united, along the middle line, by a suture which runs from the vertex of the bone to the root of the nose. This suture usually becomes obliterated within a few years after birth; but it occasionally remains throughout life, constituting the *metopic* suture. Secondary centres of ossification may appear for the nasal spine; one on either side at the internal angular process where it articulates with the lachrymal bone; and sometimes there is one on either side at the lower end of the coronal suture. This latter centre may remain ununited, and is known as the *pterion ossicle*; or it may join with the parietal, sphenoid, or temporal bone.

Fig. 221.—Frontal bone at birth. Developed by two lateral halves.



Articulations.—With twelve bones: two parietal, the sphenoid, the ethmoid, two nasal, two superior maxillary, two lachrymal, and two malar.

Attachment of Muscles.—To three pairs: the Corrugator supercilii, Orbicularis palpebrarum, and Temporal on each side.

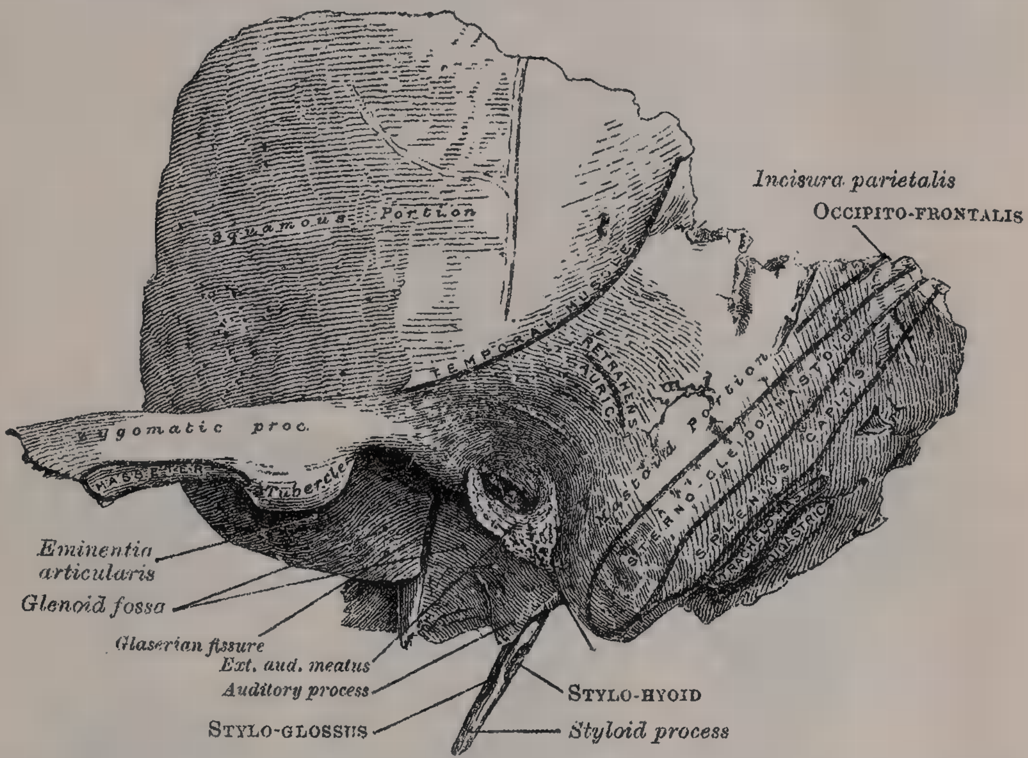
The Temporal Bones

The **Temporal Bones** (tempus, *time*) are situated at the sides and base of the skull. Each consists of four parts, viz., the *squamous* or *squamo-zygomatic*, the *petro-mastoid*, the *tympanic plate*, and the *styloid process*.

* Aldren Turner (*The Accessory Sinuses of the Nose*, 1901) gives the following measurements for a sinus of average size: height, $1\frac{1}{4}$ in.; breadth, 1 in.; depth from before backwards, 1 in.

The squamous portion (squama, *a scale*), the anterior and upper part of the bone, is scale-like in form, and thin and translucent in texture (fig. 222). Its *outer surface* is smooth, convex, and grooved at its back part for the deep temporal arteries; it affords attachment to the Temporal muscle, and forms part of the temporal fossa. At its back part may be seen a curved ridge—part of the *temporal ridge*; it serves for the attachment of the temporal fascia, and limits the origin of the Temporal muscle. The boundary between the squamous and mastoid portions of the bone, as indicated by traces of the original suture, lies fully half an inch below this ridge. Projecting from the lower part of the squamous portion is a long, arched process of bone, the *zygoma* or zygomatic process. This process is at first directed outwards, its two surfaces looking upwards and downwards; it then appears as if twisted upon itself, and runs forwards, its surfaces now looking inwards and outwards. The superior border of the process is long, thin, and sharp, and serves for the attachment of the temporal fascia. The inferior, short, thick, and arched, has attached to it some fibres of the Masseter muscle. Its outer surface is convex and subcutaneous; its inner is concave, and affords attachment to the Masseter muscle. The extremity, broad and deeply

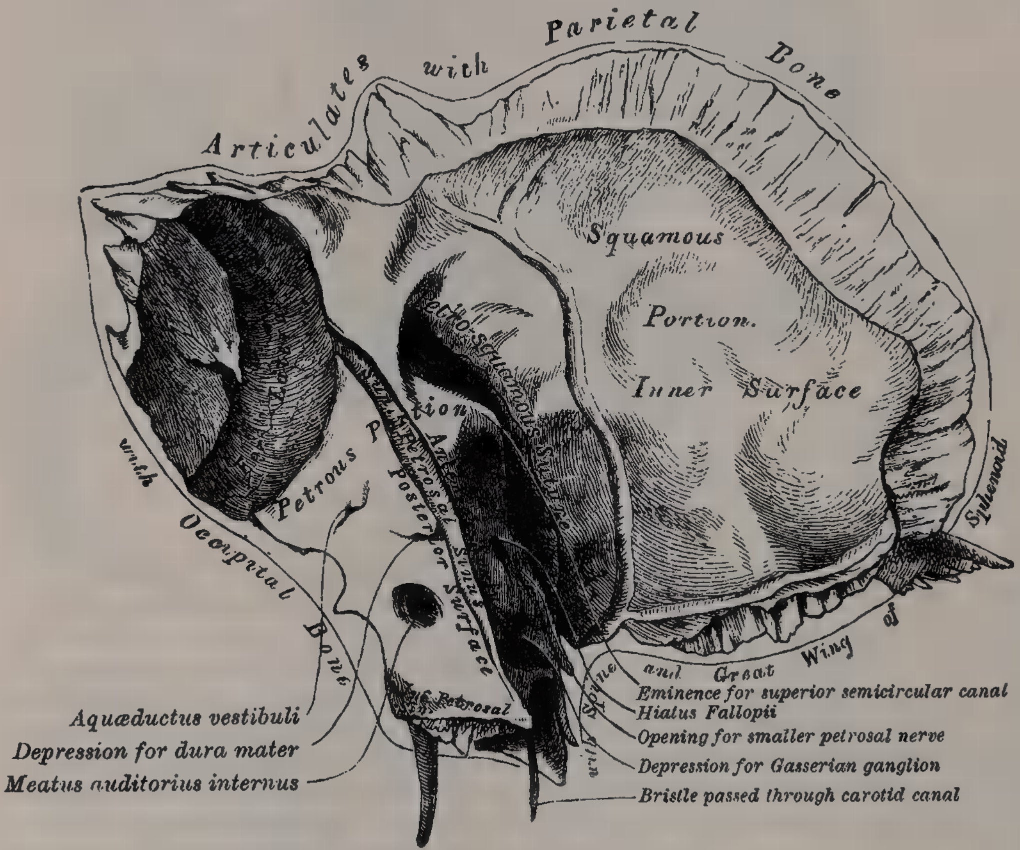
FIG. 222.—Left temporal bone. Outer surface.



serrated, articulates with the malar bone. The zygomatic process is connected to the temporal bone by three divisions, called its *roots*—an anterior, middle, and posterior. The anterior, which is short but broad and strong, is directed inwards, to terminate in a rounded eminence, the *eminentia articularis*. This eminence forms the front boundary of the glenoid fossa, and in the recent state is covered with cartilage. The middle root is known as the *post-glenoid process*, and is prominent in young bones. It separates the mandibular portion of the glenoid fossa from the external auditory meatus, and terminates at the commencement of a well-marked fissure, the *Glaserian fissure*. The posterior root, which is strongly marked, runs from the upper border of the zygoma, backwards above the external auditory meatus. It is termed the *supra-mastoid crest*, and forms the posterior part of the lower temporal ridge. At the junction of the anterior root with the zygoma is a projection, called the *tubercle*, for the attachment of the external lateral ligament of the lower jaw; and between the anterior and middle roots is an oval depression, forming part of the glenoid fossa (γλήνη, *a socket*), for the reception of the condyle of the lower jaw. The glenoid fossa is bounded, in front, by the eminentia articularis; behind by the *tympanic plate*, which separates it from the external auditory meatus; it is divided into two parts by a narrow

slit, the *Glaserian fissure.* The anterior or mandibular part, formed by the squamous portion of the bone, is smooth, covered in the recent state with cartilage, and articulates with the condyle of the lower jaw. This part of the fossa presents posteriorly a small conical eminence, the *post-glenoid process*, already referred to. This process is the representative of a prominent tubercle which, in some of the mammalia, descends behind the condyle of the jaw, and prevents it being displaced backwards during mastication (Humphry). The posterior part of the glenoid fossa, which lodges a portion of the parotid gland, is formed by the *tympanic plate*, which constitutes the anterior, the inferior, and part of the posterior wall of the external auditory meatus. This plate of bone terminates above in the Glaserian fissure, and below forms a sharp edge, the *vaginal* process, which encircles the root of the styloid process. The Glaserian fissure, which leads into the tympanum, lodges the processus gracilis of the malleus, and transmits the tympanic branch of the internal maxillary artery. The chorda tympani nerve passes through a canal (*canal of Huguier*), separated from the anterior edge of the Glaserian fissure by a thin scale of bone and situated on the outer side of the Eustachian tube, in the retiring angle between the squamous and petrous portions of the temporal bone. This thin scale of bone is derived from the roof of the tympanum, and forms the greater part of the outer wall of the bony portion of the Eustachian tube. Between the posterior bony wall of the external auditory meatus and the posterior root of the zygoma is the area called the *suprameatal triangle* of Macewen. Through this space the surgeon pushes his instrument in order to reach the antrum of the mastoid process.

Fig. 223.—Left temporal bone. Inner surface.



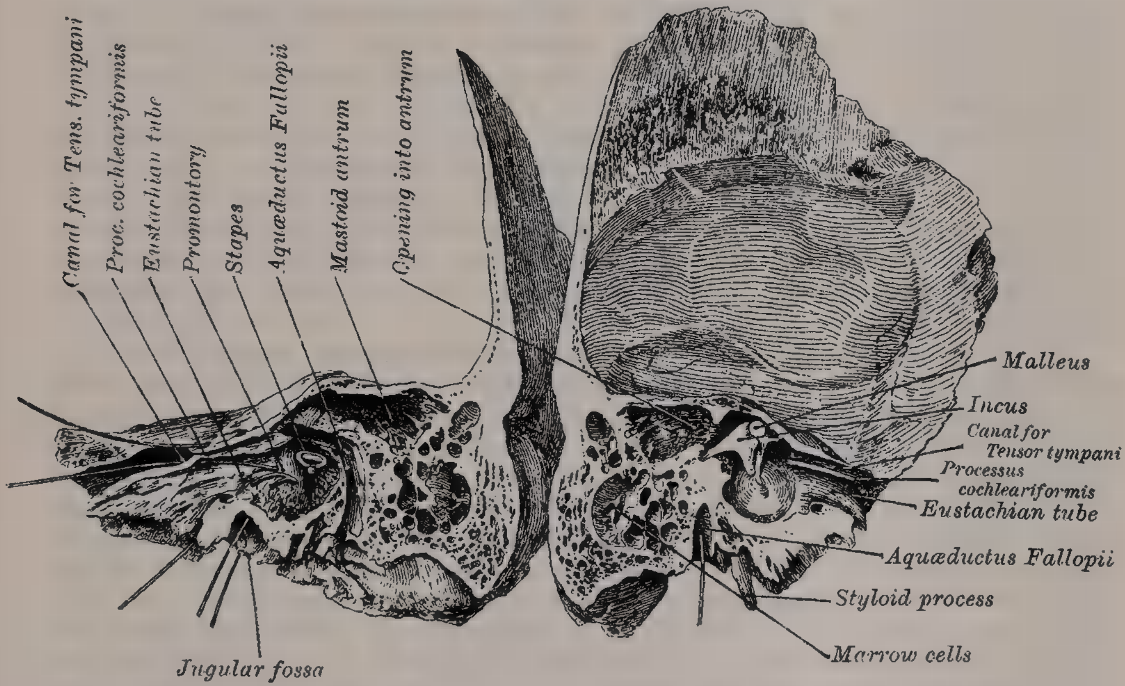
The **internal surface** of the squamous portion (fig. 223) is concave, presents numerous depressions for the convolutions of the cerebrum, and two well-marked grooves for the branches of the middle meningeal artery.

Borders.—The superior border is thin, bevelled at the expense of the internal surface, so as to overlap the lower border of the parietal bone, forming the squamous suture. The anterior inferior border is thick, serrated, and bevelled, alternately at the expense of the inner and outer surfaces, for articulation with the great wing of the sphenoid. Posteriorly, the superior border ends by forming an angle with the mastoid portion of the bone, called the *incisura parietalis*.

The **Petro-mastoid Portion** consists of (*a*) the *mastoid process*, which forms a prominent, nipple-like mass behind the external auditory meatus; and (*b*) the *petrous portion*, which is pyramidal in shape, and projects inwards and forwards to form part of the floor of the skull.

The **Mastoid Portion** (μαστός, *a nipple* or *teat*) is situated at the posterior part of the bone; its outer surface is rough, and gives attachment to the Occipito-frontalis and Retrahens auriculam muscles. It is perforated by numerous foramina; one of these, of large size, situated near the posterior border of the bone, is termed the *mastoid foramen*; it transmits a vein to the lateral sinus and a small artery from the occipital, to supply the dura mater. The position and size of this foramen are very variable. It is not always present; sometimes it is situated in the occipital bone, or in the suture between the temporal and the occipital. The mastoid portion is continued below into a conical projection, the *mastoid process*, the size and form of which vary somewhat; it is larger in the male than in the female. This process serves for the attachment of the Sterno-mastoid, Splenius capitis, and Trachelo-mastoid muscles. On the inner side of the mastoid process is a deep groove, the *digastric fossa* or *incisura mastoidea*, for

FIG. 224.—Section through the temporal bone, showing the communication of the cavity of the tympanum with the mastoid antrum.



the attachment of the Digastric muscle; and, running parallel with it, but more internal, the *occipital groove*, which lodges the occipital artery. The internal surface of the mastoid portion presents a deep, curved groove, the *fossa sigmoidea*, which lodges part of the lateral sinus; and into it may be seen opening the mastoid foramen. The groove for the lateral sinus is separated from the innermost of the mastoid air-cells by only a thin lamina of bone, and even this may be partly deficient. A section of the mastoid process shows it to be hollowed out into a number of cellular spaces, communicating with each other, called the *mastoid cells*, which exhibit the greatest possible variety as to their size and number. At the upper and front part of the bone these cells are large and irregular and contain air, but towards the lower part of the bone they diminish in size, while those at the apex of the mastoid process are quite small and usually contain marrow. Occasionally they are entirely absent, and the mastoid is solid throughout. In addition to these a large irregular cavity (fig. 224) is situated at the upper and front part of the bone. It is called the *mastoid antrum*, and must be distinguished from the mastoid cells, though it communicates with them. Like the mastoid cells it is filled with air and lined by a prolongation of the mucous membrane of the tympanic cavity, with which it communicates. The mastoid antrum is bounded above by a thin plate of bone, the *tegmen tympani*, which

separates it from the middle fossa of the base of the skull; below by the mastoid process; externally by the squamous portion of the bone just below the supramastoid crest, and internally by the external semicircular canal of the internal ear which projects into its cavity. The opening by which it communicates with the tympanum is situated at the superior internal angle of the posterior wall of that cavity, and opens into that portion of the tympanic cavity which is known as the *attic* or *epitympanic recess*; that is to say, the portion of the tympanic cavity which is above the level of the membrana tympani.

The mastoid cells are not developed until towards puberty; hence the prominence of the mastoid process in the adult: the mastoid antrum, on the other hand, is of large size at birth.

In consequence of the communication which exists between the tympanic cavity and mastoid antrum, inflammation of the lining membrane of the former cavity may easily travel backwards to that of the antrum and mastoid air-cells, leading to caries and necrosis of their walls and the risk of transference of the inflammation to the lateral sinus or encephalon.

Borders.—The superior border of the mastoid portion is broad and rough, its serrated edge sloping outwards, for articulation with the posterior inferior angle of the parietal bone. The posterior border, also uneven and serrated, articulates with the inferior border of the occipital bone between its lateral angle and jugular process. Anteriorly it is fused with the squamous portion of the bone above, and below enters into the formation of the external auditory meatus and the cavity of the tympanum.

The **Petrous Portion** (πέτρος, *a stone*), so named from its extreme density and hardness, is a pyramidal process of bone, wedged in at the base of the skull between the sphenoid and occipital bones. It is directed inwards, forwards, and a little upwards. It presents for examination a base, an apex, three surfaces, and three borders; and contains, in its interior, the essential parts of the organ of hearing. The *base* is applied against the internal surface of the squamous and mastoid portions.

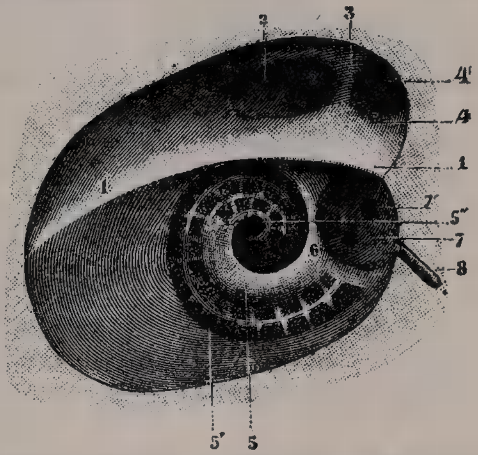
The **apex** of the petrous portion, rough and uneven, is received into the angular interval between the posterior border of the greater wing of the sphenoid and the basilar process of the occipital; it presents the anterior or internal orifice of the carotid canal, and forms the posterior and external boundary of the foramen lacerum medium.

The **anterior surface** of the petrous portion (fig. 223) forms the posterior part of the middle fossa of the base of the skull. This surface is continuous with the squamous portion, to which it is united by a suture, the *petro-squamous suture*, the remains of which are distinct even at a late period of life. It is marked by digital depressions for the convolutions of the brain, and presents six points for examination: 1. an eminence (*eminentia arcuata*) near the centre, which indicates the situation of the superior semicircular canal: 2. in front and a little to the outer side of this eminence a depression, indicating the position of the tympanum; here the layer of bone which separates the tympanum from the cranial cavity is extremely thin, and is known as the *tegmen tympani*: 3. a shallow groove, sometimes double, leading outwards and backwards to an oblique opening, the *hiatus Fallopii*, for the passage of the large superficial petrosal nerve and the petrosal branch of the middle meningeal artery: 4. a smaller opening, occasionally seen external to the latter, for the passage of the small superficial petrosal nerve: 5. near the apex of the bone, the termination of the carotid canal, the wall of which in this situation is deficient in front: 6. above this canal a shallow depression for the reception of the Gasserian ganglion.

The **posterior surface** forms the front part of the posterior fossa of the base of the skull, and is continuous with the inner surface of the mastoid portion of the bone. It presents three points for examination: 1. about its centre is a large orifice, the *meatus acusticus internus*, the size of which varies considerably; its margins are smooth and rounded; and it leads into a short canal, about four lines in length, which runs directly outwards. This canal is closed externally by a vertical plate, the *lamina cribrosa*, which is divided by a horizontal crest, the *crista falciformis*, into two unequal portions (fig. 225). Each portion is further subdivided by a little vertical ridge into anterior and posterior parts. The *lower*

portion presents three sets of foramina; one group, just below the posterior part of the crest, forms the *area cribrosa media*, and consists of a number of small openings for the nerves to the saccule; below and posterior to this, the *foramen singulare*, or opening for the nerve to the posterior semicircular canal; in front and below the first, the *tractus spiralis foraminosus*, consisting of a number of small spirally arranged openings, which terminate in the *canalis centralis cochleæ* and transmit the nerves to the cochlea. The *upper* portion, that above the crista, presents behind a series of small openings, the *area cribrosa superior*, for the passage of filaments to the utricle and superior and external semicircular canals, and, in front, the *area facialis*, with one large opening, the commencement of the aquæductus Fallopii, for the passage of the facial nerve: 2. behind the meatus auditorius is a small slit almost hidden by a thin plate of bone, leading to a canal, the *aquæductus vestibuli*, which transmits the *ductus endolymphaticus* together with a small artery and vein: 3. in the interval between these two openings, but above them, is an angular depression which lodges a process of the dura mater, and transmits a small vein into the cancellous tissue of the bone. In the child this depression is represented by a large fossa, the *fossa subarcuata*, which extends backwards as a blind tunnel under the superior semicircular canal.

Fig. 225.—Diagrammatic view of the fundus of the internal auditory meatus. (Testut.)



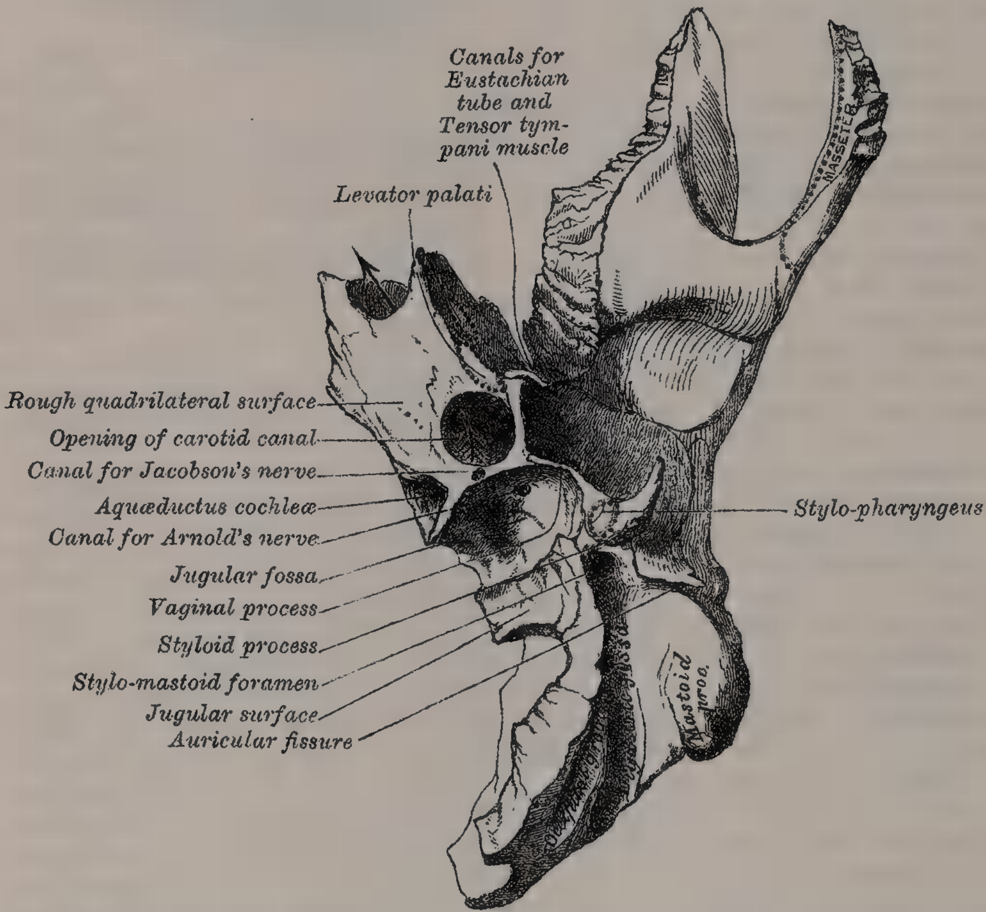
1. Crista falciformis. 2. Area facialis, with (2') Internal opening of the aquæductus Fallopii. 3. Ridge separating the area facialis from the area cribrosa superior. 4. Area cribrosa superior, with (4') Openings for nerve filaments. 5. Anterior inferior cribriform area, with (5') the tractus spiralis foraminosus, and (5'') the canalis centralis of the cochlea. 6. Ridge separating the tractus spiralis foraminosus from the area cribrosa media. 7. Area cribrosa media, with (7') orifices for nerves to saccule. 8. Foramen singulare.

The **inferior** or **basilar surface** (fig. 226) is rough and irregular, and forms part of the base of the skull. Passing from the apex to the base, this surface presents eleven points for examination: 1. a rough surface, quadrilateral in form, which serves partly for the attachment of the Levator palati muscle and cartilaginous portion of the Eustachian tube; and partly for connection with the basilar process of the occipital bone through the intervention of dense fibrous tissue: 2. the large, circular aperture of the carotid canal, which ascends at first vertically, and then, making a bend, runs horizontally forwards and inwards; it transmits the internal carotid artery, and the carotid plexus of nerves: 3. to the inner side of the opening for the carotid canal and close to the posterior border, in front of the jugular fossa, is a triangular depression, on the floor of which is a small opening, the *aquæductus cochleæ*, which lodges a tubular prolongation of the dura mater and transmits a vein from the cochlea to join the internal jugular: 4. behind these openings a deep depression, the *jugular fossa*, which varies in depth and size in different skulls; it lodges the bulb of the internal jugular vein, and, with a similar depression on the margin of the jugular process of the occipital bone, forms the foramen lacerum posterius, or jugular foramen: 5. a small foramen for the passage of Jacobson's nerve (the tympanic branch of the glossopharyngeal); this foramen is seen in the bony ridge dividing the carotid canal from the jugular fossa: 6. a small foramen in the outer part of the jugular fossa, for the entrance of the auricular branch of the pneumogastric (Arnold's nerve): 7. behind the jugular fossa, a quadrilateral area, the *jugular surface*; it is covered with cartilage in the recent state, and articulates with the jugular process of the occipital bone: 8. the *vaginal process*, a very broad, sheath-like plate of bone, which extends backwards from the carotid canal and divides behind into two laminæ, the outer of which is continuous with the tympanic plate, the inner with the jugular process; between these laminæ is the 9th point for examination, the *styloid process*, a sharp spine, about an inch in length: 10. the *stylo-mastoid foramen*, a rather large orifice, placed between the styloid and mastoid processes; it is the termination of the aquæductus Fallopii, and transmits the facial nerve and stylo-mastoid artery: 11. the *auricular fissure*, situated between the tympanic

plate and mastoid processes, for the exit of the auricular branch of the pneumogastric nerve.

Borders.—The *superior*, the longest, is grooved for the superior petrosal sinus, and has attached to it the tentorium cerebelli; at its inner extremity is a semilunar notch, upon which the fifth nerve lies. The *posterior* border is intermediate in length between the superior and the anterior. Its inner half is marked by a groove, which, when completed by its articulation with the occipital bone, forms the channel for the inferior petrosal sinus. Its outer half presents an excavation—the *jugular fossa*—which, with a similar notch on the occipital, forms the foramen lacerum posterius. A projecting eminence of bone occasionally stands out from the centre of the notch, and divides the foramen into two. The *anterior* border is divided into two parts—an outer joined to the squamous portion by a suture (*petro-squamous*), the remains of which are distinct; an inner, free, articulating with the spinous process of the sphenoid. At the angle of junction of the petrous and squamous portions are seen two canals, separated from

Fig. 226.—Left temporal bone. Inferior surface.



one another by a thin plate of bone, the *processus cochleariformis*; they both lead into the tympanum, the upper one transmitting the Tensor tympani muscle, the lower one forming the bony part of the Eustachian tube.

The tympanic cavity and auditory ossicles, and the internal ear, are described with the organ of hearing.

The **Tympanic Plate** consists of a curved plate of bone lying below the squamous portion and in front of the mastoid process. Its postero-superior surface is concave, and forms the anterior wall, the floor, and part of the posterior wall of the bony external auditory meatus. Internally, it presents a narrow furrow, the *sulcus tympanicus*, for the attachment of the membrana tympani. Its antero-inferior surface is quadrilateral and slightly concave; it constitutes the posterior boundary of the glenoid cavity, and is in contact with the retro-mandibular part of the parotid gland. Its outer border is free and rough; it is named the *external auditory process*, and gives attachment to the cartilaginous part of the external auditory meatus. Internally, the tympanic plate is fused with the petrous

portion, and appears in the retreating angle between it and the squamous portion, where it lies below and to the outer side of the orifice of the Eustachian tube. Posteriorly, it blends with the squamous and mastoid parts, and forms the anterior boundary of the auricular fissure. Its antero-superior border fuses externally with the back of the post-glenoid process, while internally it bounds the Glaserian fissure. The lower border is thin and sharp at its inner part; its outer part splits to enclose the root of the styloid process, and is therefore named the *vaginal process.* The central portion of the tympanic plate is thin, and in a considerable percentage of skulls is perforated by a hole, the *foramen of Huschke.*

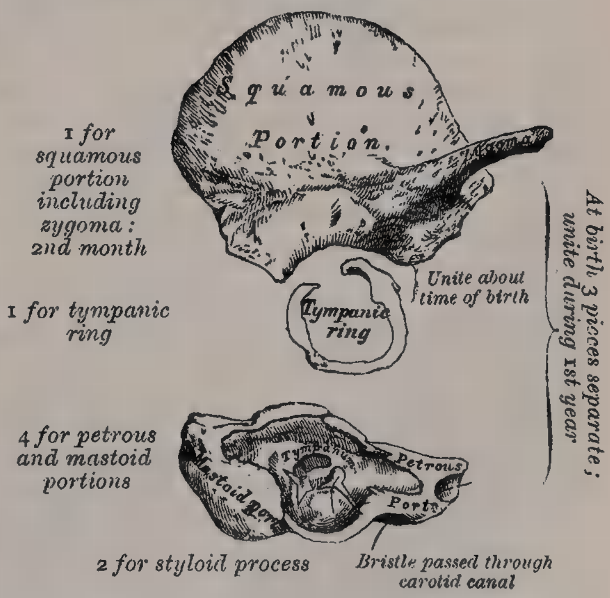
The **external auditory meatus** is directed inwards and slightly forwards: at the same time it forms a slight curve, so that the floor of the canal is convex upwards. It measures about three-quarters of an inch in length, and presents an oval or elliptical shape—its long axis being directed downwards and slightly backwards. As has been pointed out, its anterior wall, its floor, and the lower part of its posterior wall are formed by the tympanic plate; the roof and upper part of the posterior wall belong to the squamous portion. Its inner end is closed, in the recent state, by the membrana tympani: the upper limit of its outer orifice is formed by the posterior root of the zygoma, immediately below which there is sometimes seen a small spine, the *suprameatal* spine, situated at the upper and posterior part of the orifice.

The **Styloid process** is slender, pointed, and of varying length; it projects downwards and forwards, from the under aspect of the temporal bone, beyond the tympanic plate. Its proximal part (*tympano-hyal*) is ensheathed by the vaginal process, while its projecting portion (*stylo-hyal*) gives attachment to the stylo-hyoid and stylo-mandibular ligaments, and to the Stylo-glossus, Stylo-hyoid, and Stylo-pharyngeus muscles. The stylo-hyoid ligament extends from the apex of the process to the lesser cornu of the hyoid bone, and may undergo partial or complete ossification.

Structure.—The squamous portion is like that of the other cranial bones: the mastoid portion cellular, and the petrous portion dense and hard.

Development (fig. 227).—The temporal bone is developed by *eight* centres, exclusive of those for the internal ear and the ossicula—viz. one for the squamous portion including the zygoma, one for the tympanic plate, four for the petro-mastoid part, and two for the styloid process. Just before the close of fœtal life the temporal bone consists of four parts: 1. The *squamo-zygomatic*, which is ossified in membrane from a single nucleus; this appears near the root of the zygoma about the second month. 2. The *petro-mastoid*, which is developed from four centres; these make their appearance in the cartilaginous ear-capsule about the fifth or sixth month. One (*prootic*) appears in the neighbourhood of the eminentia arcuata, spreads in front and above the internal auditory meatus and extends to the apex of the bone; it forms part of the cochlea, vestibule, superior semicircular canal, and inner wall of the tympanic cavity. A second (*opisthotic*) appears at the promontory on the inner wall of the tympanum and surrounds the fenestra rotunda; it forms the floor of the tympanum and vestibule, surrounds the carotid canal, invests the outer and lower part of the cochlea, and spreads inwards below the internal auditory meatus. A third (*pterotic*) roofs in the antrum and tympanic cavity; while the fourth (*epiotic*) appears near the posterior semicircular canal and extends to form the mastoid process (Vrolik). 3. The *tympanic ring*, an incomplete circle in the concavity of which is a groove,

Fig. 227.—Development of the temporal bone. By eight centres.



the *sulcus tympanicus*, for the attachment of the circumference of the tympanic membrane. This is also ossified from a single centre which appears about the third month. 4. The *styloid process*, which is developed from the proximal part of the cartilage of the second visceral arch by two centres: one for the base, which appears before birth, and is termed the *tympano-hyal*; the other, comprising the rest of the process, is named the *stylo-hyal*, and does not appear until after birth. Shortly before birth the tympanic plate joins with the squamous. The petro-mastoid joins with the squamous during the first year, and the tympano-hyal portion of the styloid process about the same time. The stylo-hyal does not join the rest of the bone until after puberty, and in some skulls never becomes united. The chief subsequent changes in this bone are: (1) The tympanic ring extends outwards and backwards so as to form the tympanic plate. This extension does not, however, take place at an equal rate all round the circumference of the ring, but occurs most rapidly on its anterior and posterior portions, and these outgrowths meet and blend, and thus, for a time, there exists in the floor of the meatus a foramen, the *foramen of Huschke*: this foramen may persist throughout life. (2) The glenoid cavity is at first extremely shallow, and looks outwards as well as downwards; it becomes deeper and is ultimately directed downwards. Its change in direction is accounted for as follows: The part of the squamous temporal which supports it lies at first *below* the level of the zygoma. As, however, the base of the skull increases in width, this lower part of the squama is directed horizontally inwards to contribute to the middle fossa of the skull, and its surfaces therefore come to look upwards and downwards; the attached portion of the zygoma becomes everted, and projects like a shelf at right angles to the squama. (3) The mastoid portion is at first quite flat, and the stylo-mastoid foramen and rudimentary styloid process lie immediately behind the tympanic ring. With the development of the air-cells the outer part of the mastoid portion grows downwards and forwards to form the mastoid process, and the styloid process and stylo-mastoid foramen now come to lie on the under surface. The descent of the foramen is necessarily accompanied by a corresponding lengthening of the aqueduct of Fallopius. (4) The downward and forward growth of the mastoid process also pushes forward the tympanic plate, so that the portion of it which formed the original floor of the meatus and contained the foramen of Huschke is ultimately found in the anterior wall. (5) With the gradual increase in size of the petrous portion, the *fossa subarcuata* becomes filled up and almost obliterated.

Articulations.—With five bones: occipital, parietal, sphenoid, inferior maxillary, and malar.

Attachment of Muscles.—To fourteen: to the squamous portion, the Temporal; to the zygoma, the Masseter; to the mastoid portion, the Occipito-frontalis, Sterno-mastoid, Splenius capitis, Trachelo-mastoid, Digastricus, and Retrahens auriculam; to the styloid process, the Stylo-pharyngeus, Stylo-hyoid, and Stylo-glossus; and to the petrous portion, the Levator palati, Tensor tympani, and Stapedius.

The Sphenoid Bone

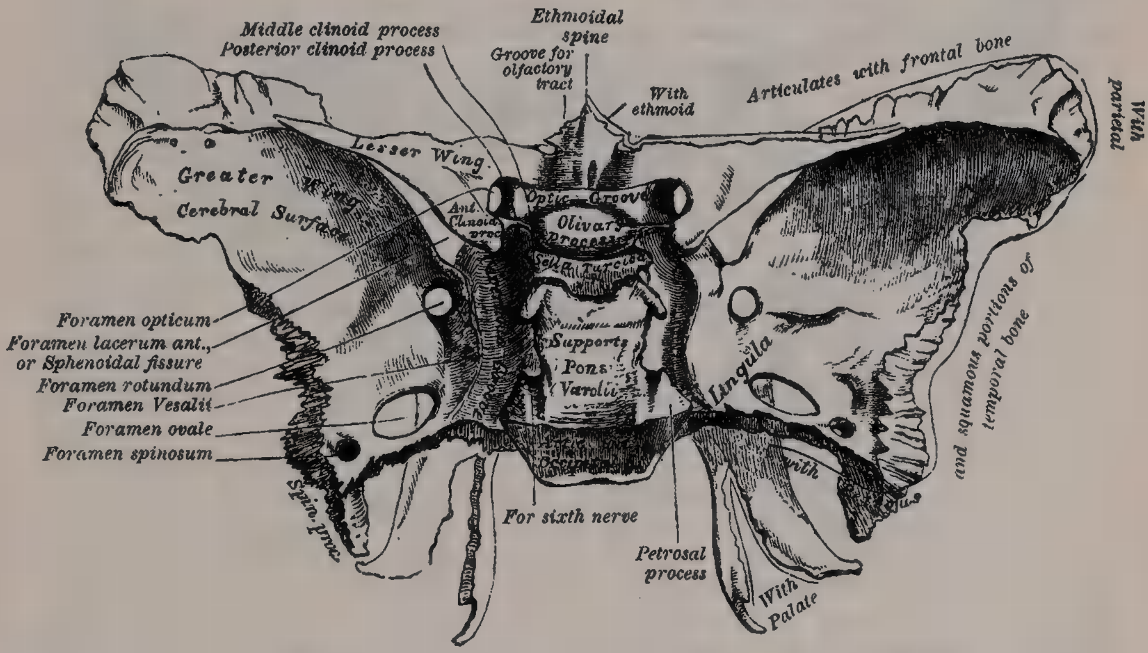
The **Sphenoid Bone** (*σφήν, a wedge*) is situated at the anterior part of the base of the skull, articulating with all the other cranial bones, and binding them firmly and solidly together. In its form it somewhat resembles a bat with its wings extended; and is divided into a central portion or body, two greater and two lesser wings extending outwards on each side of the body, and two processes—the pterygoid processes—which project from it below.

The **body** is of large size, and hollowed out in its interior so as to form a mere shell of bone. It presents for examination *four* surfaces—a superior, an inferior, an anterior, and a posterior.

The Superior Surface (fig. 228).—In front is seen a prominent spine, the *ethmoidal spine*, for articulation with the cribriform plate of the ethmoid; behind this a smooth surface presenting, in the median line, a slight longitudinal eminence, with a depression on each side, for lodging the olfactory lobes of the brain. This surface is bounded behind by a ridge, which forms the anterior border of a narrow, transverse groove, the *optic groove*, above and behind which lies the optic commissure; the groove terminates on either side in the *optic foramen*, for the passage of the optic nerve and ophthalmic artery. Behind the

optic groove is a small eminence, olive-like in shape, the *olivary process*; and still more posteriorly, a deep depression, the *pituitary fossa*, or *sella turcica*, which lodges the pituitary body. This fossa is perforated by numerous foramina, for the transmission of nutrient vessels into the substance of the bone. It is bounded in front by two small eminences, one on either side, called the *middle clinoid processes* (*κλίνη, a bed*), which are sometimes connected by a spiculum of bone to the anterior clinoid processes (see below), and behind by a square-shaped plate of bone, the *dorsum ephippii* or *dorsum sellæ*, terminating at its superior angles in two tubercles, the *posterior clinoid processes*, the size and form of which vary considerably in different individuals. These processes deepen the pituitary fossa, and serve for the attachment of prolongations from the tentorium cerebelli. The sides of the dorsum ephippii are notched for the passage of the sixth pair of nerves, and below present a sharp process, the *petrosal process*, which is joined to the apex of the petrous portion of the temporal bone, forming the inner boundary of the middle lacerated foramen. Behind the dorsum sellæ, the bone presents a shallow depression, which slopes obliquely backwards, and is continuous with the basilar groove of the occipital bone; it is called the *clivus*, and supports the upper part of the pons Varolii. On either side of the body is a

Fig. 228.—Sphenoid bone. Superior surface.

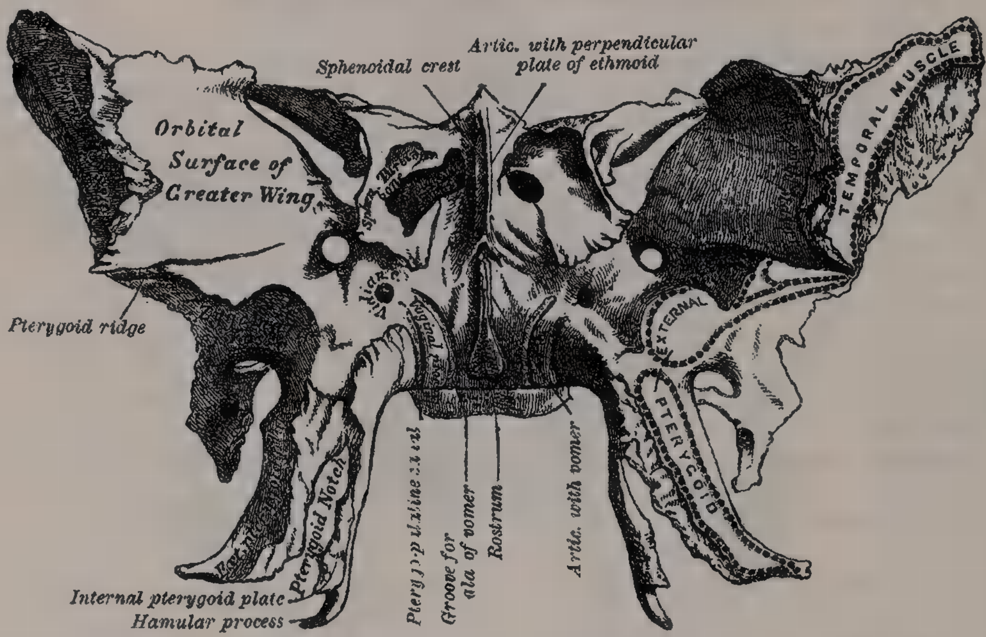


broad groove, curved something like the italic letter *f*; it lodges the internal carotid artery and the cavernous sinus, and is called the *carotid* or *cavernous groove*. Along the outer margin of this groove, at its posterior part, is a ridge of bone, in the angle between the body and greater wing, called the *lingula*. The **posterior surface**, quadrilateral in form, is joined to the basilar process of the occipital bone. During childhood these bones are separated by a layer of cartilage; but in after-life (between the eighteenth and twenty-fifth years) this becomes ossified, ossification commencing above and extending downwards; and the two bones then form one piece. The **anterior surface** (fig. 229) presents, in the middle line, a vertical ridge of bone, the *sphenoidal crest*, which articulates with the perpendicular plate of the ethmoid, forming part of the septum of the nose. On either side of it are irregular openings leading into the *sphenoidal air-cells* or *sinuses*. These are two large, irregular cavities hollowed out of the interior of the body of the sphenoid bone, and separated from one another by a more or less complete perpendicular bony septum. Their form and size vary considerably; * they are seldom symmetrical, and are often partially subdivided by irregular osseous laminæ. Occasionally, they extend into the basilar process of the occipital nearly as far as the foramen magnum. The septum is seldom

* Aldren Turner (*op. cit.*) gives the following as their average measurements: vertical height, $\frac{7}{8}$ in.; antero-posterior depth, $\frac{7}{8}$ in.; transverse breadth, $\frac{3}{4}$ in.

quite vertical, being commonly bent to one or the other side. These sinuses begin to be developed in the third year, and are of a considerable size by the age of six. They are partially closed, in front and below, by two thin, curved plates of bone, the *sphenoidal turbinated* bones, leaving a round opening at their upper parts, by which they communicate with the upper and back part of the nose and occasionally with the posterior ethmoidal cells or sinuses. The lateral margin of this surface presents a serrated edge, which articulates with the os planum of the ethmoid, completing the posterior ethmoidal cells; the lower margin, also rough and serrated, articulates with the orbital process of the palate bone; and the upper margin with the orbital plate of the frontal bone. The **inferior surface** presents, in the middle line, a triangular spine, the *rostrum*, which is continuous with the sphenoidal crest on the anterior surface, and is received into a deep fissure between the alæ of the vomer. On each side may be seen a projecting lamina of bone, which runs horizontally inwards from near the base of the pterygoid process: these laminæ are termed the *vaginal processes*, and articulate with the edges of the vomer. Close to the root of the pterygoid process is a groove, formed into a complete canal when articulated with the

FIG. 229.—Sphenoid bone. Anterior surface.*



sphenoidal process of the palate bone; it is called the *pterygo-palatine canal*, and transmits the pterygo-palatine vessels and pharyngeal nerve.

The **Greater Wings** are two strong processes of bone, which arise from the sides of the body, and are curved in a direction upwards, outwards and backwards and prolonged behind into a sharp-pointed extremity, the *spinous process* of the sphenoid. Each wing presents three surfaces and a circumference. The **superior** or **cerebral surface** (fig. 228) forms part of the middle fossa of the skull; it is deeply concave, and presents depressions for the convolutions of the brain. At its anterior and internal part is seen a circular aperture, the *foramen rotundum*, for the transmission of the second division of the fifth nerve. Behind and external to this is a large, oval foramen, the *foramen ovale*, for the transmission of the third division of the fifth nerve, the small meningeal artery, and sometimes the small superficial petrosal nerve.† At the inner side of the foramen ovale, a small aperture, the *foramen Vesalii*, may occasionally be seen opposite the root of the pterygoid process; it opens near the scaphoid fossa, and transmits a small vein from the cavernous sinus. Lastly, in the posterior angle, near to the spine of the sphenoid, is a short canal, sometimes double,

* In this figure, both the anterior and inferior surfaces of the body of the sphenoid bone are shown, the bone being held with the pterygoid processes almost horizontal.

† The small petrosal nerve sometimes passes through a special canal (*canaliculus innominatus* of Arnold) situated on the inner side of the foramen spinosum, the foramen ovale.

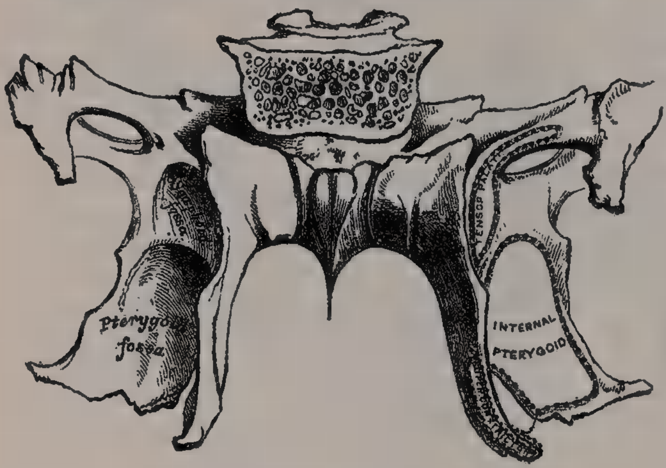
the *foramen spinosum*; it transmits the middle meningeal artery and vein and a recurrent branch from the third division of the fifth cranial nerve. The **external surface** (fig. 229) is convex, and divided by a transverse ridge, the *pterygoid ridge* or *infratemporal crest*, into two portions. The superior or larger, convex from above downwards, concave from before backwards, enters into the formation of the temporal fossa, and gives attachment to part of the Temporal muscle. The inferior portion, smaller in size and concave, enters into the formation of the zygomatic fossa, and affords attachment to the External pterygoid muscle. It presents the opening of the foramen ovale, and, at its posterior part, a sharp-pointed eminence of bone, the *spinous process*, which is perforated by the foramen spinosum and frequently grooved on its inner aspect for the chorda tympani nerve. To the spinous process are connected the internal lateral ligament of the mandible and the Tensor palati muscle. The cartilaginous part of the Eustachian tube is supported by the inner surface of the spine of the sphenoid. The pterygoid ridge, dividing the temporal and zygomatic portions, gives attachment to part of the External pterygoid muscle. At its inner and anterior extremity is a triangular spine of bone, which serves to increase the extent of origin of this muscle. The **anterior** or **orbital surface**, smooth, and quadrilateral in shape, forms the greater part of the outer wall of the orbit. It is bounded above by a serrated edge, for articulation with the frontal bone; below, by a rounded border, which enters into the formation of the spheno-maxillary fissure. Internally, it presents a sharp border, which forms the lower boundary of the sphenoidal fissure and has projecting from about its centre a little tubercle of bone, which gives attachment to the inferior common ligament of origin of the muscles of the eyeball; and at its upper part is a notch for the transmission of a recurrent branch of the lachrymal artery; externally, it presents a serrated margin for articulation with the malar bone. At the inner and lower part of the anterior surface, immediately below the inner end of the sphenoidal fissure, is a grooved surface, which presents the opening of the foramen rotundum and forms the posterior wall of the spheno-maxillary fossa. *Circumference of the great wing* (fig. 228): commencing from behind; that portion of the circumference which extends from the body of the sphenoid to the spine is serrated and articulates by its outer half with the petrous portion of the temporal bone; while the inner half forms the anterior boundary of the foramen lacerum medium, and presents the posterior aperture of the Vidian canal for the passage of the Vidian nerve and artery. In front of the spine the circumference of the great wing presents a serrated edge, bevelled at the expense of the inner table below, and of the outer table above, which articulates with the squamous portion of the temporal bone. At the tip of the great wing a triangular portion is seen, bevelled at the expense of the internal surface, for articulation with the anterior inferior angle of the parietal bone; this region is named the *pterion*. Internal to this is a triangular, serrated surface, for articulation with the frontal bone: this surface is continuous internally with the sharp inner edge of the orbital plate, which assists in the formation of the sphenoidal fissure, and externally with the serrated margin for articulation with the malar bone.

The **Lesser Wings** (*processes of Ingrassias*) are two thin, triangular plates of bone, which arise from the upper and lateral parts of the body of the sphenoid, and, projecting transversely outwards, terminate in sharp points (fig. 228). The superior surface of each is smooth, flat, broader internally than externally, and supports part of the frontal lobe of the brain. The inferior surface forms the back part of the roof of the orbit, and the upper boundary of the sphenoidal fissure or foramen lacerum anterius. It gives attachment, close to the margin of the optic foramen, to the Levator palpebræ superioris muscle. The *sphenoidal fissure* is of a triangular form, and leads from the cavity of the cranium into the orbit: it is bounded internally by the body of the sphenoid; above, by the lesser wing; below, by the internal margin of the orbital surface of the great wing; and is converted into a foramen by the articulation of this bone with the frontal. It transmits the third, the fourth and the sixth nerves, the three branches of the ophthalmic division of the fifth nerve, some filaments from the cavernous plexus of the sympathetic, the orbital branch of the middle meningeal artery, a recurrent branch from the lachrymal artery to the dura mater, and the ophthalmic vein. The anterior border of the lesser wing is serrated for

articulation with the frontal bone; the posterior, smooth and rounded, is received into the Sylvian fissure of the brain. The inner extremity of this border forms the *anterior clinoid process*, to which the tentorium cerebelli is attached. The lesser wing is connected to the side of the body by two roots, the upper thin and flat, the lower thicker, obliquely directed, and presenting on its outer side, near its junction with the body, a small tubercle, for the attachment of the superior common tendon of origin of three of the muscles of the eye. Between the two roots is the *optic foramen*, for the transmission of the optic nerve and ophthalmic artery.

The **Pterygoid Processes** (πτέρυξ, *a wing* ; εἶδος, *likeness*), one on each side, descend perpendicularly from the point where the body and greater wing unite (fig. 230). Each process consists of an external and an internal plate, which are joined together by their anterior borders above, but are separated below, leaving an angular cleft, the *pterygoid notch*, in which the pterygoid process or tuberosity of the palate bone is received. The two plates diverge from each other from their line of connection in front, so as to form a V-shaped fossa, the *pterygoid fossa*. The *external pterygoid plate* is broad and thin, and turned a little outwards ; its outer surface forms part of the inner wall of the zygomatic fossa, and gives attachment to the External pterygoid ; its inner surface forms part of the pterygoid fossa, and gives attachment to the Internal pterygoid. The *internal pterygoid plate* is much narrower and longer, curving outwards, at its extremity, into a hook-like process of bone, the *hamular process*, around which turns the tendon of the Tensor palati muscle. The outer surface of this plate forms part of the pterygoid fossa, the inner surface constitutes the outer boundary of the posterior aperture of the nares. On the posterior surface of the base of the process, above the pterygoid fossa, is a small, oval, shallow depression, the *scaphoid fossa*, from which arises the Tensor palati, and above which is seen the posterior orifice of the Vidian canal. Below and to the inner side of the Vidian canal, on the posterior surface of the base of the internal plate, is a little prominence, which is known by the name of the *pterygoid tubercle*. The pharyngeal aponeurosis is attached to the posterior edge of the internal plate, and to its lower third the Superior constrictor of the pharynx. The anterior surface of the pterygoid process is very broad at its base, and forms the posterior wall of the spheno-maxillary fossa. It supports Meckel's ganglion. It presents, above, the anterior orifice of the Vidian canal ; and below, a rough margin, which articulates with the perpendicular plate of the palate bone.

Fig. 230.—Sphenoid bone. Posterior surface.

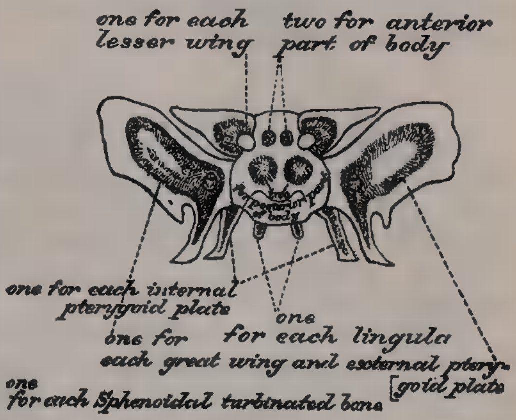


The **Sphenoidal Spongy Bones** are two thin, curved plates of bones, which exist as separate pieces until puberty, and occasionally are not joined to the sphenoid in the adult. They are situated at the anterior and inferior part of the body of the sphenoid, an aperture of variable size being left in their anterior wall, through which the sphenoidal sinuses open into the nasal fossæ. They are irregular in form, and taper to a point behind, being broader and thinner in front. Their upper surface, which looks towards the cavity of the sinus, is concave ; their under surface is convex, and forms part of the roof of the nasal fossæ. Each bone articulates in front with the ethmoid, externally with the palate ; its pointed posterior extremity is placed above the vomer, and is received between the root of the pterygoid process on the outer side and the rostrum of the sphenoid on the inner.*

* A small portion of sphenoidal turbinated bone sometimes enters into the formation of the inner wall of the orbit, between the os planum of the ethmoid in front, the orbital plate of the palate below, and the frontal above. Cleland, *Roy. Soc. Trans.* 1862.

Development.—Up to about the eighth month of fœtal life the sphenoid bone consists of two distinct parts: a posterior or *post-sphenoid* part, which comprises the pituitary fossa, the greater wings, and the pterygoid processes; and an anterior or *pre-sphenoid* part, to which the anterior part of the body and lesser wings belong. It is developed by fourteen centres: eight for the post-sphenoid division, and six for the pre-sphenoid (fig. 231). The eight centres for the post-sphenoid are—one for each greater wing and external pterygoid plate, one for each internal pterygoid plate, two for the posterior part of the body, and one on each side for the lingula. The six for the pre-sphenoid are one for each lesser wing, two for the anterior part of the body, and one for each sphenoidal turbinated bone.*

Fig. 231.—Plan of the development of sphenoid. By fourteen centres.



Post-sphenoid Division.—The first nuclei to appear are those for the greater wings (*ali-sphenoids*). They make their appearance between the foramen rotundum and foramen ovale about the eighth week, and from them the external pterygoid plates are also formed.† Soon after, the nuclei for the posterior part of the body appear, one on either side of the sella turcica, and become blended together about the middle of fœtal life. The internal pterygoid plates are ossified in membrane, and their centres probably appear about the ninth or tenth week (Fawcett, *op. cit.*); they become joined to the external pterygoid plate about the sixth month. The remaining centres appear about the fourth month, and those for the lingulæ speedily become joined to the rest of the bone.

Pre-sphenoid Division.—The first nuclei to appear are those for the lesser wings (*orbito-sphenoids*). They make their appearance about the ninth week, at the outer borders of the optic foramina. A second pair of nuclei appear on the inner side of the foramina shortly after, and becoming united, form the front part of the body of the bone. The remaining two centres for the sphenoidal turbinated bones make their appearance about the fifth month. At birth they consist of small triangular laminæ, and it is not till the third year that they become hollowed out and cone-shaped. About the fourth year they become fused with the lateral masses of the ethmoid, i.e. several years before they unite with the sphenoid, and hence, from an embryological point of view, may be regarded as belonging to the ethmoid.

The pre-sphenoid is united to the post-sphenoid about the eighth month, so that at birth the bone consists of three pieces—viz. the body in the centre, and on each side the great wings with the pterygoid processes. The lesser wings become joined to the body at about the time of birth. In the first year after birth the greater wings and body are united. From the tenth to the twelfth year the spongy bones are partially united to the sphenoid, their junction being completed by the twentieth year. Lastly, the sphenoid joins the occipital from the eighteenth to the twenty-fifth year. Between the pre- and post-sphenoid divisions there are occasionally seen the remains of a canal (cranio-pharyngeal canal), through which, in early fœtal life, the pituitary diverticulum (or pouch of Rathke) of the buccal ectoderm is transmitted.

The sphenoid has attached to it certain intrinsic ligaments, which have received special names. The most important of these are: the *pterygo-spinous*, which is attached to the spinous process and the internal pterygoid plate (see *cervical fascia*); the *spheno-mandibular*, or internal lateral ligament of the lower jaw (see *temporo-mandibular joint*); the *interclinoid*, a fibrous process which passes from the anterior to the posterior clinoid process; and the *carotico-clinoid*,

* According to Cleland, the sphenoidal turbinated bones are ossified from four distinct centres.

† Fawcett (*Anatomischer Anzeiger*, March 1905) states that the external pterygoid plate is ossified in membrane, and is not a downward continuation of the cartilaginous great wing.

which passes from the anterior to the middle clinoid process. These ligaments occasionally ossify, and form adventitious foramina.

Articulations.—The sphenoid articulates with *all* the bones of the cranium, and five of the face—the two malar, two palate, and vomer: the exact extent of articulation with each bone is shown in the accompanying figures.*

Attachment of Muscles.—To eleven pairs: the Temporal, External pterygoid, Internal pterygoid, Superior constrictor, Tensor palati, Levator palpebræ, and Superior oblique, Superior rectus, Internal rectus, Inferior rectus, External rectus of the eyeball.

The Ethmoid Bone

The **Ethmoid** (ἠθμός, *a sieve*) is an exceedingly light, spongy bone, of a cubical shape, situated at the anterior part of the base of the cranium, between the two orbits, at the root of the nose, and contributing to each of these cavities. It consists of three parts: a horizontal plate, which forms part of the base of the cranium; a perpendicular plate, which constitutes part of the septum nasi; and two lateral masses of cells.

The **Horizontal** or **Cribriform Plate** (fig. 232) forms part of the anterior fossa of the base of the skull, and is received into the ethmoid notch of the frontal bone between the two orbital plates, roofing in the nasal fossæ below. Projecting upwards from the middle line of this plate is a thick, smooth, triangular process of bone, the *crista galli,* so called from its resemblance to a cock's comb. Its base joins the cribriform plate. Its posterior border, long, thin, and slightly curved, serves for the attachment of the falx cerebri. Its anterior border, short and thick, articulates with the frontal bone, and presents two small projecting alæ, which are received into corresponding depressions in the frontal, completing the foramen cæcum behind. Its sides are smooth and sometimes bulging; in which case it is found to enclose a small air-sinus.† On each side of the crista galli, the cribriform plate is narrow, and deeply grooved, to support the bulb of the olfactory lobe of the cerebrum, and perforated by foramina for the passage of the olfactory nerves. These foramina are arranged in three rows: the innermost, which are the largest and least numerous, are lost in grooves on the upper part of the septum; the foramina of the outer row are continued on to the surface of the upper spongy bone. The foramina of the middle row are the smallest; they perforate the bone, and transmit nerves to the roof of the nose. At the front part of the cribriform plate, on each side of the crista galli, is a small fissure, which transmits the nasal branch of the ophthalmic nerve; and at its posterior part a triangular notch, which receives the ethmoidal spine of the sphenoid.

Fig. 232.—Ethmoid bone.
Outer surface of right lateral mass (enlarged).

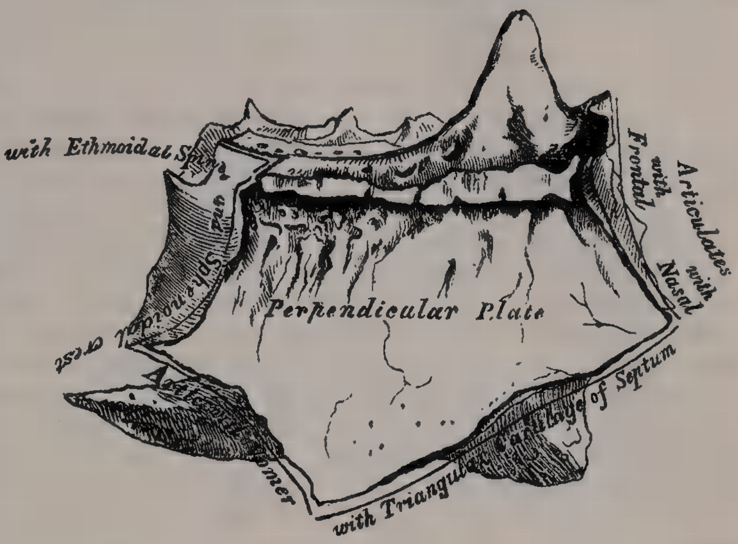
The **Perpendicular Plate** (fig. 233) is a thin, flattened lamella of bone, which descends from the under surface of the cribriform plate, and assists in forming the septum of the nose. It is much thinner in the middle than at the circumference, and is generally deflected a little to one side. Its anterior border articulates with the nasal spine of the frontal bone and the crest of the nasal bones. Its posterior border, divided into two parts, articulates by its upper half

* It also sometimes articulates with the tuberosity of the maxilla (see page 210).

† Sir George Humphry states that the crista galli is commonly inclined to one side, usually the opposite to that towards which the lower part of the perpendicular plate is bent.—*The Human Skeleton*, 1858, p. 277.

with the sphenoidal crest of the sphenoid, by its lower half with the vomer. The inferior border serves for the attachment of the septal cartilage of the nose. On each side of the perpendicular plate numerous grooves and canals are seen, leading from foramina on the cribriform plate; they lodge filaments of the olfactory nerves.

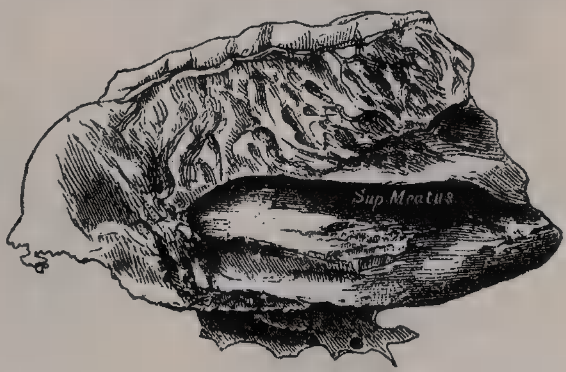
Fig. 233.—Perpendicular plate of ethmoid (enlarged). Shown by removing the right lateral mass.



The **Lateral Masses** of the ethmoid consist of a number of thin-walled cellular cavities, the *ethmoidal cells*, interposed between two vertical plates of bone, the outer one of which forms part of the orbit, and the inner one part of the nasal fossa of the corresponding side. In the disarticulated bone many of these cells appear to be broken; but when the bones are articulated, they are closed in at every part, except where they open into the nasal fossæ. The upper surface of each lateral mass presents a number of apparently half-broken cellular spaces; these are closed in, when articulated, by the edges of the ethmoidal notch of the frontal bone. Crossing this surface are two grooves on each side, converted into canals by articulation with the frontal; they are the *anterior* and *posterior ethmoidal* canals, and open on the inner wall of the orbit. The posterior surface also presents large, irregular cellular cavities, which are closed in by articulation with the sphenoidal turbinated bones and orbital process of the palate. The cells at the anterior surface are completed by the lachrymal bone and nasal process of the superior maxillary, and those below by the superior maxillary. The outer surface of each lateral mass is formed of a thin, smooth, oblong plate of bone, called the *os planum*; it forms part of the inner wall of the orbit, and articulates, above, with the orbital plate of the frontal; below, with the superior maxillary; in front, with the lachrymal; and behind, with the sphenoid and orbital process of the palate.

From the inferior part of each lateral mass, immediately behind the os planum, there projects downwards and backwards an irregular lamina of bone, called the *unciform process*, from its hook-like form; it serves to close in the upper part of the orifice of the antrum of Highmore, and articulates with the ethmoidal process of the inferior turbinated bone. It is often broken in disarticulating the bones.

Fig. 234.—Ethmoid bone. Inner surface of right lateral mass (enlarged).



The inner surface of each lateral mass (fig. 234) forms part of the outer wall of the nasal fossa of the corresponding side. It is formed of a thin lamella of bone, which descends from the under surface of the cribriform plate, and terminates below in a free, convoluted margin, the *middle turbinated* bone. The whole of this surface is rough, and marked above by numerous grooves, which run nearly vertically downwards from the cribriform plate; they lodge branches of the olfactory nerve, which are distributed on the mucous membrane covering the superior turbinated bone. The back part of this surface is subdivided by a narrow oblique fissure, the *superior meatus* of the nose, bounded

above by a thin, curved plate of bone, the *superior turbinated* bone. By means of an orifice at the upper part of this fissure, the posterior ethmoidal cells open into the nose. Below, and in front of the superior meatus, is seen the convex surface of the middle turbinated bone. It extends along the whole length of the inner surface of each lateral mass; its lower margin is free and thick, and its concavity, directed outwards, assists in forming the middle meatus of the nose. It is by a large orifice at the upper and front part of the middle meatus that the anterior ethmoidal cells, and through them the frontal sinuses, communicate with the nose, by means of a funnel-shaped canal, the *infundibulum*. The cellular cavities of each lateral mass, thus walled in by the os planum on the outer side, and by the other bones already mentioned, are divided by transverse bony partitions into three sets, which do not communicate with each other; they are termed the *anterior*, *middle*, and *posterior ethmoidal air-cells*. The anterior cells communicate with the frontal sinuses above, and the middle meatus below, by means of a long, flexuous canal, the *infundibulum*; the middle also open into the middle meatus; the posterior open into the superior meatus, and communicate (occasionally) with the sphenoidal sinuses.

Development.—The ethmoid ossifies in the cartilage of the nasal capsule by *three* centres: one for the perpendicular lamella, and one for each lateral mass.

The lateral masses are first developed, ossific granules making their appearance in the os planum between the fourth and fifth months of fœtal life, and extending into the spongy bones. At birth, the bone consists of the two lateral masses, which are small and ill developed. During the first year after birth, the perpendicular plate and crista galli begin to ossify, from a single nucleus, and become joined to the lateral masses about the beginning of the second year. The cribriform plate is ossified partly from the perpendicular plate and partly from the lateral masses. The formation of the ethmoidal cells does not commence until about the fourth or fifth year.

Articulations.—With fifteen bones: the sphenoid, two sphenoidal turbinated, the frontal, and eleven of the face—the two nasal, two superior maxillary, two lachrymal, two palate, two inferior turbinated, and the vomer.

No muscles are attached to this bone.

The Fontanelles (figs. 235, 236)

The early stages of the development of the cranium have already been described in the section on development. Before birth, the bones at the vertex and sides of the cranium are separated from each other by membranous intervals, in which bone is deficient. These intervals are principally found at the four angles of the parietal bones; hence there are six of them. Their formation is due to the wave of ossification in the parietal bones being

Fig. 235.—Skull at birth, showing the anterior and posterior fontanelles.

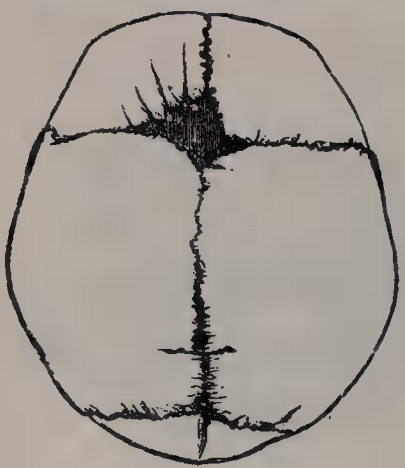


Fig. 236.—The lateral fontanelles.

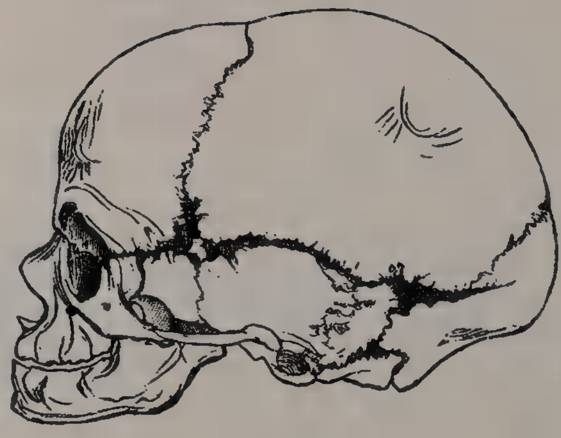


circular and the bones quadrilateral; the ossific matter first meets at the margins of the bones, at the points nearest to their centres of ossification, and spaces are left at the angles, which are called *fontanelles*, so named from the pulsations of the brain, which are perceptible at the anterior fontanelle, and were likened to the rising of water in a fountain.

The anterior fontanelle is the largest; it is lozenge-shaped, and corresponds to the junction of the sagittal and coronal sutures; the posterior fontanelle, of smaller size, is triangular, and is situated at the junction of the sagittal and lambdoid sutures; the remaining ones are situated at the inferior angles of each parietal bone. The latter are closed soon after birth; the two at the two superior angles remain open longer: the posterior being closed in a few months after birth; the anterior remaining open until the first or second year. These spaces are gradually filled in by an extension of the ossifying process, or by the development of a Wormian bone. Sometimes the anterior fontanelle remains open beyond two years, and is rarely persistent throughout life.

Supernumerary or Wormian* Bones

In addition to the constant centres of ossification of the cranium, additional ones may be found in the course of the sutures. These form irregular, isolated bones, interposed between the cranial bones, and have been termed *Wormian bones* or *ossa triquetra.* They are most frequently found in the course of the lambdoid suture, but occasionally also occupy the situation of the fontanelles, especially the posterior and, more rarely, the anterior. One, the *pterion ossicle*, is often found between the anterior inferior angle of the parietal bone and the greater wing of the sphenoid (fig. 236). They have a tendency to be more or less symmetrical on the two sides of the skull, and they vary much in size, being in some cases not larger than a pin's head, and confined to the outer table; in other cases so large that one pair of these bones may form the whole of the occipital bone above the superior curved lines, as described by Béclard and Ward. Their number is generally limited to two or three; but more than a hundred have been found in the skull of an adult hydrocephalic skeleton. In their development, structure, and mode of articulation, they resemble the other cranial bones.

Congenital Fissures and Gaps

An arrest in the ossifying process may give rise to deficiencies, or gaps; or to fissures which are of importance from a medico-legal point of view, as they are liable to be mistaken for fractures. The fissures generally extend from the margins towards the centre of the bone, but the gaps may be found in the middle as well as at the edges. In course of time they may become filled with a thin lamina of bone.

Bones of the Face

The Facial Bones are fourteen in number—viz. the

Two Nasal.	Two Palate.
Two Superior Maxillary.	Two Inferior Turbinated.
Two Lachrymal.	Vomer.
Two Malar.	Inferior Maxillary or Mandible.

'Of these, the upper and lower jaws are the fundamental bones for mastication, and the others are accessories; for the chief function of the facial bones is to provide an apparatus for mastication, while subsidiary functions are to provide for the sense-organs (eye, nose, tongue) and a vestibule to the respiratory and vocal organs. Hence the variations in the shape of the face in man and the lower animals depend chiefly on the question of the character of their food and their mode of obtaining it.' †

Nasal Bones

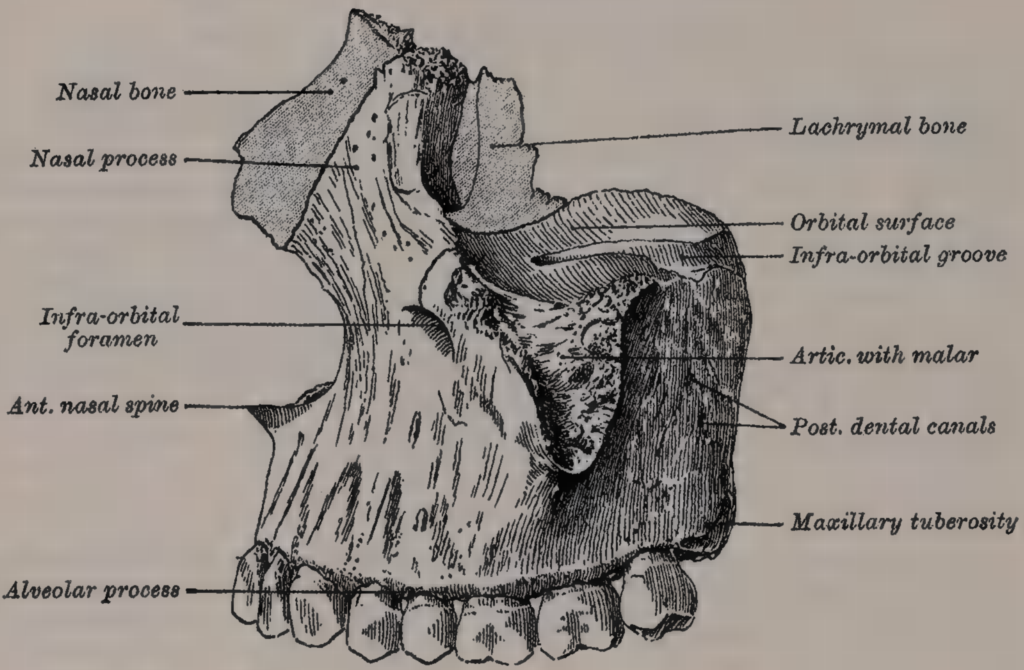
The **Nasal** (nasus, *the nose*) are two small oblong bones, varying in size and form in different individuals; they are placed side by side at the middle and upper part of the face, forming, by their junction, 'the bridge' of the nose (fig. 237). Each bone presents for examination two surfaces and four borders. The *outer* surface (fig. 238) is concavo-convex from above downwards, convex from side to side; it is covered by the Pyramidalis and Compressor nasi muscles, and gives attachment at its upper part to a few fibres of the Occipito-frontalis muscle (Theile). It is marked by numerous small arterial furrows, and perforated about its centre by a foramen, sometimes double, for the transmission of

* Wormius, a physician in Copenhagen, is said to have given the first detailed description of these bones.

† W. W. Keen. American edition.

a small vein. The *inner* surface (fig. 239) is concave from side to side, and is traversed from above downwards by a longitudinal groove (sometimes a canal), for the passage of a branch of the nasal nerve. The *superior* border is narrow, thick, and serrated for articulation with the nasal notch of the frontal bone. The *inferior* border is broad, thin, sharp, inclined obliquely downwards, outwards, and backwards, and serves for the attachment of the upper lateral cartilage of the nose. It presents, about its middle, a notch, through which

Fig. 237.—Nasal bone and Lachrymal bone *in situ.*



passes the branch of the nasal nerve above referred to; and is prolonged at its inner extremity into a sharp spine, which, when articulated with the opposite bone, forms the *nasal angle.* The *external* border is serrated, bevelled at the expense of the internal surface above, and of the external below, to articulate with the nasal process of the superior maxillary. The *internal* border, thicker above than below, articulates with its fellow of the opposite side, and is prolonged behind into a vertical crest, which forms part of the septum of the nose:

Fig. 238.—Right nasal bone. Outer surface.

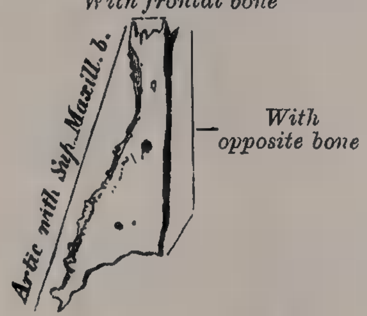


Fig. 239.—Left nasal bone. Inner surface.

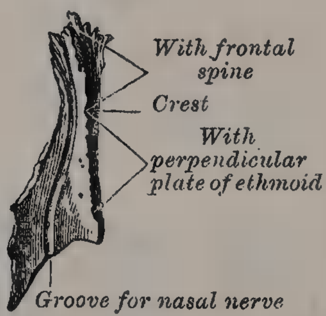


this crest articulates, from above downwards, with the nasal spine of the frontal, the perpendicular plate of the ethmoid, and the septal cartilage of the nose.

Development.—By *one* centre for each bone, which appears about the eighth week.

Articulations.—With four bones: two of the cranium, the frontal and ethmoid, and two of the face, the opposite nasal and the superior maxillary.

Attachment of Muscles.—A few fibres of the Occipito-frontalis muscle.

Superior Maxillary Bones or Maxillæ

The **Superior Maxillary Bones** (maxilla, *the jaw-bone*) are the most important bones of the face from a surgical point of view, on account of the number of diseases to which some of their parts are liable. Their careful examination is, therefore, a matter of considerable interest. They are the largest bones of the face, excepting the mandible, and form, by their union, the whole of the upper jaw. Each bone assists in the formation of three cavities, viz.: the roof of the mouth, the floor and outer wall of the nasal fossæ, and the floor of the orbit; it also enters into the formation of two fossæ, the zygomatic and spheno-maxillary, and two fissures, the spheno-maxillary and pterygo-maxillary.

The bone presents for examination a body and four processes—malar, nasal, alveolar, and palate.

The **body** is somewhat pyramidal in shape, and is hollowed out in its interior to form a large cavity, the *antrum of Highmore*, or *maxillary sinus*. Its surfaces are four—an external or facial, a posterior or zygomatic, a superior or orbital, and an internal or nasal.

The **external** or **facial surface** (fig. 240) is directed forwards and outwards. It presents at its lower part a series of eminences corresponding to the position

Fig. 240.—Left superior maxillary bone. Outer surface.

of the fangs of the teeth. Just above those of the incisor teeth is a depression, the *incisive* or *myrtiform fossa*, which gives origin to the Depressor alæ nasi; and, below it, to the alveolar border is attached a slip of the Orbicularis oris. Above and a little external to it, the Compressor nasi arises. More external is another depression, the *canine fossa*, larger and deeper than the incisive fossa, from which it is separated by a vertical ridge, the *canine eminence*, corresponding to the socket of the canine tooth. The canine fossa gives origin to the Levator anguli oris. Above the canine fossa is the *infra-orbital foramen*, the termination of the infra-orbital canal; it transmits the infra-orbital vessels and nerve. Sometimes the infra-orbital canal opens by two, very rarely by three, orifices on the face. Above the infra-orbital foramen is the margin of the orbit, which affords partial attachment to the Levator labii superioris proprius. Internally, the facial surface is limited by a deep concavity, the *nasal notch*, to the sharp margin of which is attached the Dilatator naris posterior.

The **posterior** or **zygomatic surface** is convex, directed backwards and outwards, and forms part of the zygomatic fossa. It is separated from the facial surface by the malar process and by a strong ridge of bone, which extends upwards from the socket of the second molar tooth. It presents about its centre several apertures leading to canals in the substance of the bone; they are termed the *posterior dental canals*, and transmit the posterior dental vessels and nerves. At the lower part of this surface is a rounded eminence, the *maxillary tuberosity*, especially prominent after the growth of the wisdom-tooth, rough on its inner side for articulation with the tuberosity of the palate-bone and sometimes with the external pterygoid plate. It gives attachment to a few fibres of origin of the Internal pterygoid muscle. Immediately above this is a smooth surface, which forms the anterior boundary of the spheno-maxillary fossa; from this fossa a groove, for the lodgment of the second division of the fifth nerve, extends outwards and becomes continuous with the infra-orbital groove on the orbital surface of the bone; a second groove runs obliquely downwards, and is converted into a canal by articulation with the palate-bone, forming the *posterior palatine* canal for the large palatine nerve and descending palatine artery.

The **superior** or **orbital surface** is thin, smooth, triangular, and forms part of the floor of the orbit. It is bounded internally by an irregular margin which in front presents a notch, the *lachrymal notch*, for the reception of the lachrymal bone; in the middle it articulates with the os planum of the ethmoid, and behind with the orbital process of the palate-bone; it is bounded behind by a smooth, rounded edge which enters into the formation of the spheno-maxillary fissure, and which sometimes articulates at its outer extremity with the orbital plate of the sphenoid; and it is bounded in front by part of the circumference of the orbit, which is continuous, on the inner side with the nasal, on the outer side with the malar process of the bone. Near the middle line of the orbital surface is a deep groove, the *infra-orbital*, for the passage of the infra-orbital vessels and nerve. The groove commences at the middle of the outer border of this surface, where it is continuous with that near the upper edge of the posterior surface, and, passing forwards, terminates in a canal, which subdivides into two branches. One of the canals, the *infra-orbital*, opens just below the margin of the orbit; the other, which is smaller, runs downwards in the substance of the anterior wall of the antrum; it is called the *anterior dental canal*, and transmits the anterior dental vessels and nerve to the front teeth of the upper jaw. From the back part of the infra-orbital canal, a second small canal is sometimes given off, which runs downwards in the outer wall of the antrum, and conveys the middle dental nerve to the bicuspid teeth. Occasionally, this canal is derived from the anterior dental. At the inner and fore part of the orbital surface, just external to the lachrymal groove for the nasal duct, is a depression, which gives origin to the Inferior oblique muscle of the eye.

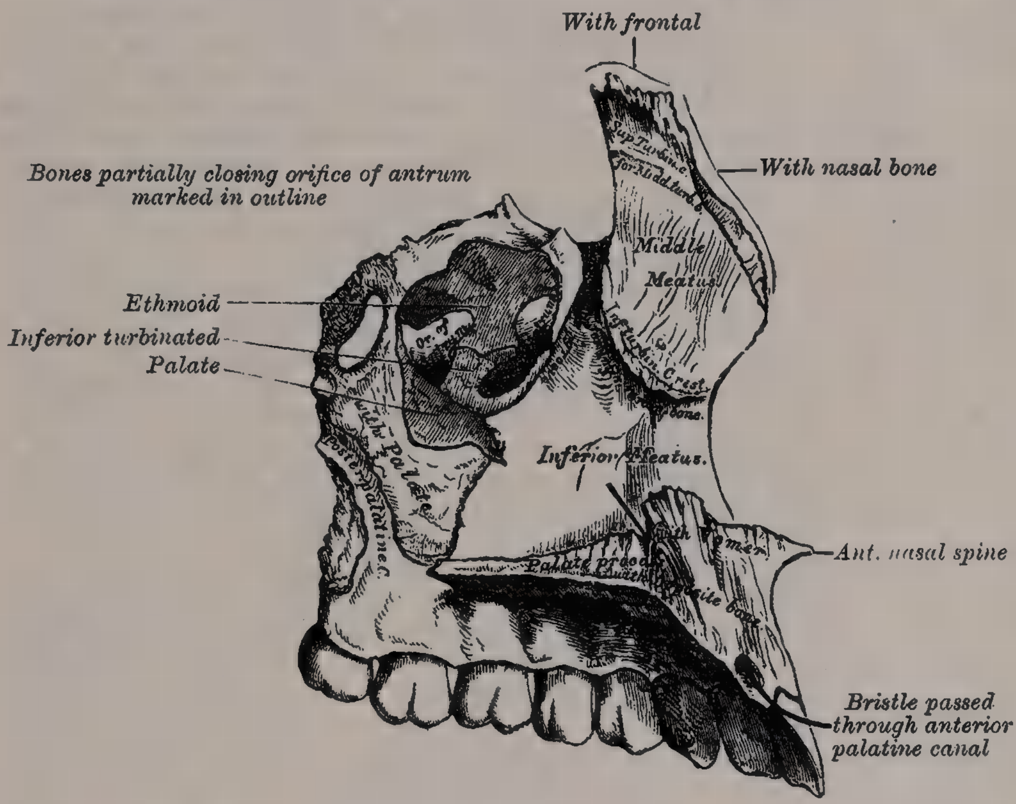
The **internal surface** (fig. 241) is unequally divided into two parts by a horizontal projection of bone, the *palate process*: the portion above the palate process forms part of the outer wall of the nasal fossæ; that below it forms part of the cavity of the mouth. The superior division of this surface presents a large, irregular opening leading into the *antrum of Highmore*. At the upper border of this aperture are numerous broken cellular cavities, which, in the articulated skull, are closed in by the ethmoid and lachrymal bones. Below the aperture is a smooth concavity which forms part of the inferior meatus of the nasal fossæ, and behind it is a rough surface for articulation with the perpendicular plate of the palate bone and is traversed by a groove which, commencing near the middle of the posterior border, runs obliquely downwards and forwards, and forms, when completed by its articulation with the palate-bone, the *posterior palatine canal*. In front of the opening of the antrum is a deep groove, converted into a canal by the lachrymal and inferior turbinated bones. It is called the *lachrymal groove*, and lodges the nasal duct. More anteriorly is a well-marked rough ridge, the *inferior turbinated crest*, for articulation with the inferior turbinated bone. The shallow concavity above this ridge forms part of the middle meatus of the nose; while that below it forms part of the inferior meatus. The portion of this surface below the palate process is concave, rough and uneven, and perforated by numerous small foramina for the passage of nutrient vessels. It enters into the formation of the roof of the mouth.

The **Antrum of Highmore,** or **Maxillary Sinus,** is a large pyramidal cavity,

hollowed out of the body of the maxillary bone: its apex, directed outwards, is formed by the malar process; its base, by the outer wall of the nose. Its walls are everywhere exceedingly thin, and correspond to the orbital, facial, and zygomatic surfaces of the body of the bone. Its inner wall, or base, presents, in the disarticulated bone, a large, irregular aperture, which communicates with the nasal fossa. The margins of this aperture are thin and ragged, and the aperture itself is much contracted by the articulation of its margins with the ethmoid above, the inferior turbinated below, and the palate-bone behind.* In the articulated skull, this cavity communicates with the middle meatus of the nasal fossa, generally by two small apertures left between the above-mentioned bones. In the recent state, usually only one small opening exists, near the upper part of the cavity, sufficiently large to admit the end of a probe; the other being closed by mucous membrane.

The infra-orbital canal usually projects into the cavity of the antrum as a well-marked ridge, which passes downwards and inwards from the roof to the

FIG. 241.—Left superior maxillary bone. Inner surface.



anterior wall, and additional ridges are sometimes seen in the cavity. On its posterior wall are the *posterior dental canals*, transmitting the posterior dental vessels and nerves to the teeth. The floor is formed by the alveolar process of the jaw, and, in a cavity of average size, is on a level with the floor of the nose; where the cavity is large it reaches below this level. Projecting into it are several conical processes, corresponding to the roots of the first and second molar teeth;† in some cases it is perforated by the teeth in this situation. The size of the cavity varies in different skulls, and even on the two sides of the same skull.‡

* In some cases, at any rate, the lachrymal bone also encroaches slightly on the anterior superior portion of the opening, and assists in forming the inner wall of the antrum.

† The number of teeth whose fangs are in relation with the floor of the antrum is variable. The antrum 'may extend so as to be in relation to all the teeth of the true maxilla, from the canine to the *dens sapientiæ*.'—See Salter on Abscess of the Antrum, in *A System of Surgery*, edited by T. Holmes, 2nd edit. vol. iv. p. 356.

‡ Aldren Turner (*op. cit.*) gives the following measurements as those of an average-sized antrum: vertical height opposite first molar tooth, $1\frac{1}{2}$ in.; transverse breadth, 1 in.; and antero-posterior depth, $1\frac{1}{4}$ in.

The extreme thinness of the walls of this cavity enables one to explain how a tumour growing from the antrum encroaches upon the adjacent parts, pushing up the floor of the orbit, and displacing the eyeball, projecting inwards into the nose, protruding forwards on to the cheek, and making its way backwards into the zygomatic fossa, and downwards into the mouth.

The **Malar Process** is a rough triangular eminence, situated at the angle of separation of the facial from the zygomatic surface. In front it forms part of the facial surface; behind, it is concave, and forms part of the zygomatic fossa; above, it is rough and serrated for articulation with the malar bone; while below, a prominent ridge marks the division between the facial and zygomatic surfaces. A small part of the Masseter muscle arises from this process.

The **Nasal Process** is a strong, triangular plate of bone, which projects upwards, inwards, and backwards, by the side of the nose, forming part of its lateral boundary. Its *external* surface is concave, smooth, perforated by numerous foramina, and gives attachment to the Levator labii superioris alæque nasi, the Orbicularis palpebrarum, and Tendo oculi. Its *internal* surface forms part of the outer wall of the nasal fossa: at its upper part it presents a rough, uneven surface, which articulates with the ethmoid bone, closing in the anterior ethmoidal cells; below this is a transverse ridge, the *superior turbinated crest*, for articulation with the middle turbinated bone of the ethmoid, bounded below by a shallow smooth concavity which forms part of the middle meatus; below this again is the inferior turbinated crest (already described), where the nasal process joins the body of the bone. Its *upper* border articulates with the frontal bone. Its *anterior* border is thin, directed obliquely upwards and forwards, and presents a serrated edge for articulation with the nasal bone; its *posterior* border is thick, and hollowed into a groove, the *lachrymal groove*, for the nasal duct: of the two margins of this groove, the inner articulates with the lachrymal bone, the outer forms part of the circumference of the orbit. Where the latter joins the orbital surface is a small tubercle, the *lachrymal tubercle*; this serves as a guide to the position of the lachrymal sac in the operation for fistula lachrymalis. The lachrymal groove in the articulated skull is converted into a canal by the lachrymal bone and lachrymal process of the inferior turbinated bone; it is directed downwards, and a little backwards and outwards, is about the diameter of a goose-quill, slightly narrower in the middle than at either extremity, and terminates below in the inferior meatus. It lodges the nasal duct.

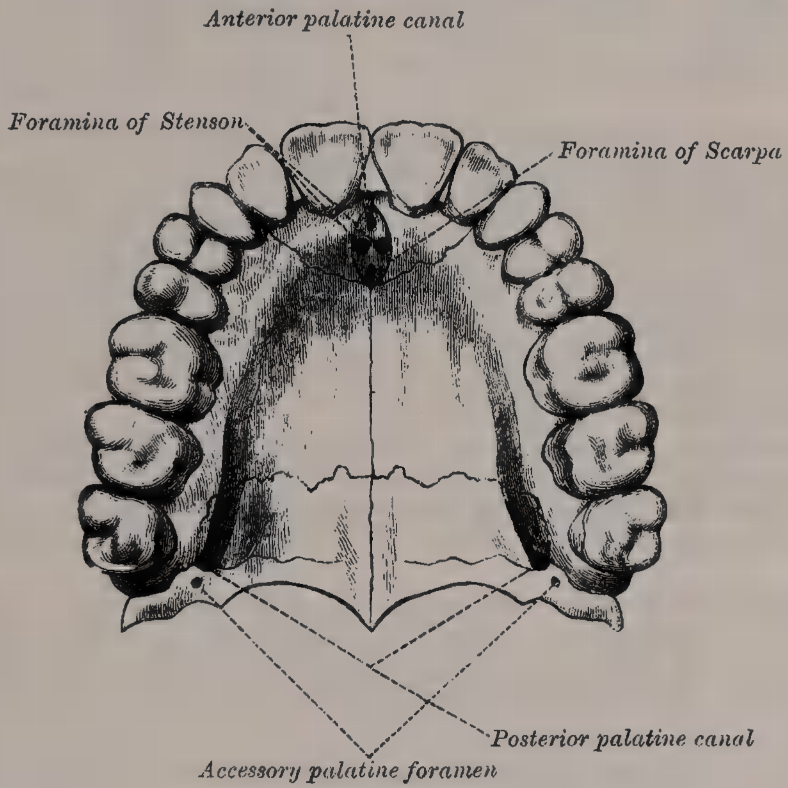
The **Alveolar Process** is the thickest and most spongy part of the bone, broader behind than in front, and excavated into deep cavities for the reception of the teeth. These cavities are eight in number, and vary in size and depth according to the teeth they contain. That for the canine tooth is the deepest; those for the molars are the widest, and subdivided into minor cavities by septa; those for the incisors are single, but deep and narrow. The Buccinator muscle arises from the outer surface of this process, as far forward as the first molar tooth. When the superior maxillary bones are articulated with each other, their alveolar processes together form the *alveolar arch*; the centre of the anterior margin of this arch is named the *alveolar point*.

The **Palate Process**, thick and strong, projects horizontally inwards from the inner surface of the bone. It is much thicker in front than behind, and forms a considerable part of the floor of the nose and the roof of the mouth.

Its *inferior* surface (fig. 242) is concave, rough and uneven, and forms, when articulated with the palatal process of the opposite bone, the anterior three-fourths of the hard palate. This surface is perforated by numerous foramina for the passage of the nutrient vessels; channelled at the back part of its alveolar border by a longitudinal groove, sometimes a canal, for the transmission of the posterior palatine vessels, and the anterior or large palatine nerve from Meckel's ganglion; and presents little depressions for the lodgment of the palatine glands. When the two superior maxillary bones are articulated together, a large orifice may be seen in the middle line, immediately behind the incisor teeth. This is the *anterior palatine canal* or *fossa*. On examining the bottom of this fossa four canals are seen: two branch off laterally to the right and left nasal fossæ, and two lie in the middle line. The lateral canals are named the *foramina of Stenson*, and through each of them passes the anterior or terminal branch of the descending or posterior palatine arteries, which ascends from the mouth to

the nasal fossæ, and in them is lodged the remains of the organ of Jacobson. The canals in the middle line are termed the *foramina of Scarpa*, and transmit the naso-palatine nerves, the left passing through the anterior, and the right through the posterior canal. On the palatal surface of the process, a delicate linear suture, well seen in young skulls, may sometimes be noticed extending from the anterior palatine fossa to the interval between the lateral incisor and the canine tooth. This marks out the *intermaxillary*, or *incisive bone*, which in some animals exists permanently as a separate piece. It includes the whole thickness of the alveolus, the corresponding part of the floor of the nose and the anterior nasal spine, and contains the sockets of the incisor teeth. The *upper* surface is concave from side to side, smooth, and forms part of the floor of the nose. It presents the upper orifices of the foramina of Stenson and Scarpa, the former being on either side of the middle line, the latter in the intermaxillary suture, and therefore not visible unless the two bones are placed in apposition. The *outer* border of the palate process is incorporated with the rest of the bone. The *inner* border is thicker in front than

Fig. 242.—The palate and alveolar arch.



behind, and is raised above into a ridge, the *nasal crest*, which, with the corresponding ridge in the opposite bone, forms a groove for the reception of the vomer. In front, this ridge rises to a considerable height, and this portion is named the *incisor crest*. The *anterior* margin is bounded by the thin, concave border of the opening of the nose prolonged forwards internally into a sharp process, forming, with a similar process of the opposite bone, the *anterior nasal spine*. The *posterior* border is serrated for articulation with the horizontal plate of the palate-bone. The middle of the inferior border of the anterior nasal aperture at the base of the nasal spine is named the *subnasal point*.

Development.—This bone commences to ossify at a very early period, and ossification proceeds in it with such rapidity that it is difficult to ascertain with certainty its precise number of centres. It appears probable, however, that it is ossified from six centres, which are deposited in membrane. One, the *orbito-nasal*, forms that portion of the body of the bone which lies internal to the infra-orbital canal, including the floor of the orbit and the outer wall of the nasal fossa; a second, the *malar*, gives origin to that portion of the bone which lies external to the infra-orbital canal and the malar process; from a third, the *palatine*, is developed the palatine process posterior to Stenson's canal and

the adjoining part of the nasal wall; a fourth, the *pre-maxillary*, forms the front part of the alveolus which carries the incisor teeth and corresponds to the pre-maxillary bone of the lower animals;* a fifth, the *nasal*, gives rise to the nasal process and the portion of the bone above the canine tooth; and a sixth, the *infravomerine*, lies between the palatine and pre-maxillary centres and beneath the vomer; this centre, together with the corresponding centre of the opposite bone, separates the foramina of Stenson from each other. These centres appear about the eighth week, and by the tenth week the three first-named have fused together and the bone consists of two portions, one the maxilla proper,

Fig. 243.—Development of superior maxillary bone. At birth.

ANTERIOR SURFACE INFERIOR SURFACE

and the other the pre-maxilla. The suture between these two portions persists on the palate till middle life, but is not to be seen on the facial surface. This is believed by Callender to be due to the fact that the front wall of the sockets of the incisor teeth is not formed by the pre-maxillary bone, but by an outgrowth from the facial part of the superior maxilla. The antrum appears as a shallow groove on the inner surface of the bone at an earlier period than any of the other nasal sinuses, its development commencing about the fourth month of fœtal life. The sockets for the teeth are formed by the growing downwards of two plates from the dental groove, and by the subsequent growth of partitions jutting across from the one to the other.

Articulations.—With *nine* bones: two of the cranium, the frontal and ethmoid, and seven of the face—viz. the nasal, malar, lachrymal, inferior turbinated, palate, vomer, and its fellow of the opposite side. Sometimes it articulates with the orbital plate of the sphenoid, and sometimes with its external pterygoid plate.

Attachment of Muscles.—To twelve: the Orbicularis palpebrarum, Obliquus oculi inferior, Levator labii superioris alæque nasi, Levator labii superioris proprius, Levator anguli oris, Compressor nasi, Depressor alæ nasi, Dilatator naris posterior, Masseter, Buccinator, Internal pterygoid, and Orbicularis oris.

Changes produced in the Upper Jaw by Age

At birth the transverse and antero-posterior diameters of the bone are greater than the vertical. The nasal process is well marked and the body of the bone consists of little more than the alveolar process, while the teeth-sockets reach almost to the floor of the orbit. The antrum of Highmore presents the appearance of a slit-like furrow on the outer wall of the nose. In the adult the vertical diameter is the greater, owing to the development of the alveolar process and the increase in size of the antrum. In old age the bone approaches again in character to the infantile condition: its height is diminished, and after the loss of the teeth the alveolar process is absorbed, and the lower part of the bone contracted and diminished in thickness.

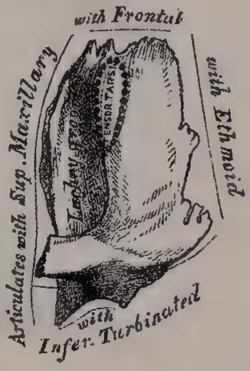
The Lachrymal Bones

The **Lachrymal** (lachryma, *a tear*) are the smallest and most fragile bones of the face. They are situated at the front part of the inner wall of the orbit (fig. 237), and resemble somewhat in form, thinness, and size, a finger-nail; hence they are termed the *ossa unguis*. Each bone presents for examination

* Some anatomists believe that the pre-maxillary bone is ossified by two centres (see page 250).

two surfaces and four borders. The *external* or *orbital* surface (fig. 244) is divided by a vertical ridge, the *lachrymal crest*, into two parts. The portion of bone in front of this ridge presents a smooth, concave, longitudinal groove, the free margin of which unites with the nasal process of the superior maxillary bone, completing the lachrymal groove. The upper part of this groove lodges the lachrymal sac; the lower part the nasal duct. The portion of bone behind the ridge is smooth, slightly concave, and forms part of the inner wall of the orbit. The ridge, with a part of the orbital surface immediately behind it, affords attachment to the Tensor tarsi muscle: it terminates below in a small, hook-like projection, the *hamular process*, which articulates with the lachrymal tubercle of the superior maxillary bone, and completes the upper orifice of the lachrymal groove. It sometimes exists as a separate piece, which is then called the *lesser lachrymal bone*. The *internal* or *nasal* surface presents a depressed furrow, corresponding to the ridge on its outer surface. The surface of bone in front of this forms part of the middle meatus of the nose; and that behind it articulates with the ethmoid bone, filling in the anterior ethmoidal cells. Of the *four borders* the *anterior* is the longest, and articulates with the nasal process of the superior maxillary bone. The *posterior*, thin and uneven, articulates with the os planum of the ethmoid. The *superior*, the shortest and thickest, articulates with the internal angular process of the frontal bone. The *inferior* is divided by the lower edge of the vertical crest into two parts: the posterior part articulates with the orbital plate of the superior maxillary bone; the anterior portion is prolonged downwards into a pointed process (the *descending* or *turbinal process*), which articulates with the lachrymal process of the inferior turbinated bone, and assists in the formation of the lachrymal groove.

Fig. 244.—Left lachrymal bone. External surface. (Slightly enlarged.)



Development.—By a single centre, which makes its appearance soon after ossification of the vertebræ has commenced.

Articulations.—With four bones: two of the cranium, the frontal and ethmoid, and two of the face, the superior maxillary and the inferior turbinated.

Attachment of Muscles.—To one muscle, the Tensor tarsi.

The Malar Bones

The **Malar** (mala, *the cheek*) are two small, quadrangular bones, situated at the upper and outer part of the face: they form the prominence of the cheek, part of the outer wall and floor of the orbit, and part of the temporal and zygomatic fossæ (fig. 245). Each bone presents for examination an external and an internal surface; four processes, the frontal, orbital, maxillary, and zygomatic; and four borders.

The **external surface** (fig. 246) is smooth, convex, and perforated near its centre by one or two small apertures, the *malar foramina*, for the passage of the malar nerves and vessels; it is covered by the Orbicularis palpebrarum muscle, and affords attachment to the Zygomaticus major and minor muscles.

The **internal surface** (fig. 247), directed backwards and inwards, is concave, presenting internally a rough, triangular surface, for articulation with the superior maxillary bone, and externally a smooth, concave surface, which above forms the anterior boundary of the temporal fossa, and below, where it is wider, a part of the zygomatic fossa. This surface presents, a little above its centre, the aperture of one or two malar canals, and affords attachment to a portion of the Masseter muscle at its lower part.

Of the four processes, the **frontal** is thick and serrated, and articulates with the external angular process of the frontal bone. To its orbital margin is attached the external tarsal ligament. The **orbital** process is a thick, strong plate, which projects backwards from the orbital margin of the bone. Its *supero-internal* surface, smooth and concave, forms, by its junction with the orbital surface of the superior maxillary bone and with the great wing of the sphenoid, part of the floor and outer wall of the orbit. Its *infero-external*

surface, smooth and convex, forms part of the zygomatic and temporal fossæ. Its *anterior* margin, smooth and rounded, forms part of the circumference of the orbit. Its *superior* margin, rough, and directed horizontally, articulates

Fig. 245.—Malar bone *in situ.*

with the frontal bone behind the external angular process. Its *posterior* margin is rough, and serrated for articulation with the great wing of the sphenoid;

Fig. 246.—Left malar bone. Outer surface.

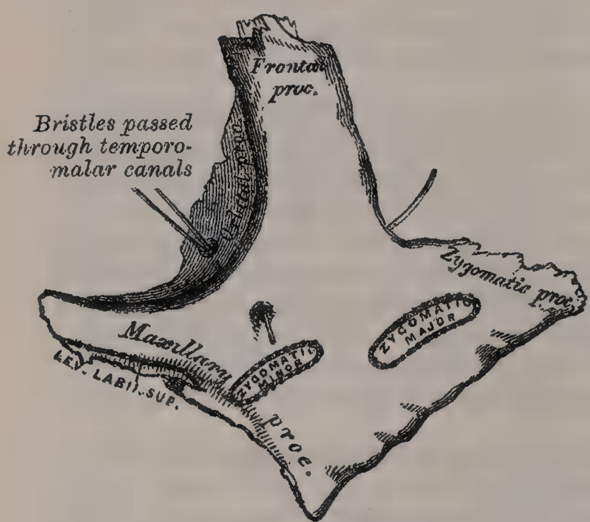


Fig. 247.—Left malar bone. Inner surface.

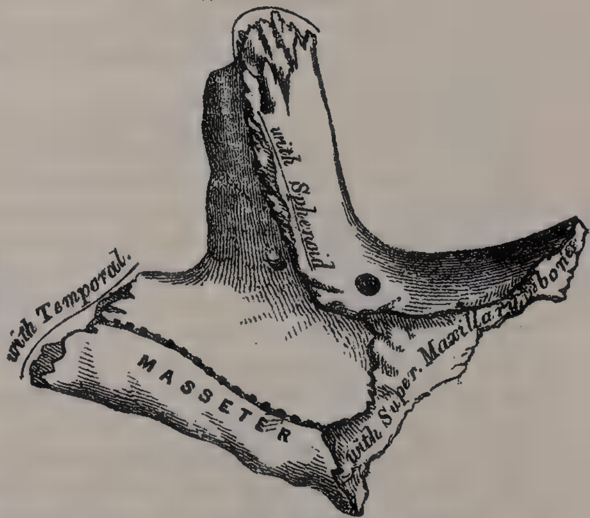


internally it is also serrated for articulation with the orbital surface of the superior maxillary. At the angle of junction of the sphenoidal and maxillary portions, a short, rounded, non-articular margin is generally seen; this forms the

anterior boundary of the spheno-maxillary fissure: occasionally, this non-articular margin does not exist, the fissure being completed by the direct junction of the maxillary and sphenoid bones, or by the interposition of a small Wormian bone in the angular interval between them. On the *inner* surface of the orbital process are seen the orifices of one or two temporo-malar canals; one of these usually opens on the posterior surface, the other (occasionally there are two) on the facial surface: they transmit filaments (temporo-malar) of the orbital branch of the superior maxillary nerve. The **maxillary** process is a rough, triangular surface which articulates with the superior maxillary bone. The **zygomatic** process, long, narrow, and serrated, articulates with the zygomatic process of the temporal bone. Of the **four borders,** the *antero-superior* or *orbital* is smooth, concave, and forms a considerable part of the circumference of the orbit. The *antero-inferior* or *maxillary* border is rough, and bevelled at the expense of its inner table, to articulate with the superior maxillary bone; affording attachment by its margin to the Levator labii superioris proprius, just at its point of junction with the superior maxillary. The *postero-superior* or *temporal* border, curved like an italic letter *f*, is continuous above with the commencement of the temporal ridge; below, with the upper border of the zygomatic arch: it affords attachment to the temporal fascia. The *postero-inferior* or *zygomatic* border is continuous with the lower border of the zygomatic arch, affording attachment by its rough edge to the Masseter muscle.

Development.—The malar bone ossifies generally from three centres, which appear about the eighth week—one for the zygomatic and two for the orbital portion—and fuse about the fifth month of fœtal life. After birth, the bone is sometimes seen to be divided, by a horizontal suture, into an upper and larger and a lower and smaller division. In some quadrumana the malar bone consists of two parts, an orbital and a malar.

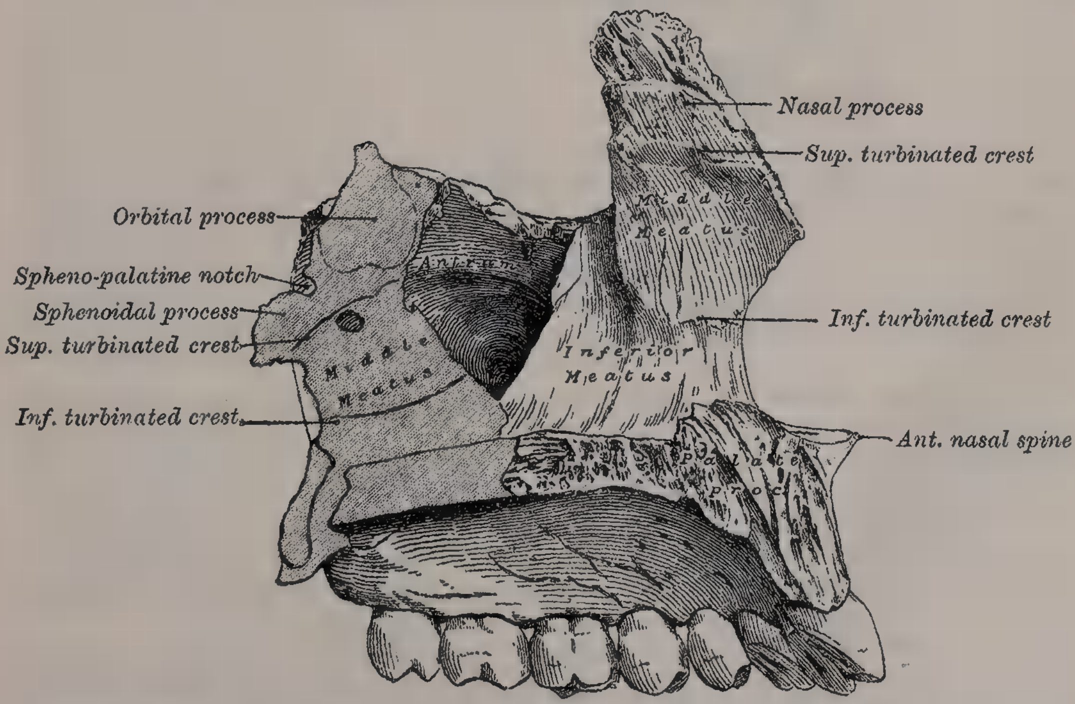
Articulations.—With four bones: three of the cranium, frontal, sphenoid, and temporal; and one of the face, the superior maxillary.

Attachment of Muscles.—To four: the Levator labii superioris proprius, Zygomaticus major and minor, and Masseter.

The Palate Bones

The **Palate Bones** (palatum, *the palate*) are situated at the back part of the nasal fossæ: they are wedged in between the superior maxillary bones and the

Fig. 248.—Palate bone *in situ.*

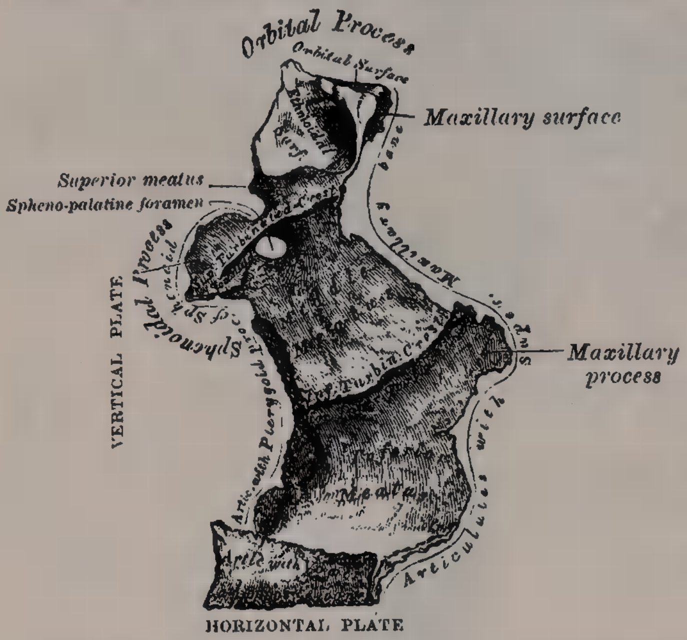


pterygoid processes of the sphenoid (fig. 248). Each bone assists in the formation of three cavities: the floor and outer wall of the nose, the roof of the mouth, and

the floor of the orbit; it enters into the formation of two fossæ: the spheno-maxillary and pterygoid, and one fissure, the spheno-maxillary. In form the palate-bone somewhat resembles the letter L, and may be divided into an inferior or horizontal plate and a superior or vertical plate.

The **Horizontal Plate** is quadrilateral, and presents two surfaces and four borders. The *superior* surface, concave from side to side, forms the back part of the floor of the nose. The *inferior* surface, slightly concave and rough, forms the posterior fourth of the hard palate. At its posterior part may be seen a transverse ridge, more or less marked, for the attachment of part of the aponeurosis of the Tensor palati muscle. At the outer extremity of this ridge is a deep groove converted into a canal by its articulation with the tuberosity of the superior maxillary bone, and forming the *posterior palatine canal*. Near this groove, the orifices of one or two small canals, *accessory posterior palatine*, may be seen. The *anterior* border is serrated, bevelled at the expense of its inferior surface, and articulates with the palate process of the superior maxillary bone. The *posterior* border is concave, free, and serves for the attachment of the soft palate. Its inner extremity is sharp and pointed, and, when united with the opposite bone, forms a projecting process, the *posterior nasal spine*, for the attachment of the Azygos uvulæ muscle. The *external* border is united with the lower part of the perpendicular plate almost at right angles. The *internal* border, the thickest, is serrated for articulation with its fellow of the opposite side; its superior edge is raised into a ridge, which, united with the opposite bone, forms a crest for articulation with the posterior part of the lower edge of the vomer.

Fig. 249.—Left palate bone. Internal view. (Enlarged.)



The **Vertical Plate** (fig. 249) is thin, of an oblong form, and directed upwards and a little inwards. It presents two surfaces, an external and an internal, and four borders.

The **internal surface** exhibits at its lower part a broad, shallow depression, which forms part of the inferior meatus of the nose. Immediately above this is a well-marked, horizontal ridge, the *inferior turbinated crest*, for articulation with the inferior turbinated bone; superior to this, a second broad, shallow depression, which forms part of the middle meatus, surmounted above by a horizontal ridge less prominent than the inferior, the *superior turbinated crest*, for articulation with the middle turbinated bone. Above the superior turbinated crest is a narrow, horizontal groove, which forms part of the superior meatus.

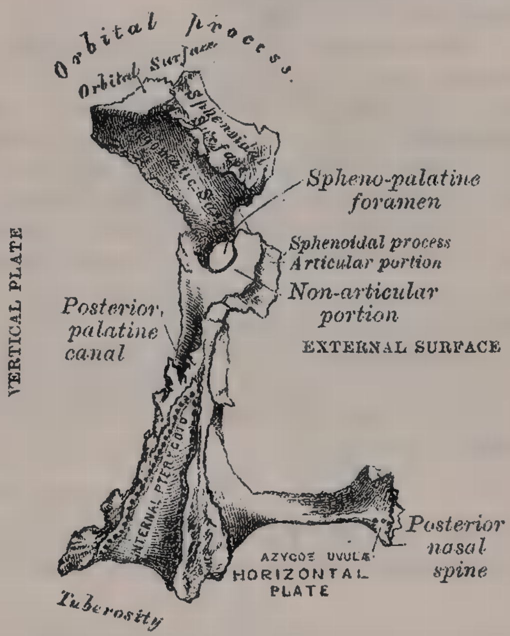
The **external surface** is rough and irregular throughout the greater part of its extent, for articulation with the inner surface of the superior maxillary bone, its upper and back part being smooth where it enters into the formation of the spheno-maxillary fossa; it is also smooth in front, where it covers the posterior part of the orifice of the antrum. Towards the back part of this surface is a deep groove, converted into a canal, the *posterior palatine*, by its articulation with the superior maxillary bone. It transmits the posterior or descending palatine vessels, and the large palatine nerve from Meckel's ganglion.

The *anterior* border is thin, irregular, and presents, opposite the inferior turbinated crest, a pointed, projecting lamina, the *maxillary process*, which is directed forwards, and closes in the lower and back part of the opening of the antrum. The *posterior* border (fig. 250) presents a deep groove, the edges of which are serrated for articulation with the pterygoid process of the sphenoid.

At the lower part of this border is seen a pyramidal process of bone, the *pterygoid process* or *tuberosity* of the palate, which is received into the angular interval between the two pterygoid plates of the sphenoid at their inferior extremity. This process presents at its back part a median groove and two lateral surfaces. The groove is smooth, and forms part of the pterygoid fossa affording attachment to the Internal pterygoid muscle; while the lateral surfaces are rough and uneven, for articulation with the anterior border of each pterygoid plate. The base of this process, continuous with the horizontal portion of the bone, presents the apertures of the *posterior* and *external accessory palatine canals*, through which pass the posterior and external palatine branches of Meckel's ganglion; while its outer surface is rough, for articulation with the inner surface of the body of the superior maxillary bone.

The *superior* border of the vertical plate presents two well-marked processes separated by an intervening notch or foramen. The anterior, or larger, is called the *orbital process*; the posterior, the *sphenoidal*.

Fig. 250.—Left palate bone. Posterior view. (Enlarged.)



The **Orbital Process**, directed upwards and outwards, is placed on a higher level than the sphenoidal. It presents five surfaces, which enclose a hollow cellular cavity, and is connected to the perpendicular plate by a narrow, constricted neck. Of these five surfaces, three are articular, two non-articular or free. The three articular are: (1) the *anterior* or *maxillary* surface, directed forwards, outwards, and downwards, of an oblong form, and rough for articulation with the superior maxillary bone. (2) The *posterior* or *sphenoidal* surface is directed backwards, upwards, and inwards. It ordinarily presents a small, open cell, which communicates with the sphenoidal cell, and the margins of which are serrated for articulation with the vertical part of the sphenoidal turbinated bone. (3) The *internal* or *ethmoidal* surface is directed inwards, upwards, and forwards, and articulates with the lateral mass of the ethmoid bone. In some cases, the cellular cavity above mentioned opens on this surface of the bone; it then communicates with the posterior ethmoidal cells. More rarely it opens on both surfaces, and then communicates with the posterior ethmoidal and the sphenoidal cells. The non-articular or free surfaces are the *superior* or *orbital*, directed upwards and outwards, of a triangular shape, concave, smooth, and forming the back part of the floor of the orbit; and the *external* or *zygomatic* surface, smooth and of an oblong form, is directed outwards, backwards, and downwards towards the spheno-maxillary fossa, and is separated from the orbital by a rounded border, which enters into the formation of the spheno-maxillary fissure.

The **Sphenoidal Process** of the palate-bone is a thin, compressed plate, much smaller than the orbital, and directed upwards and inwards. It presents three surfaces and two borders. The *superior* surface, the smallest of the three, articulates with the under surface of the sphenoidal turbinated bone, and reaches as far as the ala of the vomer; it presents a groove, which contributes to the formation of the pterygo-palatine canal. The *internal* surface is concave, and forms part of the outer wall of the nasal fossa. The *external* surface is divided into an articular and non-articular portion: the former is rough, for articulation with the inner surface of the internal pterygoid plate of the sphenoid; the latter is smooth, and forms part of the spheno-maxillary fossa. The *anterior* border forms the posterior boundary of the spheno-palatine foramen. The *posterior* border, serrated at the expense of the outer table, articulates with the inner surface of the internal pterygoid plate.

The orbital and sphenoidal processes are separated from one another by a

deep notch, which is converted into a foramen, the *spheno-palatine*, by articulation with the sphenoidal turbinated bone. Sometimes the two processes are united above, and form between them a complete foramen, or the notch is crossed by one or more spiculæ of bone, giving rise to two or more foramina. In the articulated skull, this foramen opens into the back part of the outer wall of the superior meatus, and transmits the spheno-palatine vessels and the superior nasal and naso-palatine nerves.

Development.—From a single centre, which makes its appearance about the second month at the angle of junction of the two plates of the bone. From this point ossification spreads inwards to the horizontal plate, downwards into the tuberosity, and upwards into the vertical plate. Some authorities describe the bone as ossifying from four centres: one for the tuberosity and portion of the vertical plate behind the posterior palatine groove; a second for the rest of the vertical and the horizontal plates; a third for the orbital, and a fourth for the sphenoidal process. In the fœtus, the horizontal plate is much longer than the vertical; and even after it is fully ossified, the whole bone is at first remarkable for its shortness.

Articulations.—With six bones: the sphenoid, ethmoid, superior maxillary, inferior turbinated, vomer, and opposite palate.

Attachment of Muscles.—To three: the Tensor palati, Azygos uvulæ, and Internal pterygoid.

The Inferior Turbinated Bones

The **Inferior Turbinated Bones** (turbo, *a whirl*) are situated one on each side of the outer wall of the nasal fossæ. Each consists of a layer of thin, spongy bone, curled upon itself like a scroll—hence its name 'turbinated'—and extends horizontally along the outer wall of the nasal fossa, immediately below the orifice of the antrum (fig. 251). Each bone presents two surfaces, two borders, and two extremities.

Fig. 251.—Inferior turbinated bone and Lachrymal bone *in situ.*

Its *internal surface* (fig. 252) is convex, perforated by numerous apertures, and traversed by longitudinal grooves and canals for the lodgment of arteries and veins. In the recent state it is covered by the lining membrane of the nose. Its *external surface* is concave (fig. 253), and forms part of the inferior meatus. Its *upper border* is thin, irregular, and connected to various bones along the outer wall of the nose. It may be divided into three portions: of these, the anterior articulates with the inferior turbinated crest of the superior maxillary bone; the posterior with the inferior turbinated crest of the palate-bone; the middle portion of the superior border presents three well-marked processes, which vary much in their size and form. Of these, the anterior and smallest is situated at the junction of the anterior fourth with the posterior three-fourths of the bone: it is small and pointed, and is called the *lachrymal process*; it articulates, by its apex, with the descending or turbinal process of the lachrymal bone, and, by its margins, with the groove on the back of the nasal process of the superior maxillary, and thus assists in forming the canal for the nasal duct. At the junction of the two middle fourths of the bone, but encroaching on its posterior fourth, a broad, thin

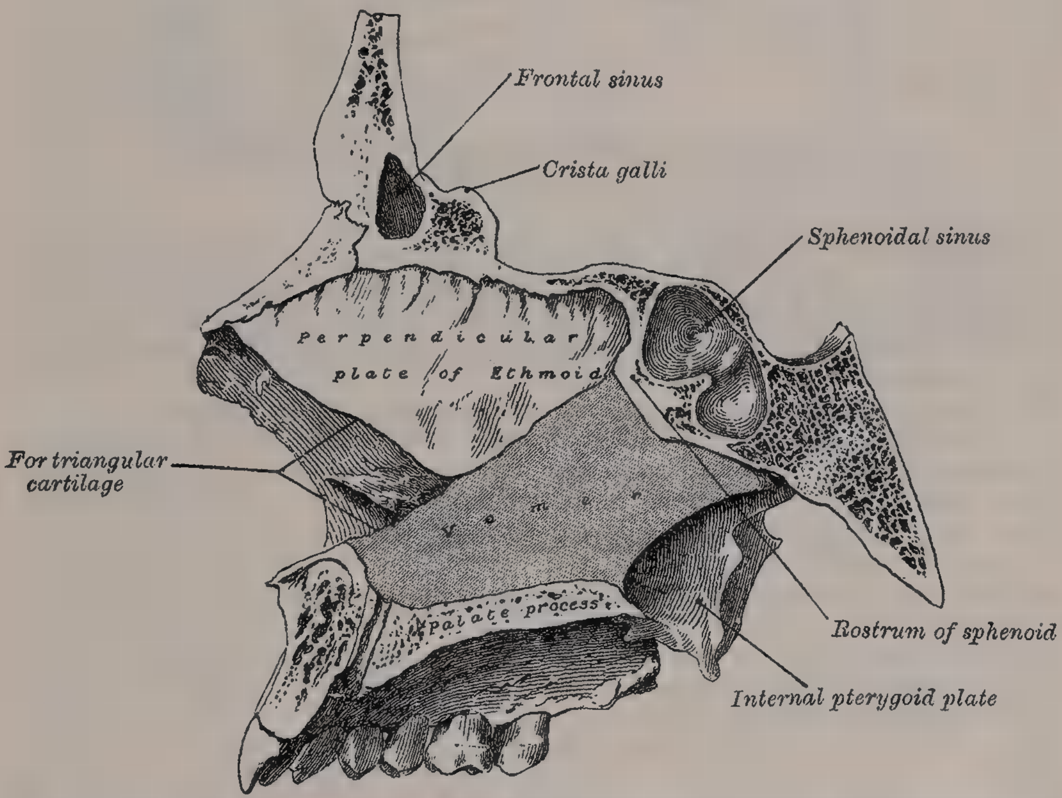
plate, the *ethmoidal process*, ascends to join the unciform process of the ethmoid; from the lower border of this process a thin lamina of bone curves downwards and outwards, hooking over the lower edge of the orifice of the antrum, which it narrows below: it is called the *maxillary process*, and fixes the bone firmly to

FIG. 252.—Right inferior turbinated bone. Internal surface.

FIG. 253.—Right inferior turbinated bone. External surface.

the outer wall of the nasal fossa. The *inferior border* is free, thick, and cellular in structure, more especially in the middle of the bone. Both *extremities* are more or less narrow and pointed, the posterior being the more tapering. If the bone is held so that its outer concave surface is directed backwards (i.e. towards

FIG. 254.—Vomer *in situ*.



the holder), and its superior border, from which the lachrymal and ethmoidal processes project, upwards, the lachrymal process will be directed to the side to which the bone belongs.*

Development.—By a single centre, which makes its appearance about the middle of fœtal life.

Articulations.—With four bones: one of the cranium, the ethmoid, and three of the face, the superior maxillary, lachrymal, and palate.

No muscles are attached to this bone.

THE VOMER

The **Vomer** (vomer, *a ploughshare*) is a single bone, situated vertically at the back part of the nasal fossæ, forming part of the septum of the nose (fig. 254).

* If the lachrymal process is broken off, as is often the case, the side to which the bone belongs may be known by recollecting that the maxillary process is nearer the back than the front of the bone.

It is thin, somewhat like a ploughshare in form; but it varies in different individuals, being frequently bent to one or the other side; it presents for examination two surfaces and four borders. The *lateral surfaces* (fig. 255) are smooth, marked by small furrows for the lodgment of blood-vessels, and by a groove, sometimes a canal, the *naso-palatine*, which runs obliquely downwards and forwards to the intermaxillary suture; it transmits the naso-palatine nerve. The *superior border*, the thickest, presents a deep furrow, bounded on each side by a horizontal projecting ala of bone; it receives the rostrum of the sphenoid, while the margins of the alæ articulate with the vaginal processes of the internal pterygoid plates behind, and with the sphenoidal processes of the palate bones in front. The *inferior border* articulates with the crest formed by the superior maxillary and palate bones. The upper half of the *anterior border* usually consists of two laminæ of bone, between which is received the perpendicular plate of the ethmoid; the lower half, also separated into two lamellæ, receives between them the lower margin of the septal cartilage of the nose. The *posterior border* is free, concave, and separates the nasal fossæ behind. It is thick and bifid above, thin below.

Fig. 255.—The vomer.

The surfaces of the vomer are covered by mucous membrane, which is intimately connected with the periosteum, with the intervention of very little, if any, submucous connective tissue. Hence polypi are rarely found growing from this surface, though they frequently grow from the outer walls of the nasal fossæ, where the submucous tissue is abundant.

Development.—The vomer at an early period consists of two laminæ, separated by a very considerable interval, and enclosing between them a plate of cartilage, the *vomerine cartilage*, which is prolonged forwards to form the remainder of the septum. Ossification commences in the membrane overlying the cartilage, and not from the cartilage itself, at its postero-inferior part by two centres, one on each side of the middle line, which extend to form the two laminæ. They begin to coalesce at the lower part, the cartilage becoming absorbed, but their union is not complete until after puberty.

Articulations.—With six bones: two of the cranium, the sphenoid and ethmoid; and four of the face, the two superior maxillary and the two palate-bones; and with the cartilage of the nasal septum.

The vomer has no muscles attached to it.

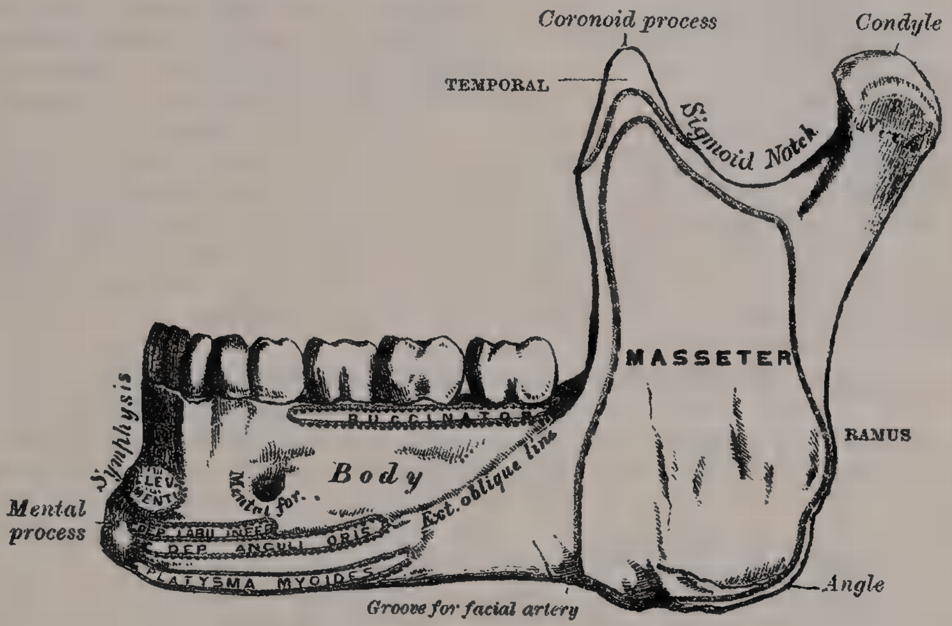
The Inferior Maxillary Bone, or Mandible

The **Inferior Maxillary Bone**, or **Mandible**, the largest and strongest bone of the face, serves for the reception of the lower teeth. It consists of a curved, horizontal portion, the *body*, and two perpendicular portions, the *rami*, which join the back part of the body nearly at right angles.

The **Horizontal Portion,** or **Body** (fig. 256), is convex in its general outline, and curved somewhat like a horseshoe. It presents for examination two surfaces and two borders. The **external surface** is convex from side to side, concave from above downwards. In the median line is a faint ridge, the *symphysis*, which extends from the upper to the lower border of the bone, and indicates the line of junction of the two pieces of which the bone is composed at an early period of life. The lower part of the ridge terminates in a prominent triangular eminence, the *mental process*. This eminence is rounded below, and often presents a median depression separating two processes, the *mental tubercles*. It forms the chin, a feature peculiar to the human skull. On either side of the symphysis,

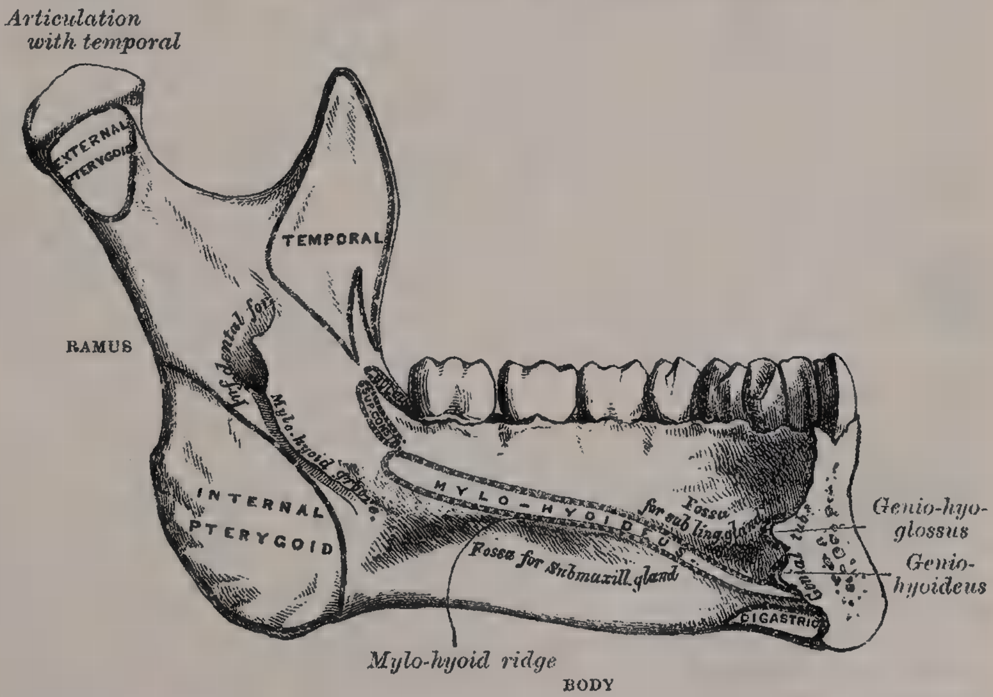
just below the cavities for the incisor teeth, is a depression, the *incisive fossa*, for the attachment of the Levator menti (Levator labii inferioris); more externally is attached a small portion of the Orbicularis oris, and, still more externally, is a foramen, the *mental foramen*, for the passage of the mental vessels and nerve. This foramen is placed below the interval between the two bicuspid teeth.

FIG. 256.—Inferior maxillary bone. Outer surface. Side view.



Running outwards from the base of the mental process on each side is a ridge, the *external oblique* line. The ridge is at first nearly horizontal, but afterwards inclines upwards and backwards, and is continuous with the anterior border of the ramus: it affords attachment to the Depressor labii inferioris and Depressor anguli oris; below it the Platysma myoides is attached.

FIG. 257.—Inferior maxillary bone. Inner surface. Side view.



The **internal surface** (fig. 257) is concave from side to side, convex from above downwards. In the middle line is an indistinct linear depression, corresponding to the symphysis externally; on either side of this depression, just below its centre, are four prominent tubercles, placed in pairs, two above and two below;

they are called the *genial tubercles*, and afford attachment, the upper pair to the Genio-hyo-glossi muscles, the lower pair to the Genio-hyoidei muscles. Sometimes the tubercles on each side are blended into one, at others they all unite into an irregular eminence, or again, nothing but an irregularity may be seen on the surface of the bone at this part. On either side of the genial tubercles is an oval depression, the *sublingual fossa*, for lodging the sublingual gland; and beneath the fossa, a rough depression, which gives attachment to the anterior belly of the Digastric muscle. At the back part of the sublingual fossa, the *internal oblique line* or *mylo-hyoid ridge* commences; it is at first faintly marked, but becomes more distinct as it passes upwards and outwards, and is especially prominent opposite the last two molar teeth; it affords attachment throughout its whole extent to the Mylo-hyoid muscle: the Superior constrictor of the pharynx with the pterygo-mandibular ligament, being attached above its posterior extremity, near the alveolar margin. The portion of bone above this ridge is smooth, and covered by the mucous membrane of the mouth; the portion below presents an oblong depression, the *submaxillary fossa*, wider behind than in front, for the lodgment of the submaxillary gland. The external oblique line and the internal or mylo-hyoidean ridge divide the body of the bone into a superior or alveolar and an inferior or basilar portion.

The **superior** or **alveolar** border is wider, and its margins thicker, behind than in front. It is hollowed into cavities, for the reception of the teeth; these cavities are sixteen in number, and vary in depth and size according to the teeth which they contain. To its outer side, the Buccinator muscle is attached as far forward as the first molar tooth. The **inferior** border is rounded, longer than the superior and thicker in front than behind; it may present a shallow groove, just where the body joins the ramus, over which the facial artery turns.

The **Perpendicular Portions**, or **Rami**, are of a quadrilateral form. Each presents for examination two surfaces, four borders, and two processes. The *external surface* is flat, marked with ridges, and gives attachment throughout nearly the whole of its extent to the Masseter muscle. The *internal surface* presents about its centre the oblique aperture of the inferior dental canal, for the passage of the inferior dental vessels and nerve. The margin of this opening is irregular; it presents in front a prominent ridge, surmounted by a sharp spine, the *lingula*, which gives attachment to the internal lateral ligament of the lower jaw, and at its lower and back part a notch leading to a groove, the *mylo-hyoidean*, which runs obliquely downwards to the back part of the submaxillary fossa, and lodges the mylo-hyoid vessels and nerve. Behind the groove is a rough surface, for the insertion of the Internal pterygoid muscle. The inferior dental canal runs obliquely downwards and forwards in the substance of the ramus, and then horizontally forwards in the body; it is here placed under the alveoli, with which it communicates by small openings. On arriving at the incisor teeth, it turns back to communicate with the mental foramen, giving off two small canals, which run forward, to be lost in the cancellous tissue of the bone beneath the incisor teeth. This canal, in the posterior two-thirds of the bone, is situated nearer the internal surface of the jaw; and in the anterior third, nearer its external surface. Its walls are composed of compact tissue at either extremity, and of cancellous in the centre. It contains the inferior dental vessels and nerve, from which branches are distributed to the teeth through small apertures at the bases of the alveoli. The *lower border* of the ramus is thick, straight, and continuous with the body of the bone. At its junction with the posterior border is the *angle of the jaw*, which is either inverted or everted, and marked by rough, oblique ridges on each side, for the attachment of the Masseter externally, and the Internal pterygoid internally; the stylo-mandibular ligament is attached to the angle between these muscles. The *anterior border* is thin above, thicker below, and continuous with the external oblique line. The *posterior border* is thick, smooth, rounded, and covered by the parotid gland. The *upper border* of the ramus is thin, and presents two processes, separated by a deep concavity, the *sigmoid notch*. Of these processes, the anterior is the *coronoid*, the posterior the *condyloid*.

The **Coronoid Process** is a thin, flattened triangular eminence of bone, which varies in shape and size in different subjects, and serves chiefly for the attachment of the Temporal muscle. Its *external surface* is smooth, and affords insertion to the Temporal and Masseter muscles. Its *internal surface* gives attachment to

the Temporal muscle, and presents the commencement of a longitudinal ridge, which is continued to the posterior part of the alveolar process. On the outer side of this ridge is a deep groove, continued below on the outer side of the alveolar process; this ridge and part of the groove afford attachment, above, to the Temporal; below, to the Buccinator muscle.

The **Condyloid Process**, shorter but thicker than the coronoid, consists of two portions: the *condyle*, and the constricted portion which supports the condyle, the *neck*. The *condyle* is of an oblong form, its long axis being transverse, and set obliquely on the neck in such a manner that its outer end is a little more forward and a little higher than its inner. It is convex from before backwards, and from side to side, the articular surface extending farther on the posterior than on the anterior aspect. At its outer extremity is a small tubercle for the attachment of the external lateral ligament of the temporo-mandibular joint. The *neck* of the condyle is flattened from before backwards, and strengthened by ridges which descend from the fore part and sides of the condyle. Its lateral margins are narrow, the external one giving attachment to part of the external lateral ligament. Its posterior surface is convex; its anterior is hollowed out on its inner side by a depression (the *pterygoid fossa*) for the attachment of the External pterygoid muscle.

The **Sigmoid Notch**, separating the two processes, is a deep semilunar depression, crossed by the masseteric vessels and nerve.

Development.—The lower jaw is developed principally from membrane, but partly from cartilage. The process of ossification commences early—earlier than any other bone except the clavicle. The greater part of the bone is formed from a centre of ossification (*dentary*), which appears between the fifth and sixth weeks in the membrane on the outer surface of Meckel's cartilage. A second centre (*splenial*) arises in the membrane on the inner surface of the cartilage, and from this centre the inner wall of the sockets of the teeth is formed; this terminates above in the lingula. The anterior extremity of Meckel's cartilage becomes ossified, forming the portion of the body of the bone which lies on each side of the symphysis. The central portion of the cartilage becomes absorbed and the upper or posterior part is converted into fibrous tissue and remains as a permanent structure, the internal lateral ligament of the temporo-mandibular joint; so that the upper part of the ramus and its processes have no connection with Meckel's cartilage, but are ossified from two supplemental patches of cartilage, which appear one in the condyle, the other in the coronoid process. Some authorities also describe a separate centre, preceded by a cartilaginous matrix for the angle. At birth, the bone consists of two halves, united by a fibrous symphysis, in which ossification takes place during the first year.

Articulation.—With the glenoid fossæ of the two temporal bones.

Attachment of Muscles.—To fifteen pairs; to its external surface, commencing at the symphysis, and proceeding backwards: Levator menti, Depressor labii inferioris, Depressor anguli oris, Platysma myoides, Buccinator, Masseter; a portion of the Orbicularis oris (Accessorii Orbicularis inferioris) is also attached to this surface. To its internal surface, commencing at the same point: Genio-hyo-glossus, Genio-hyoideus, Mylo-hyoideus, Digastric, Superior constrictor of the pharynx, Temporal, Internal pterygoid, External pterygoid.

Changes produced in the Lower Jaw by Age

The changes which the lower jaw undergoes after birth, relate (1) to the alterations effected in the body of the bone by the first and second dentitions, the loss of the teeth in the aged, and the subsequent absorption of the alveoli; (2) to the size and situation of the dental canal; and (3) to the angle at which the ramus joins with the body.

At birth (fig. 258), the bone consists of lateral halves, united by fibrous tissue. The body is a mere shell of bone, containing the sockets of the two incisor, the canine, and the two temporary molar teeth, imperfectly partitioned from one another. The dental canal is of large size, and runs near the lower border of the bone, the mental foramen opening beneath the socket of the first molar. The angle is obtuse (175°), and the condyloid portion nearly in the same horizontal line with the body; the neck of the condyle is short, and bent backwards. The coronoid process is of comparatively large size, and situated at right angles with the rest of the bone.

After birth (fig. 259), the two segments of the bone become joined at the symphysis, from below upwards, in the first year; but a trace of separation may be visible in the

SIDE VIEW OF THE LOWER JAW AT DIFFERENT PERIODS OF LIFE

FIG. 258.—At birth.

FIG. 259.—In childhood.

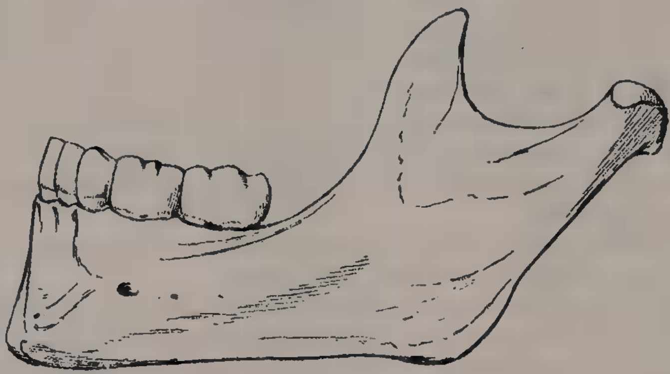


FIG. 260.—In the adult.

FIG. 261.—In old age.

beginning of the second year, near the alveolar margin. The body becomes elongated in its whole length, but more especially behind the mental foramen, to provide space for the three additional teeth developed in this part. The depth of the body becomes greater, owing to increased growth of the alveolar part, to afford room for the fangs of the teeth, and by thickening of the subdental portion which enables the jaw to withstand the powerful action of the masticatory muscles; but the alveolar portion is the deeper of the two, and, consequently, the chief part of the body lies above the oblique line. The dental canal, after the second dentition, is situated just above the level of the mylo-hyoid ridge; and the mental foramen occupies the position usual to it in the adult. The angle becomes less obtuse, owing to the separation of the jaws by the teeth. (About the fourth year it is 140°.)

In the adult (fig. 260), the alveolar and basilar portions of the body are usually of equal depth. The mental foramen opens midway between the upper and lower border of the bone, and the dental canal runs nearly parallel with the mylo-hyoid line. The ramus is almost vertical in direction, and joins the body at a little more than a right angle.

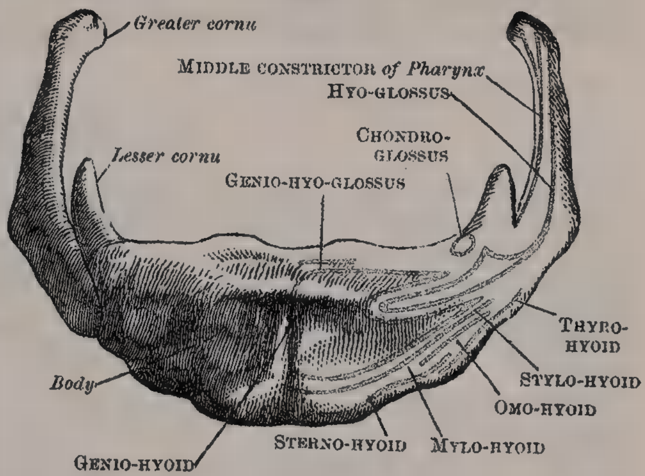
In old age (fig. 261), the bone becomes greatly reduced in size: for with the loss of the teeth the alveolar process is absorbed, and the basilar part of the bone alone remains; consequently, the chief part of the bone is below the oblique line. The dental canal, with the mental foramen opening from it, is close to the alveolar border. The ramus is oblique in direction, the angle obtuse, and the neck of the condyle more or less bent backwards.

Hyoid Bone

The **Hyoid bone** is named from its resemblance to the Greek upsilon; it is also called the *lingual bone*, because it supports the tongue, and gives attachment to its numerous muscles. It is a bony arch, shaped like a horse-shoe, and consisting of five segments, a body, two greater cornua, and two lesser cornua. It is suspended from the tips of the styloid processes of the temporal bones by ligamentous bands, the *stylo-hyoid* ligaments.

The **Body** (*basi-hyal*) forms the central part of the bone, and is of a quadrilateral form; its *anterior surface* (fig. 262), convex, directed forwards and upwards, is divided into two parts by a vertical ridge which descends along the median line, and is crossed at right angles by a horizontal ridge, so that this surface is divided into four spaces or depressions. At the point of meeting of these two lines is a prominent elevation, the *tubercle*. The portion above the horizontal ridge is directed upwards, and is sometimes described as the superior border. The anterior surface gives attachment to the Genio-hyoid in the greater part of its extent; above, to the Genio-hyo-glossus; below, to the Mylo-hyoid, Stylo-hyoid, and aponeurosis of the Digastric (suprahyoid aponeurosis); and between these to part of the Hyo-glossus. The *posterior surface* is smooth, concave, directed backwards and downwards, and separated from the epiglottis by the thyro-hyoid membrane and a quantity of loose areolar tissue; a bursa intervenes between it and the thyro-hyoid membrane. The *superior border* is rounded, and gives attachment to the thyro-hyoid membrane, part of the Genio-hyo-glossi, and Chondro-glossi muscles. The *inferior border* gives attachment, in front, to the Sterno-hyoid; behind, to the Omo-hyoid and to part of the Thyro-hyoid, at its junction with the great cornu. It also gives attachment to the Levator glandulæ thyroideæ, when this muscle is present. The *lateral surfaces*, after middle life, are joined to the greater cornua. In early life they are connected to the cornua by cartilaginous surfaces, and held together by ligaments, and occasionally a synovial membrane is found between them.

Fig. 262.—Hyoid bone. Anterior surface (enlarged).



The **Greater Cornua** (*thyro-hyal*) project backwards from the lateral surfaces of the body; they are flattened from above downwards, diminish in size from

before backwards, and terminate posteriorly in a tubercle for the attachment of the lateral thyro-hyoid ligament. The outer surface gives attachment to the Hyo-glossus; the upper border to the Middle constrictor of the pharynx; the lower to part of the Thyro-hyoid muscle.

The **Lesser Cornua** (*cerato-hyal*) are two small, conical-shaped eminences, attached by their bases to the angles of junction between the body and greater cornua, and giving attachment by their apices to the stylo-hyoid ligaments.* The smaller cornua are connected to the body of the bone by a distinct diarthrodial joint, which usually persists throughout life, but occasionally becomes ankylosed.

Development.—By *five* centres: one for the body, and one for each cornu. Ossification commences in the body about the eighth month, and in the greater cornua towards the end of fœtal life. Ossification of the lesser cornua commences during the first or second year after birth. According to some authorities there are two centres for the body.

Attachment of Muscles.— Sterno-hyoid, Thyro-hyoid; Omo-hyoid, aponeurosis of the Digastric, Stylo-hyoid, Mylo-hyoid, Genio-hyoid, Genio-hyo-glossus, Chondro-glossus, Hyo-glossus, Middle constrictor of the pharynx, and occasionally a few fibres of the Inferior lingualis. It also gives attachment to the thyro-hyoid membrane, and the stylo-hyoid, thyro-hyoid, and hyo-epiglottic ligaments.

Surface Form.—The hyoid bone can be felt in the receding angle below the chin, and the finger can be carried along the whole length of the bone to the greater cornu, which is situated just below the angle of the jaw. This process of bone is best perceived by making pressure on one cornu and so pushing the bone over to the opposite side, when the cornu of this side will be distinctly felt immediately beneath the skin. It is an important landmark in ligature of the lingual artery.

Surgical Anatomy.—The hyoid bone is occasionally fractured, generally from direct violence, as in hanging; forcible grasping of the throat in garotting or throttling, or by a blow; but cases are also recorded where it has arisen from muscular action. The fracture generally occurs about the junction of the greater cornu with the body of the bone, but sometimes takes place through the latter. In consequence of the muscles of the tongue having important connections with this bone, there is great pain upon any attempt being made to move the tongue, as in speaking or swallowing.

THE SUTURES

The bones of the Skull, with the exception of the Mandible, are connected to each other by means of *Sutures*. That is, the articulating surfaces or edges of the bones are more or less roughened or uneven, and are closely adapted to each other, a small amount of intervening fibrous tissue, the *sutural ligament*, fastening them together. The *Sutures of the Brain-case* may be divided into three sets: 1. those at the vertex; 2. those at the side; 3. those at the base.

The sutures at the vertex of the skull are four: the *metopic*, *sagittal*, *coronal*, and *lambdoid*.

The **Metopic** or **Frontal Suture** is the suture formed by the junction of the two halves of the frontal bone. At birth the two halves of the frontal bone are separated by the suture, but the greater part of it usually disappears about the fifth or sixth year. In the adult it may not exist at all, or may be represented by a slight fissure, just above the glabella; but according to Cunningham it exists in about 8 per cent. of Europeans, in whom it is of more frequent occurrence than in the lower races of man.

The **Sagittal Suture** (*interparietal*) is formed by the junction of the two parietal bones, and extends from the middle of the frontal bone, backwards to the superior angle of the occipital. In childhood, and sometimes in the adult, when the two halves of the frontal bone are not united, it is continued forwards to the root of the nose. This suture is sometimes perforated, near its posterior extremity, by the parietal foramen; and in front, where it joins the coronal suture, a space is occasionally left, which encloses a large Wormian bone.

* These ligaments in many animals are distinct bones, and in man may undergo partial ossification.

The **Coronal Suture** (*fronto-parietal*) extends transversely across the vertex of the skull, and connects the frontal with the parietal bones. It commences at the extremity of the greater wing of the sphenoid on one side, and terminates at the same point on the opposite. The dentations of the suture are more marked at the sides than at the summit, and are so constructed that the frontal rests on the parietal above, while laterally the frontal supports the parietal.

The **Lambdoid Suture** (*occipito-parietal*), so called from its resemblance to the Greek letter Λ, connects the occipital with the parietal bones. It commences on each side at the mastoid portion of the temporal bone, and inclines upwards and backwards to the end of the sagittal suture. The dentations of this suture are very deep and distinct, and are often interrupted by several small Wormian bones.

The sutures at the side of the skull extend from the external angular process of the frontal bone to the lower end of the lambdoid suture. From before backwards, they consist of the *fronto-malar, spheno-malar, spheno-frontal, spheno-parietal, squamo-sphenoidal, squamo-parietal,* and *masto-parietal.*

The **Fronto-malar** connects the external angular process of the frontal bone with the parietal.

The **Spheno-malar** is situated between the anterior border of the great wing of the sphenoid and the orbital process of the malar.

The **Spheno-frontal** joins the great wing of the sphenoid to the frontal behind its external angular process.

The **Spheno-parietal** is placed between the anterior inferior angle of the parietal and the great wing of the sphenoid. This suture varies greatly in length in different skulls, and is sometimes absent owing to the articulation of the squamous-temporal with the frontal.

The **Squamo-sphenoidal** connects the posterior border of the greater wing of the sphenoid with the anterior border of the squamous-temporal.

The **Squamo-parietal,** or **Squamous Suture,** is arched. It is formed by the squamous portion of the temporal bone overlapping the middle division of the lower border of the parietal.

The **Masto-parietal** is a short suture, deeply dentated, situated between the posterior inferior angle of the parietal and the superior border of the mastoid portion of the temporal.

The sutures at the base of the skull are, the *basilar* in the centre, and on each side, the *petro-occipital*, the *masto-occipital*, the *petro-sphenoidal*, and the *squamo-sphenoidal.*

The **Basilar Suture** is formed by the junction of the basilar surface of the occipital bone with the posterior surface of the body of the sphenoid. At an early period of life a thin plate of cartilage exists between these bones; but in the adult they become fused into one. From the outer extremity of the basilar suture to the termination of the lambdoid, an irregular suture exists, which is subdivided into two portions. The inner portion, formed by the union of the petrous part of the temporal with the occipital bone, is termed the **petro-occipital**. The outer portion, formed by the junction of the mastoid part of the temporal with the occipital, is called the **masto-occipital**. In the petro-occipital suture, a thin plate of cartilage exists; in the masto-occipital is occasionally found the opening of the mastoid foramen. Between the outer extremity of the basilar suture and the spheno-parietal, an irregular suture is seen uniting the sphenoid and temporal bones. The inner and smaller portion of this suture is termed the **petro-sphenoidal**; it runs between the petrous portion of the temporal and the great wing of the sphenoid: the outer portion, of greater length, and arched, connects the squamous portion of the temporal with the great wing of the sphenoid; it is called the **squamo-sphenoidal.**

The cranial bones are connected with those of the face, and the facial bones with each other, by numerous sutures, which, though distinctly marked, have received no special names. The only remaining suture deserving especial consideration is the **transverse.** This extends across the upper part of the face, and is formed by the junction of the frontal with the bones which lie below it; it extends from the external angular process of one side to the same point on the opposite side, and connects the frontal with the malar, the sphenoid, the ethmoid, the lachrymal, the superior maxillary, and the nasal bones.

The sutures remain separate for a considerable period after the complete formation of the skull. It is probable that they serve the purpose of permitting the growth of the bones at their margins; while their peculiar formation, together with the interposition of the sutural ligament between the bones forming them, prevents the dispersion of blows or jars received upon the skull. Humphry remarks 'that, as a general rule, the sutures are first obliterated at the parts in which the ossification of the skull was last completed—viz. in the neighbourhood of the fontanelles; and the cranial bones seem in this respect to observe a similar law to that which regulates the union of the epiphyses to the shafts of the long bones.' The same author remarks that the time of their disappearance is extremely variable: they are sometimes found well marked in skulls edentulous with age, while in others which have only just reached maturity they can hardly be traced. The obliteration of the sutures takes place sooner on the inner than on the outer surface of the skull. The sagittal and coronal sutures are as a rule the first to become ossified—the process starting near the posterior extremity of the former and the lower ends of the latter.

THE SKULL AS A WHOLE

The Skull, as a whole, varies much in size and in shape. As regards the size, it is important to note that it forms a good index of the development of the brain, and is most conveniently estimated by its capacity. It is filled with shot, and the amount required to fill it ascertained by means of a graduated measure. Skulls which contain from 1·350 to 1·450 cubic centimetres are termed *mesocephalic*; those above 1·450 c.c., *megacephalic*; and those below 1·350 c.c., *microcephalic*. Alterations in shape depend to a great extent upon the relation of the length to the breadth. On viewing a series of skulls from above, it will be found that the shape may vary from nearly circular to an elongated oval. In order to express these differences in figures, the length and the breadth of the skull are taken: the length, by measuring from the most prominent part of the glabella to the point of the occipital bone, in the median line farthest removed from the glabella; the breadth, by taking the greatest transverse diameter of the skull above the supramastoid ridges. The proportion of the breadth to the length $\left(\frac{\text{breadth} \times 100}{\text{length}}\right)$ is the cephalic index. Where this is over 80, the skull is said to be *brachycephalic*; where it is between 75 and 80, it is said to be *mesaticephalic*; and where it is below 75, it is *dolichocephalic*. The shape of the head and face also largely depends upon the size of the jaws and the extent to which they project forwards. The degree of projection is indicated by comparing the length of a line drawn from the centre of the anterior margin of the upper alveolar arch to the middle of the anterior margin of the foramen magnum, with a line drawn from the middle of the naso-frontal suture to the same point. This constitutes the *gnathic* or *alveolar index*, and may be expressed thus:

$$\frac{\text{Basi-alveolar length} \times 100}{\text{Basi-nasal length}} = \text{gnathic index.}$$

All skulls with a gnathic index below 98 are *orthognathous*; between 98 and 103, *mesognathous*; and above 103, *prognathous*. The skull may also vary in form from want of symmetry.

The Skull, formed by the union of the several cranial and facial bones already described, when considered as a whole, is divisible into five regions: a superior region or vertex, an inferior region or base, two lateral regions, and an anterior region, the face.

Vertex of the Skull

The **Superior Region,** or **Vertex,** presents two surfaces, an external and an internal.

The **external surface** is bounded, in front, by the glabella and supra-orbital ridges; behind, by the occipital protuberance and superior curved lines of the occipital bone; laterally, by an imaginary line extending from the outer end of the superior curved line, along the temporal ridge, to the external angular process

of the frontal bone. This surface includes the greater part of the vertical portion of the frontal, the greater part of the parietal, and the superior third of the occipital bone; it is smooth, convex, of an elongated oval form, crossed transversely by the coronal suture, and from before backwards by the sagittal, which terminates behind in the lambdoid, while immediately above the glabella is the remnant of the metopic suture. The point of junction of the coronal and sagittal sutures is named the *bregma*, and is represented by a line drawn vertically upwards from the external auditory meatus, the head being in its normal position. The point of junction of the sagittal and lambdoid sutures is called the *lambda*, and is about two inches and three-quarters above the external occipital protuberance. From before backwards may be seen the superciliary ridges and frontal eminences; on each side of the sagittal suture are the parietal foramen and parietal eminence, and still more posteriorly the convex surface of the occipital bone. In the neighbourhood of the parietal foramen the skull is often flattened, and the name of *obelion* is sometimes given to that point of the sagittal suture which lies in line with the two parietal foramina.

The **internal surface** is concave, presents depressions for the convolutions of the cerebrum, and numerous furrows for the lodgment of branches of the meningeal arteries. Along the middle line of this surface is a longitudinal groove, narrow in front, where it commences at the frontal crest, but broader behind; it lodges the superior longitudinal sinus, and by its margins affords attachment to the falx cerebri. On either side of it are several depressions for the Pacchionian bodies, and at its back part, the internal openings of the parietal foramina. This surface is crossed, in front, by the coronal suture; from before backwards, by the sagittal; behind by the lambdoid.

Base of the Skull

The **Inferior Region,** or **Base of the Skull,** presents two surfaces—an internal or cerebral, and an external or basilar.

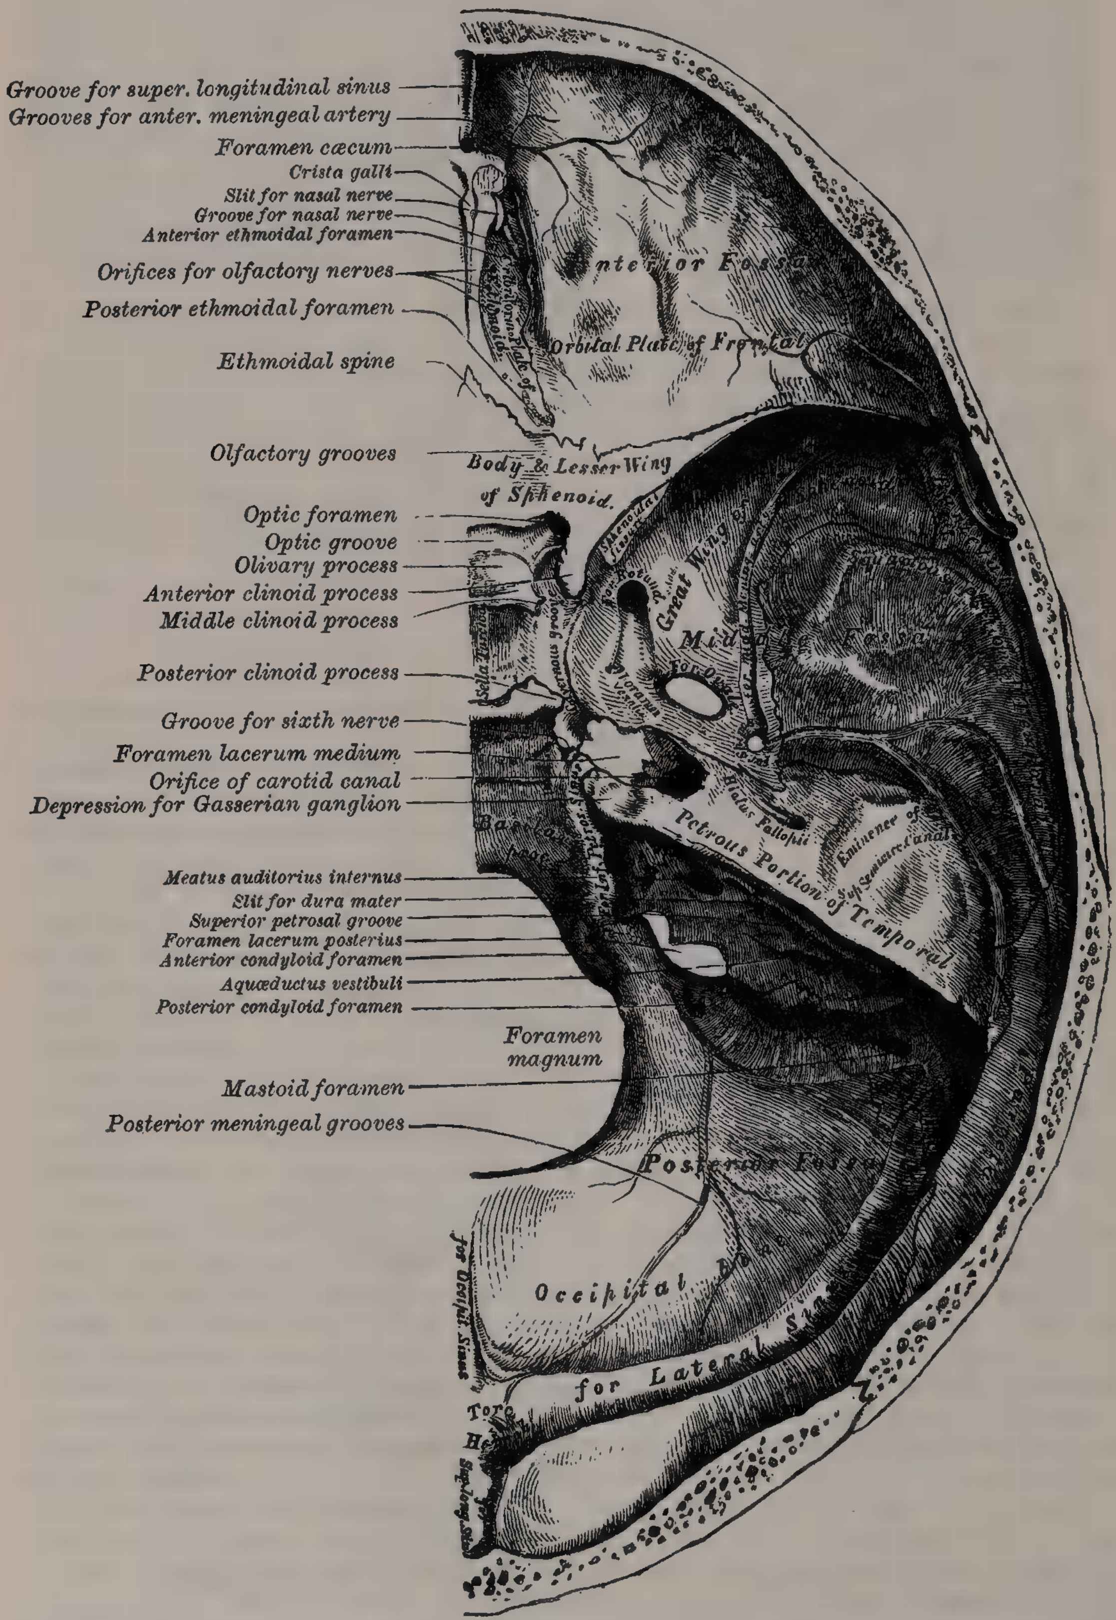
The **internal** or **cerebral surface** (fig. 263) presents three fossæ, called the *anterior*, *middle*, and *posterior* fossæ of the cranium.

The **Anterior Fossa** is formed by the orbital plates of the frontal, the cribriform plate of the ethmoid, the anterior third of the superior surface of the body, and the upper surface of the lesser wings of the sphenoid, and is defined posteriorly by the posterior border of the lesser wings of the sphenoid. It is the most elevated of the three fossæ, convex externally where it corresponds to the roof of the orbit, concave in the situation of the cribriform plate of the ethmoid. It is traversed by three sutures, the *ethmo-frontal*, *ethmo-sphenoidal*, and *fronto-sphenoidal*; and lodges the frontal lobes of the cerebrum. It presents, in the median line, from before backwards, the commencement of the *groove* for the superior longitudinal sinus, and the *frontal crest* for the attachment of the falx cerebri; the *foramen cæcum*, an aperture formed between the frontal bone and the crista galli of the ethmoid, which, if pervious, transmits a small vein from the nose to the superior longitudinal sinus; behind the foramen cæcum, the *crista galli*, the posterior margin of which affords attachment to the falx cerebri; on either side of the crista galli, the *olfactory groove* formed by the cribriform plate, which supports the olfactory bulb, and presents three rows of foramina for the transmission of its nervous filaments to the nose, and in front a slit-like opening for the nasal branch of the ophthalmic division of the fifth nerve. On the outer side of each olfactory groove are the internal openings of the *anterior* and *posterior ethmoidal foramina*; the former, situated about the middle of the outer margin of the olfactory groove, transmits the anterior ethmoidal vessels and the nasal nerve; the nerve runs in a groove along the outer edge of the cribriform plate, to the slit-like opening above mentioned; while the posterior ethmoidal foramen opens at the back part of this margin under cover of the projecting lamina of the sphenoid, and transmits a meningeal branch from the posterior ethmoidal artery. Farther back in the middle line is the *ethmoidal spine*, bounded behind by a slight elevation, separating two shallow longitudinal grooves which support the olfactory lobes. Behind this is a transverse sharp ridge, running outwards on either side to the anterior margin of the optic foramen, and separating the anterior from the middle fossa of the base of the skull. The anterior fossa presents,

laterally, depressions for the convolutions of the brain, and grooves for the lodgment of the anterior meningeal arteries.

The **Middle Fossa**, deeper than the preceding, is narrow in the middle line, but becomes wider at the side of the skull. It is bounded in front by the posterior

Fig. 263.—Base of the skull. Inner or cerebral surface.



margin of the lesser wing of the sphenoid, the anterior clinoid process, and the ridge forming the anterior margin of the optic groove; behind, by the superior border of the petrous portion of the temporal, and the dorsum ephippii;

externally by the squamous portion of the temporal, anterior inferior angle of the parietal bone, and greater wing of the sphenoid. It is traversed by four sutures, the *squamo-parietal*, *spheno-parietal*, *squamo-sphenoidal*, and *petro-sphenoidal*.

In the middle line, from before backwards, is the *optic groove*, behind which lies the optic commissure; the groove terminates on each side in the optic foramen, for the passage of the optic nerve and ophthalmic artery; behind the optic groove is the *olivary process*, and laterally the *anterior clinoid processes*, to which are attached processes of the tentorium cerebelli. Farther back is the *sella turcica*, a deep depression, which lodges the pituitary gland, bounded in front by a small eminence on either side, the *middle clinoid process*, and behind by a broad square plate of bone, the *dorsum ephippii*, surmounted at each superior angle by a tubercle, the *posterior clinoid process*; beneath the latter process is a notch, for the sixth nerve. On each side of the sella turcica is the *cavernous groove*: it is broad, shallow, and curved somewhat like the italic letter *f*; it commences behind at the foramen lacerum medium, and terminates on the inner side of the anterior clinoid process, and presents along its outer margin a ridge of bone. This groove lodges the cavernous sinus, the internal carotid artery, and the nerves of the orbit. The sides of the middle fossa are of considerable depth: they present depressions for the convolutions of the brain, and grooves for the branches of the middle meningeal arteries; the latter commence on the outer side of the foramen spinosum, and consist of two large branches, an anterior and a posterior; the former passing upwards and forwards to the anterior inferior angle of the parietal bone, the latter passing upwards and backwards. The following foramina are also to be seen from before backwards. Most anteriorly is the *foramen lacerum anterius*, or *sphenoidal fissure*, formed above by the lesser wing of the sphenoid; below, by the greater wing; internally, by the body of the sphenoid; and sometimes completed externally by the orbital plate of the frontal bone. It transmits to the orbital cavity the third, the fourth, the three branches of the ophthalmic division of the fifth, the sixth nerve, some filaments from the cavernous plexus of the sympathetic, the orbital branch of the middle meningeal artery, and from the orbital cavity a recurrent branch from the lachrymal artery to the dura mater, and the ophthalmic vein. Behind the inner extremity of the sphenoidal fissure is the *foramen rotundum*, for the passage of the second division of the fifth or superior maxillary nerve; still more posteriorly is the *foramen Vesalii*, which varies in size in different individuals, and is often absent. When present, it opens below at the outer side of the scaphoid fossa, and transmits a small vein. Behind and external to the latter opening is the *foramen ovale*, which transmits the third division of the fifth or inferior maxillary nerve, the small meningeal artery, and the small superficial petrosal nerve.* On the outer side of the foramen ovale is the *foramen spinosum*, for the passage of the middle meningeal artery and veins, and on the inner side of the foramen ovale, the *foramen lacerum medium*. The lower part of this aperture is filled up by a layer of fibro-cartilage in the recent state, while its upper and inner parts transmit the internal carotid artery and its sympathetic plexus of nerves. The Vidian nerve and a meningeal branch from the ascending pharyngeal artery pierce the layer of fibro-cartilage. On the anterior surface of the petrous portion of the temporal bone is seen, from without inwards, the eminence caused by the projection of the superior semicircular canal; in front of and a little outside this a depression corresponding to the roof of the tympanum; the groove leading to the hiatus Fallopii, for the transmission of the great superficial petrosal nerve and the petrosal branch of the middle meningeal artery; beneath it, the smaller groove, for the passage of the small superficial petrosal nerve; and, near the apex of the bone, the depression for the Gasserian ganglion and the orifice of the carotid canal, for the passage of the internal carotid artery and carotid plexus of nerves.

The **Posterior Fossa**, deeply concave, is the largest of the three, and situated on a lower level than either of the preceding. It is formed by the dorsum sellæ and clivus of the sphenoid, by the occipital, the petrous and mastoid portions of the temporal, and the posterior inferior angle of the parietal bone; it is crossed by four sutures, the *petro-occipital*, the *masto-occipital*, the *masto-parietal*, and

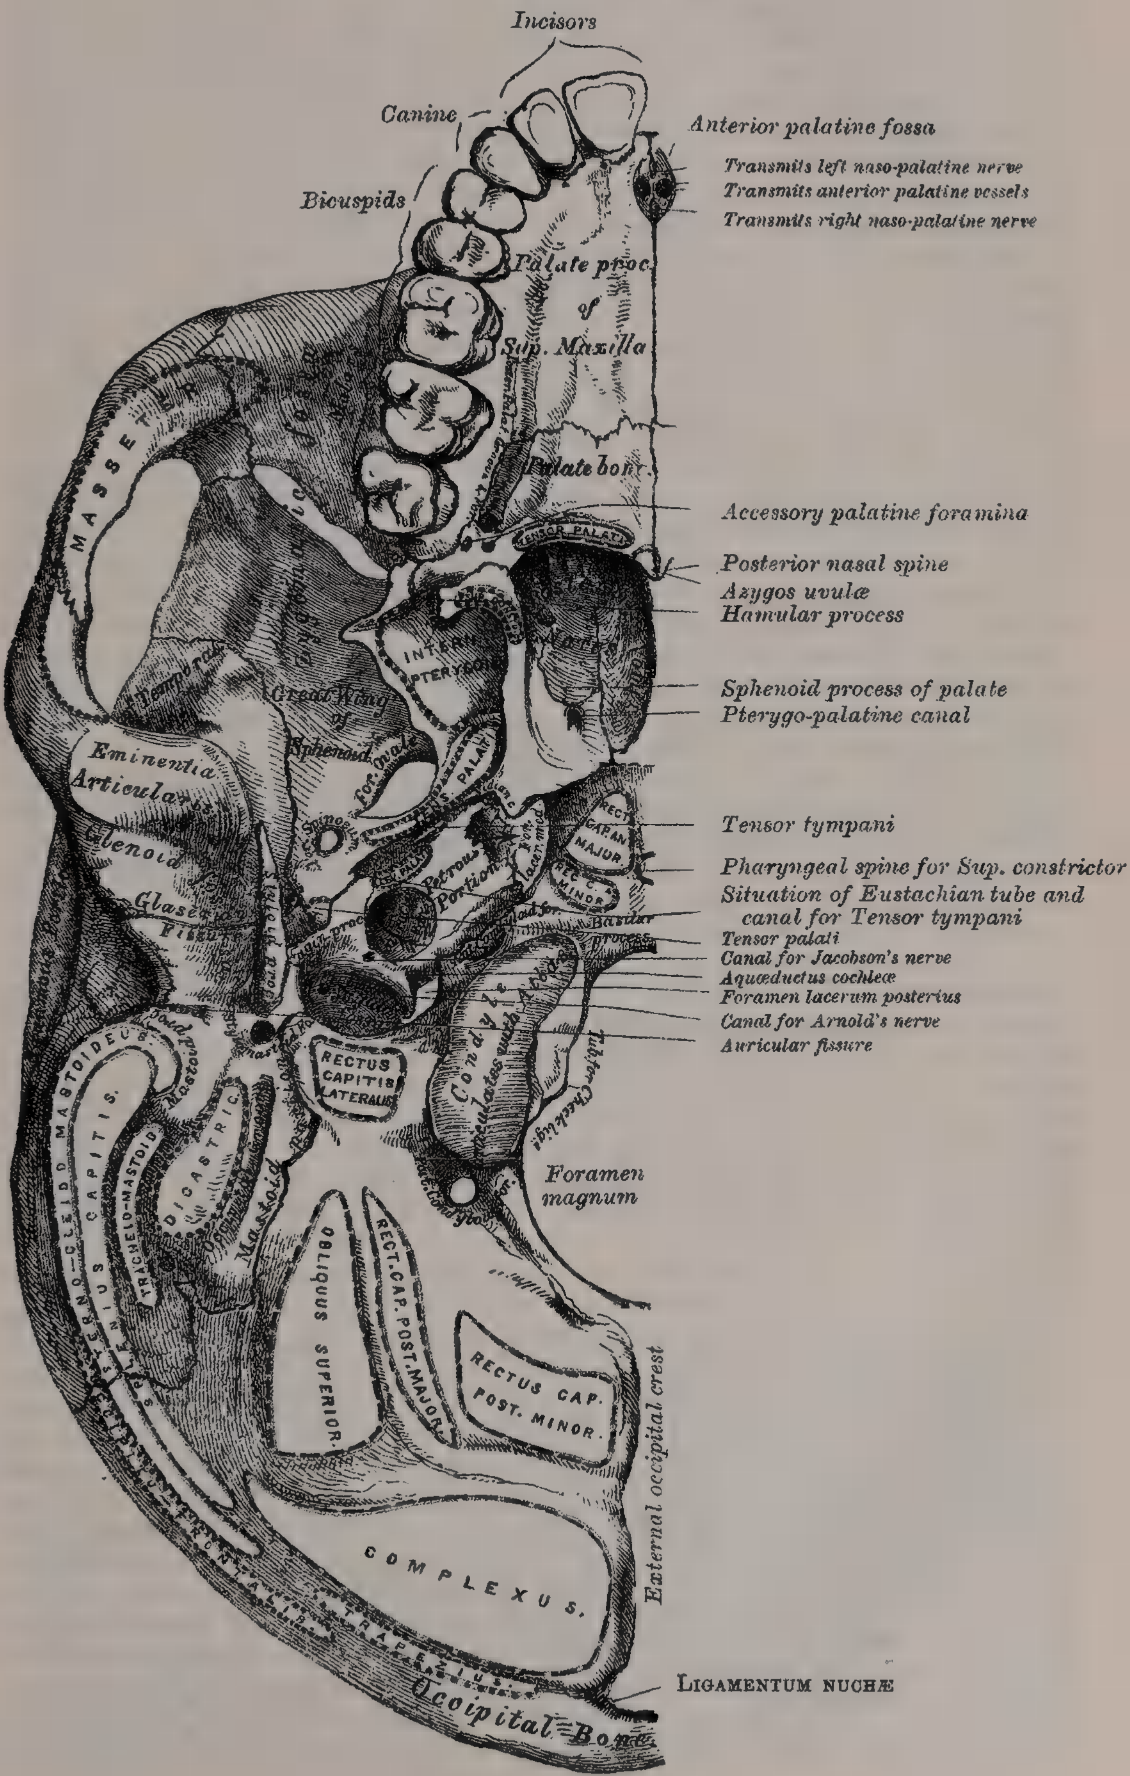
* See footnote, page 200.

(in the young skull) the *basilar*; and lodges the cerebellum, pons Varolii, and medulla oblongata. It is separated from the middle fossa in and near the median line by the dorsum ephippii, and on each side by the superior border of the petrous portion of the temporal bone. This border serves for the attachment of the tentorium cerebelli, is grooved for the superior petrosal sinus, and at its inner extremity presents a notch, upon which the fifth nerve rests. The circumference of the fossa is bounded posteriorly by the grooves for the lateral sinuses. In the centre of this fossa is the *foramen magnum*, bounded on either side by a rough tubercle, which gives attachment to the odontoid or check ligaments; and a little above these are seen the internal openings of the *anterior condyloid foramina*, through which pass the hypoglossal nerve and a meningeal branch from the ascending pharyngeal artery. In front of the foramen magnum is a grooved surface, formed by the basilar process of the occipital bone and by the posterior third of the superior surface of the body of the sphenoid, which supports the medulla oblongata and pons Varolii, and articulates on each side with the petrous portion of the temporal bone, forming the *petro-occipital suture*, the anterior half of which is grooved for the inferior petrosal sinus, the posterior half being encroached upon by the *foramen lacerum posterius*, or *jugular foramen*. Through the anterior portion of this foramen passes the inferior petrosal sinus; through the posterior, the lateral sinus and some meningeal branches from the occipital and ascending pharyngeal arteries; and through the middle, the glosso-pharyngeal, pneumogastric, and spinal accessory nerves. Above the jugular foramen is the *internal auditory meatus*, for the facial and auditory nerves and auditory artery; behind and external to this is the slit-like opening leading into the aquæductus vestibuli, which lodges the ductus endolymphaticus; while between these, and near the superior border of the petrous portion, is a small, triangular depression, the remains of the fossa subarcuata, which lodges a process of the dura mater and occasionally transmits a small vein. Behind the foramen magnum are the *inferior occipital fossæ*, which lodge the hemispheres of the cerebellum, separated from one another by the *internal occipital crest*, which serves for the attachment of the falx cerebelli, and lodges the occipital sinus. The posterior fossæ are surmounted by the deep transverse grooves for the lodgment of the *lateral sinuses*. These channels, in their passage to the jugular foramina, groove the occipital bone, the posterior inferior angle of the parietal, the mastoid portion of the temporal, and the jugular process of the occipital, and terminate at the back part of the jugular foramen. Where this sinus grooves the mastoid portion of the temporal bone, the orifice of the *mastoid foramen* may be seen; and, just previous to its termination, the *posterior condyloid foramen* opens into it. Neither foramen is constant.

The **External Surface** of the Base of the Skull (*norma basalis*) is extremely irregular (fig. 264). It is bounded in front by the incisor teeth in the upper jaw; behind, by the superior curved lines of the occipital bone; and laterally by the alveolar arch, the lower border of the malar bone, the zygoma, and an imaginary line, extending from the zygoma to the mastoid process and extremity of the superior curved line of the occiput. It is formed by the palate processes of the superior maxillary and palate bones, the vomer, the pterygoid processes, under surface of the great wing, spinous processes and part of the body of the sphenoid, the under surface of the squamous, mastoid, and petrous portions of the temporal, and the under surface of the occipital bone. The anterior part of the base of the skull is raised above the level of the rest of this surface (when the skull is turned over for the purpose of examination), and is bounded in front and laterally by the alveolar process, which is thicker behind than in front, and excavated by sixteen depressions for lodging the teeth of the upper jaw, the cavities varying in depth and size according to the teeth they contain. Immediately behind the incisor teeth is the *anterior palatine fossa*. At the bottom of this fossa may usually be seen four apertures: two placed laterally, the *foramina of Stenson*, which open above, one in the floor of each nostril, and transmit the anterior branches of the posterior palatine vessels, and two in the median line in the intermaxillary suture, the *foramina of Scarpa*, one in front of the other, the anterior transmitting the left, and the posterior (the larger) the right, naso-palatine nerve. These two latter canals are sometimes wanting, or they may join to form a single one, or one of them may open into one of the lateral canals above referred to. The palatine vault is concave, uneven,

perforated by numerous foramina, marked by depressions for the palatine glands, and crossed by a crucial suture, formed by the junction of the four bones of which it is composed. At the front part of this surface, a delicate

FIG. 264.—Base of the skull. External surface.



linear suture may be seen in the young skull, passing outwards and forwards from the anterior palatine fossa to the interval between the lateral incisor and canine teeth, and marking off the pre-maxillary portion of the bone (fig. 242). At each posterior angle of the hard palate is the *posterior palatine foramen*, for the transmission of the posterior palatine vessels and large descending palatine nerve; and running forwards and inwards from it a groove, for the same vessels and nerve. Behind the posterior palatine foramen is the *tuberosity of the palate-bone*, perforated by one or more accessory posterior palatine canals, and marked by the commencement of a ridge, which runs transversely inwards, and serves for the attachment of the tendinous expansion of the Tensor palati muscle. Projecting backwards from the centre of the posterior border of the hard palate is the *posterior nasal spine*, for the attachment of the Azygos uvulæ muscle. Behind and above the hard palate are the posterior apertures of the nares (*choanæ*), separated by the vomer, bounded above by the body of the sphenoid, below by the horizontal plate of the palate-bone, and laterally by the internal pterygoid plate of the sphenoid. Each aperture measures about an inch in the vertical, and about half an inch in the transverse direction. At the base of the vomer may be seen the expanded alæ of this bone, receiving between them the rostrum of the sphenoid. Near the lateral margins of the vomer, at the root of the pterygoid processes, are the *pterygo-palatine canals*. The pterygoid process, which bounds the posterior nares on each side, presents near its base the *pterygoid* or *Vidian canal*, for the Vidian nerve and artery. Each process consists of two plates, which bifurcate at the extremity to receive the tuberosity of the palate-bone, and are separated behind by the pterygoid fossa, which lodges the Internal pterygoid muscle. The internal plate is long and narrow, presenting on the outer side of its base the *scaphoid fossa*, for the origin of the Tensor palati muscle, and at its extremity the *hamular process*, around which the tendon of this muscle turns. The external pterygoid plate is broad, forms the inner boundary of the zygomatic fossa, and affords attachment, by its outer surface, to the External pterygoid muscle.

Behind the nasal fossæ in the middle line is the basilar surface of the occipital bone, presenting in its centre the *pharyngeal spine* for the attachment of the Superior constrictor muscle of the pharynx, with depressions on each side for the insertion of the Rectus capitis anticus major and minor. At the base of the external pterygoid plate is the *foramen ovale*, for the transmission of the third division of the fifth nerve, the small meningeal artery, and sometimes the small petrosal nerve; behind this, the *foramen spinosum*, which transmits the middle meningeal artery and veins, and the prominent spinous process of the sphenoid, which gives attachment to the internal lateral ligament of the lower jaw and the Tensor palati muscle. External to the spinous process is the *glenoid fossa*, divided into two parts by the Glaserian fissure (page 191), the anterior portion concave, smooth, bounded in front by the eminentia articularis, and serving for the articulation of the condyle of the lower jaw; the posterior portion rough, bounded behind by the tympanic plate, and serving for the reception of part of the parotid gland. Emerging from between the laminæ of the vaginal process of the tympanic plate is the *styloid process*; and at the base of this process is the *stylo-mastoid foramen*, for the exit of the facial nerve, and entrance of the stylo-mastoid artery. External to the stylo-mastoid foramen is the *auricular fissure*, for the auricular branch of the pneumogastric, between the tympanic plate and the mastoid process. Upon the inner side of the mastoid process is a deep groove, the *digastric fossa*; and a little more internally, the *occipital groove*, for the occipital artery. At the base of the internal pterygoid plate is a large and somewhat triangular aperture, the *foramen lacerum medium*, bounded in front by the great wing of the sphenoid, behind by the apex of the petrous portion of the temporal bone, and internally by the body of the sphenoid and basilar process of the occipital bone; it presents in front the posterior orifice of the Vidian canal; behind, the aperture of the carotid canal. The basilar surface of this opening is filled up in the recent state by a fibro-cartilaginous plate, across the upper or cerebral aspect of which the internal carotid artery passes. External to this aperture, the *petro-sphenoidal suture* is observed, at the outer termination of which are the orifice of the bony part of the Eustachian tube and the orifice of the canal for the Tensor tympani muscle. Behind this suture is the under surface of the

petrous portion of the temporal bone, presenting, from within outwards, the quadrilateral, rough surface, part of which affords attachment to the Levator palati muscle; external to this surface the orifice of the carotid canal and, to its inner side, the depression leading to the aquæductus cochleæ, the former transmitting the internal carotid artery and the carotid plexus of the sympathetic, the latter serving for the passage of a vein from the cochlea. Behind the carotid canal is a large aperture, the *jugular foramen*, formed in front by the petrous portion of the temporal, and behind by the occipital; it is generally larger on the right than on the left side, and is partly subdivided into three compartments. The anterior is for the passage of the inferior petrosal sinus; the posterior for the lateral sinus and some meningeal branches from the occipital and ascending pharyngeal arteries; the central one for the glosso-pharyngeal, pneumogastric, and spinal accessory nerves. On the ridge of bone dividing the carotid canal from the jugular foramen is the small foramen for the transmission of Jacobson's nerve (tympanic branch of the glosso-pharyngeal); and on the wall of the jugular foramen, near the root of the styloid process, is the small aperture for the transmission of Arnold's nerve (auricular branch of the vagus). Behind the basilar surface of the occipital bone is the *foramen magnum*, bounded on each side by the condyles, rough internally for the attachment of the check or odontoid ligaments, and presenting externally a rough surface, the *jugular process*, which serves for the attachment of the Rectus capitis lateralis muscle and the lateral occipito-atlantal ligament. The foramen magnum transmits the medulla oblongata and its membranes, the spinal accessory nerves, the vertebral arteries, the anterior and posterior spinal arteries, and the occipito-axial ligaments. On either side of each condyle anteriorly is the *anterior condyloid fossa*, perforated by the anterior condyloid foramen, for the passage of the hypoglossal nerve and a meningeal artery. Behind each condyle is the *posterior condyloid fossa*, perforated on one or both sides by the posterior condyloid foramen, for the transmission of a vein to the lateral sinus. Behind the foramen magnum is the *external occipital crest*, terminating above at the *external occipital protuberance*, while on each side are seen the *superior* and *inferior curved lines*; these, as well as the surfaces of bone between them, are rough for the attachment of the muscles, which are enumerated on page 185.

Lateral Region of the Skull

The **Lateral Region** of the Skull (fig. 265) is of a somewhat triangular form, the base of the triangle being formed by a line extending from the external angular process of the frontal bone along the temporal ridge backwards to the outer extremity of the superior curved line of the occiput: and the sides by two lines, the one drawn downwards and backwards from the external angular process of the frontal bone to the angle of the lower jaw, the other from the angle of the jaw upwards and backwards to the outer extremity of the superior curved line. This region is divisible into three portions—temporal fossa, mastoid portion, and zygomatic fossa.

The Temporal Fossa

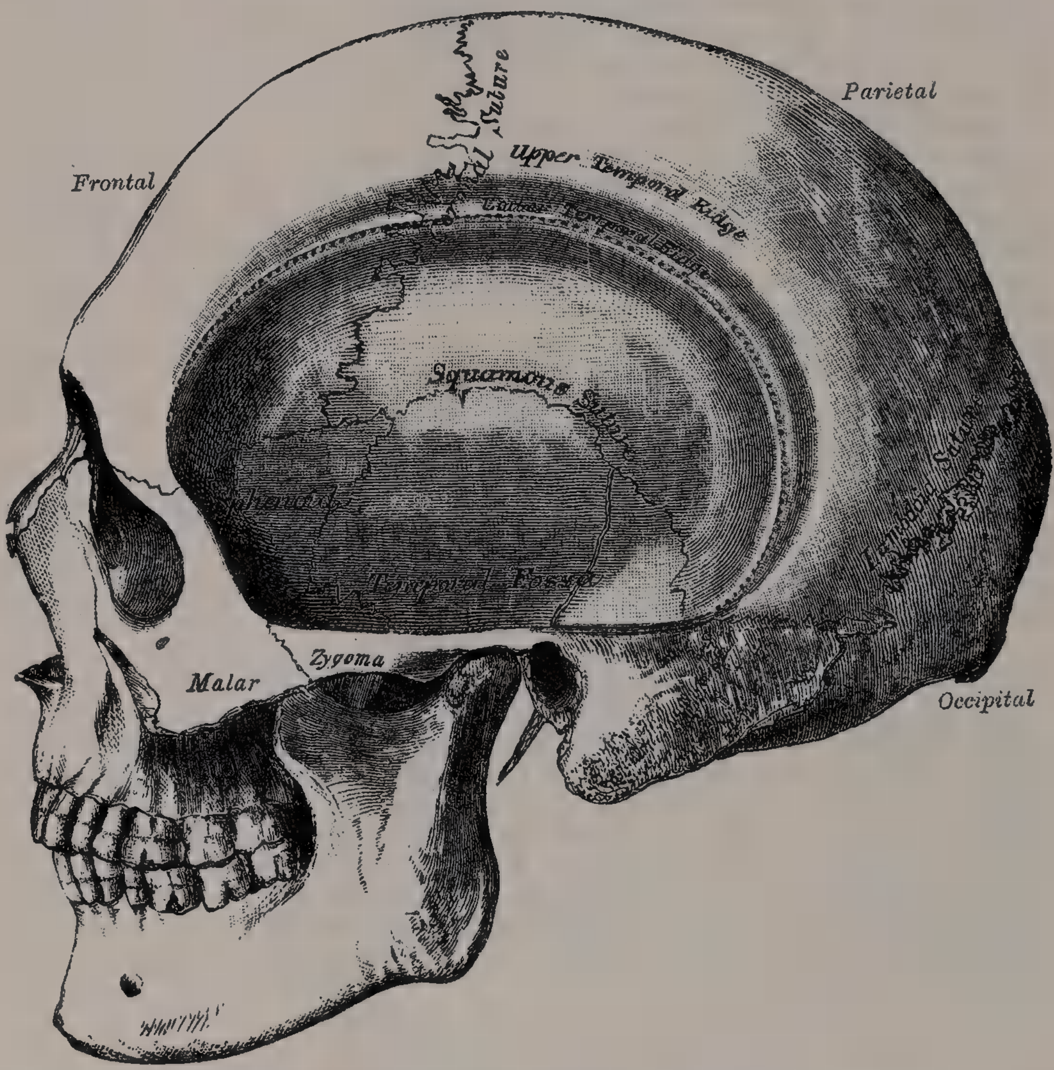
The **Temporal Fossa** is bounded above and behind by the temporal ridges, which extend from the external angular process of the frontal upwards and backwards across the frontal and parietal bones, and then curve downwards and forwards to terminate in the posterior root of the zygomatic process (*supra-mastoid crest*). In front, it is bounded by the frontal, malar, and great wing of the sphenoid; externally, by the zygomatic arch, formed conjointly by the malar and temporal bones; below, it is separated from the zygomatic fossa by the pterygoid ridge, or infratemporal crest, on the outer surface of the great wing of the sphenoid. This fossa is formed by five bones, part of the frontal, great wing of the sphenoid, parietal, squamous portion of the temporal, and malar bones, and is traversed by six sutures, part of the *transverse facial*, *spheno-malar*, *coronal*, *spheno-parietal*, *squamo-parietal*, and *squamo-sphenoidal*. The point where the coronal suture crosses the superior temporal ridge is named the *stephanion*; and the region where the parietal, frontal, squamous temporal, and

greater wing of the sphenoid meet at the anterior inferior angle of the parietal bone is named the *pterion.* This point is a little above the level of the external angular process of the frontal bone and about an inch and a quarter behind it. This fossa is deeply concave in front, convex behind, traversed by grooves which lodge branches of the deep temporal arteries, and filled by the Temporal muscle.

The Mastoid Portion

The **Mastoid Portion** of the side of the skull is bounded in front by the tubercle of the zygoma; above, by a line which runs from the posterior root of the zygoma to the end of the mastoid-parietal suture; behind and below by the

Fig. 265.—Side view of the skull.



masto-occipital suture. It is formed by the mastoid and part of the squamous and tympanic portions of the temporal bone; its surface is convex and rough for the attachment of muscles, and presents, from behind forwards, the mastoid foramen, the mastoid process, the suprameatal triangle, the external auditory meatus, bounded behind, below and in front by the tympanic plate, and, most anteriorly, the temporo-maxillary articulation.

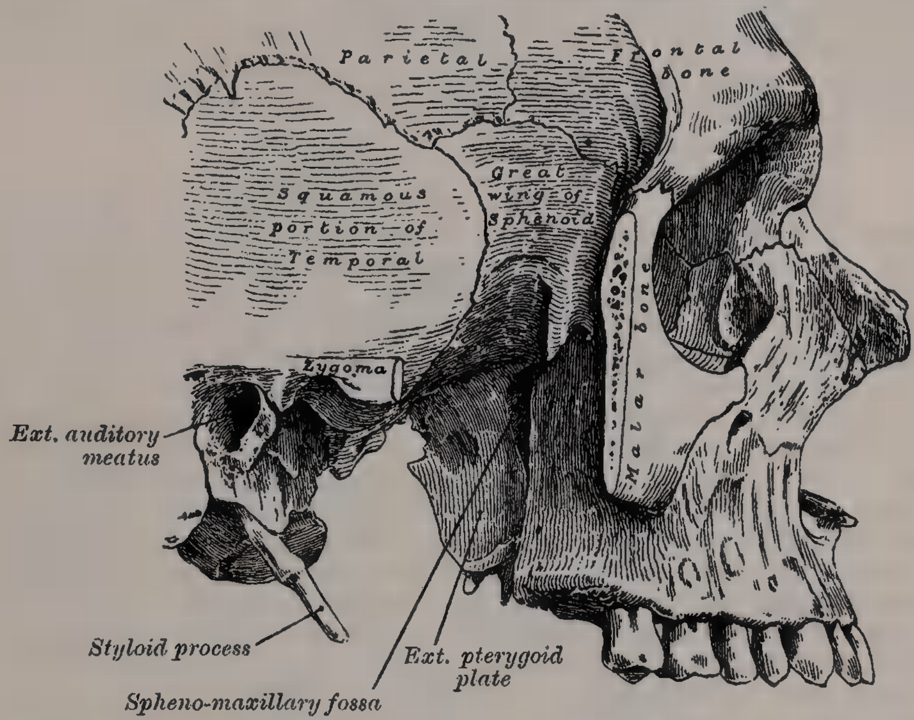
The point where the posterior inferior angle of the parietal meets the occipital bone and mastoid portion of the temporal is named the *asterion.*

The Zygomatic Fossa

The **Zygomatic Fossa** (fig. 266) is an irregularly shaped cavity, situated below and on the inner side of the zygoma; bounded, in front, by the zygomatic surface of the superior maxillary bone and the ridge which descends from its malar

process; behind, by the eminentia articularis and spine of sphenoid; above, by the great wing of the sphenoid below the pterygoid ridge and by the under part of the squamous temporal; below, by the alveolar border of the superior maxilla; internally, by the external pterygoid plate; and externally, by the zygomatic arch and by the ramus and coronoid process of the lower jaw. It contains the lower part of the Temporal, the External and Internal pterygoid muscles, together with the internal maxillary artery and vein, and inferior maxillary nerve, and their branches. The foramen ovale and foramen spinosum open on its roof, and the posterior dental canals on its anterior wall. At its upper

Fig. 266.—Zygomatic fossa.



and inner part may be observed two fissures, which together form a F-shaped fissure, the horizontal limb being named the spheno-maxillary, and the vertical one the pterygo-maxillary fissure.

The **Spheno-maxillary Fissure**, horizontal in direction, opens into the outer and back part of the orbit. It is formed above by the lower border of the orbital surface of the great wing of the sphenoid; below, by the external border of the orbital surface of the superior maxilla and the orbital process of the palate-bone; externally, by a small part of the malar bone:* internally, it joins at right angles with the pterygo-maxillary fissure. This fissure opens a communication from the orbit into three fossæ—the temporal, zygomatic, and spheno-maxillary; it transmits the superior maxillary nerve and its temporo-malar branch, the infra-orbital vessels, the ascending branches from Meckel's ganglion, and a vein which connects the ophthalmic vein with the pterygoid venous plexus.

The **Pterygo-maxillary Fissure** is vertical, and descends at right angles from the inner extremity of the preceding; it is a triangular interval, formed by the divergence of the superior maxillary bone from the pterygoid process of the sphenoid. It serves to connect the spheno-maxillary fossa with the zygomatic fossa, and transmits branches of the internal maxillary artery.

The Spheno-maxillary Fossa

The **Spheno-maxillary Fossa** is a small, triangular space situated at the angle of junction of the spheno-maxillary and pterygo-maxillary fissures, and placed beneath the apex of the orbit. It is formed above by the under surface of the body of the sphenoid and by the orbital process of the palate-bone; in front, by

* Occasionally the superior maxillary bone and the sphenoid articulate with each other at the anterior extremity of this fissure; the malar is then excluded from it.

the superior maxillary bone; behind, by the anterior surface of the base of the pterygoid process and lower part of the anterior surface of the great wing of the sphenoid; internally, by the vertical plate of the palate. This fossa has three fissures terminating in it, the *sphenoidal, spheno-maxillary*, and *pterygo-maxillary*; it communicates with the orbit by the spheno-maxillary fissure; with the nasal fossæ by the spheno-palatine foramen, and with the zygomatic fossa by the pterygo-maxillary fissure. It also communicates with the cavity of the cranium, and has five foramina opening into it. Of these there are three on the posterior wall: the *foramen rotundum* above; below, and internal to this, the *Vidian canal*; and still more inferiorly and internally, the *pterygo-palatine canal*. On the inner wall is the *spheno-palatine foramen* by which the spheno-maxillary communicates with the nasal fossa; and below is the superior orifice of the *posterior palatine canal*, besides occasionally the orifices of the *accessory posterior palatine* canals. The fossa contains the superior maxillary nerve and Meckel's ganglion, and the termination of the internal maxillary artery.

Anterior Region of the Skull

The **Anterior Region** of the Skull (*norma frontalis*), which forms the face, is of an oval form, presents an irregular surface, and is excavated for the reception of two of the organs of sense, the eye and the nose. It is bounded above by the glabella and margins of the orbit; below, by the lower border of the body of the mandible; on each side, by the malar bone, and ramus of the jaw. In the median line are seen from above downwards the *glabella*, and diverging from it are the *superciliary ridges*, which indicate the situation of the frontal sinuses and support the eyebrows. Beneath the glabella is the *fronto-nasal suture*, the mid-point of which is termed the *nasion*, and below this is the arch of the nose, formed by the nasal bones, and the nasal processes of the superior maxillary. The nasal arch is convex from side to side, concavo-convex from above downwards, presenting in the median line the internasal suture between the nasal bones, and laterally the naso-maxillary suture between the nasal bone and the nasal process of the superior maxillary bone. Below the nasal bones is seen the opening of the anterior nares, which is heart-shaped, with the narrow end upwards, and presents laterally the thin, sharp margins serving for the attachment of the lateral cartilages of the nose, and in the middle line, a prominent process, the *anterior nasal spine*.* Still lower is the *intermaxillary suture*, and on each side of it the *incisive fossa*. Beneath this fossa are the alveolar processes of the upper and lower jaws, containing the incisor teeth, and at the lower part of the median line, the *symphysis of the chin*, the *mental process*, with its two *mental tubercles*, separated by a median groove, and the *incisive fossa* of the lower jaw.

On each side, proceeding from above downwards, is the *supra-orbital ridge*, terminating externally in the external angular process at its junction with the malar, and internally in the internal angular process; towards the inner third of this ridge is the *supra-orbital notch* or *foramen*, for the passage of the supra-orbital vessels and nerve. Beneath the supra-orbital ridge is the opening of the orbit, bounded externally by the orbital ridge of the malar bone; below, by the orbital ridge formed by the malar and superior maxillary bones; internally, by the nasal process of the superior maxillary, and the internal angular process of the frontal bone. On the outer side of the orbit is the quadrilateral anterior surface of the malar bone perforated by one or two small malar foramina. Below the inferior margin of the orbit is the *infra-orbital foramen*, the termination of the infra-orbital canal, and beneath this the *canine fossa*, which gives attachment to the Levator anguli oris; still lower are the alveolar processes, containing the teeth of the upper and lower jaws. Beneath the alveolar arch of the lower jaw

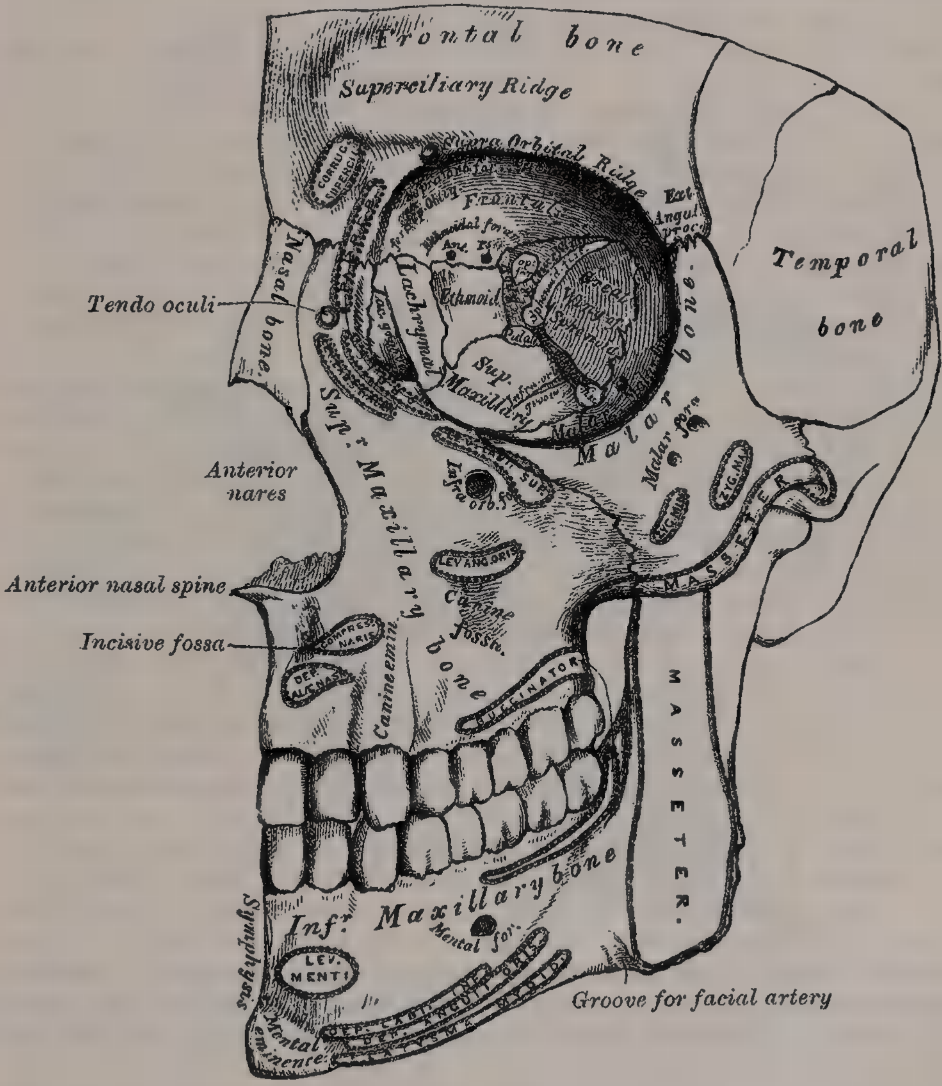
* Skulls may be classified according to the shape of the anterior opening of the nose. This is expressed by the *nasal index* thus: $\frac{\text{nasal width} \times 100}{\text{nasal height}}$ = the nasal index. Skulls are termed: (1) *leptorhine*, where the nasal index is below 48, as in the mixed Europeans, Eskimos, and American Indians; (2) *mesorhine*, where the index is between 48 and 53, as in the Chinese, Burmese, and Malays; (3) *platyrhine*, where the index is above 53, as in the Negro, Kaffir, and native Australian.

is the *mental foramen* for the passage of the mental vessels and nerve, the *external oblique line*, and at the lower border of the bone, at the point of junction of the body with the ramus, a shallow groove for the passage of the facial artery.

The Orbits

The **Orbits** (fig. 267) are two quadrilateral pyramidal cavities, situated at the upper and anterior part of the face, their bases being directed forwards and outwards, and their apices backwards and inwards, so that the axes of the two, if continued backwards, would meet over the body of the sphenoid bone. Each orbit is formed of *seven* bones, the frontal, sphenoid, ethmoid, superior maxillary, malar, lachrymal, and palate; but three of these, the frontal, ethmoid, and

Fig. 267.—Anterior region of the skull.



sphenoid, enter into the formation of *both* orbits, so that the two cavities are formed of *eleven* bones only. Each cavity presents for examination a roof, a floor, an inner and an outer wall, four angles, a circumference or base, and an apex. The **roof** is concave, directed downwards and slightly forwards, and formed in front by the orbital plate of the frontal; behind by the lesser wing of the sphenoid. This surface presents internally the depression for the cartilaginous pulley of the Superior oblique muscle; externally, the depression for the lachrymal gland; and posteriorly, the suture connecting the frontal and lesser wing of the sphenoid.

The **floor** is directed upwards and outwards, and is of less extent than the roof; it is formed chiefly by the orbital process of the superior maxillary bone; in front, to a small extent, by the orbital process of the malar, and behind, by

the superior surface of the orbital process of the palate. The floor presents at its anterior and internal part, just external to the lachrymal groove, a depression for the attachment of the Inferior oblique muscle; externally, the suture between the malar and superior maxillary bones; near its middle, the infra-orbital groove; and posteriorly, the suture between the maxillary and palate bones.

The **inner wall** is flattened, nearly vertical, and formed from before backwards by the nasal process of the superior maxilla, the lachrymal, os planum of the ethmoid, and a small part of the body of the sphenoid. This surface presents the lachrymal groove, the crest of the lachrymal bone, and the sutures connecting the lachrymal with the superior maxillary, the ethmoid with the lachrymal in front, and the ethmoid with the sphenoid behind.

The **outer wall** is directed forwards and inwards, and is formed in front by the orbital process of the malar bone; behind, by the orbital surface of the greater wing of the sphenoid. On it are seen the orifices of one or two malar canals, and the suture connecting the sphenoid and malar bones.

Angles.—The *superior external angle* is formed by the junction of the upper and outer walls; it presents, from before backwards, the suture connecting the frontal with the malar in front, and with the great wing of the sphenoid behind; quite posteriorly is the foramen lacerum anterius, or sphenoidal fissure, which transmits the third, the fourth, the three branches of the ophthalmic division of the fifth, the sixth nerve, some filaments from the cavernous plexus of the sympathetic, the orbital branch of the middle meningeal artery, a recurrent branch from the lachrymal artery to the dura mater, and the ophthalmic vein. The *superior internal angle* is formed by the junction of the upper and inner wall, and presents the suture connecting the frontal bone with the lachrymal in front, and with the ethmoid behind. The point of junction of the *anterior* border of the lachrymal with the frontal has been named the *dacryon.* This angle presents two foramina, the anterior and posterior ethmoidal, the former transmitting the anterior ethmoidal vessels and nasal nerve, the latter the posterior ethmoidal vessels. The *inferior external angle*, formed by the junction of the outer wall and floor, presents the spheno-maxillary fissure, which transmits the superior maxillary nerve and its orbital branches, the infra-orbital vessels, and the ascending branches from the spheno-palatine or Meckel's ganglion. The *inferior internal angle* is formed by the union of the lachrymal and os planum of the ethmoid, with the superior maxillary and palate bones. The *circumference*, or base, of the orbit, quadrilateral in form, is bounded above by the supra-orbital ridge; below, by the anterior border of the orbital plate of the malar and superior maxillary bones; externally, by the external angular process of the frontal and the malar bones; internally, by the internal angular process of the frontal, and the nasal process of the superior maxillary. The circumference is marked by three sutures, the fronto-maxillary internally, the fronto-malar externally, and the malo-maxillary below; it contributes to the formation of the lachrymal groove, and presents, above, the supra-orbital notch (or foramen), for the passage of the supra-orbital vessels and nerve. The *apex*, situated at the back of the orbit, corresponds to the optic foramen,* a short, circular canal, which transmits the optic nerve and ophthalmic artery. It will thus be seen that there are *nine* openings communicating with each orbit—viz. the optic foramen, sphenoidal fissure, spheno-maxillary fissure, supra-orbital foramen, infra-orbital canal, anterior and posterior ethmoidal foramina, malar foramina, and canal for the nasal duct.

The Nasal Fossæ

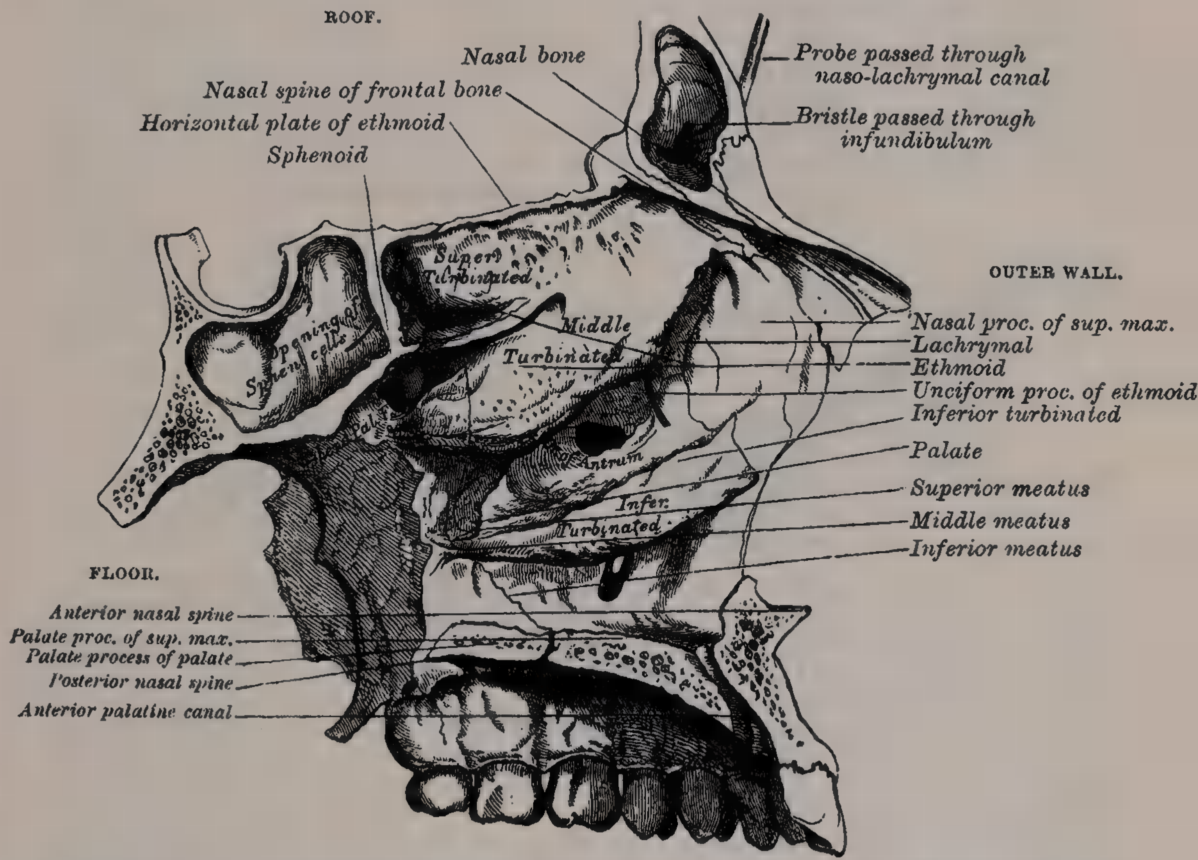
The **Nasal Fossæ** are two large, irregular cavities, situated one on either side of the middle line of the face, extending from the base of the cranium to the roof of the mouth, and separated from each other by a thin vertical septum. They communicate by two large apertures, the *anterior nares*, with the front of the face; and by the two *posterior nares* with the naso-pharynx behind. These fossæ are much narrower above than below, and in the middle than at the

* Quain, Testut, and others give the apex of the orbit as corresponding with the inner end of the sphenoidal fissure. It seems better, however, to adopt the statement in the text, since the muscles of the eyeball take origin around the optic foramen, and diverge from it to the globe of the eye.

anterior or posterior openings: their depth, which is considerable, is much greater in the middle than at either extremity. Each nasal fossa communicates with four sinuses, the frontal above, the sphenoidal behind, and the maxillary and ethmoidal on the outer wall. Each fossa also communicates with four cavities: with the orbit by the lachrymal groove, with the mouth by the anterior palatine canal, with the cranium by the olfactory foramina, and with the spheno-maxillary fossa by the spheno-palatine foramen; and they occasionally communicate with each other by an aperture in the septum. The bones entering into their formation are fourteen in number: three of the cranium, the frontal, sphenoid, and ethmoid, and all the bones of the face, excepting the malar and lower jaw. Each cavity is bounded by a roof, a floor, an inner and an outer wall.

The **upper wall,** or **roof** (fig. 268), is long, narrow, and horizontal in its centre, but sloped downwards at its anterior and posterior extremities; it is formed in

FIG. 268.—Roof, floor, and outer wall of left nasal fossa.

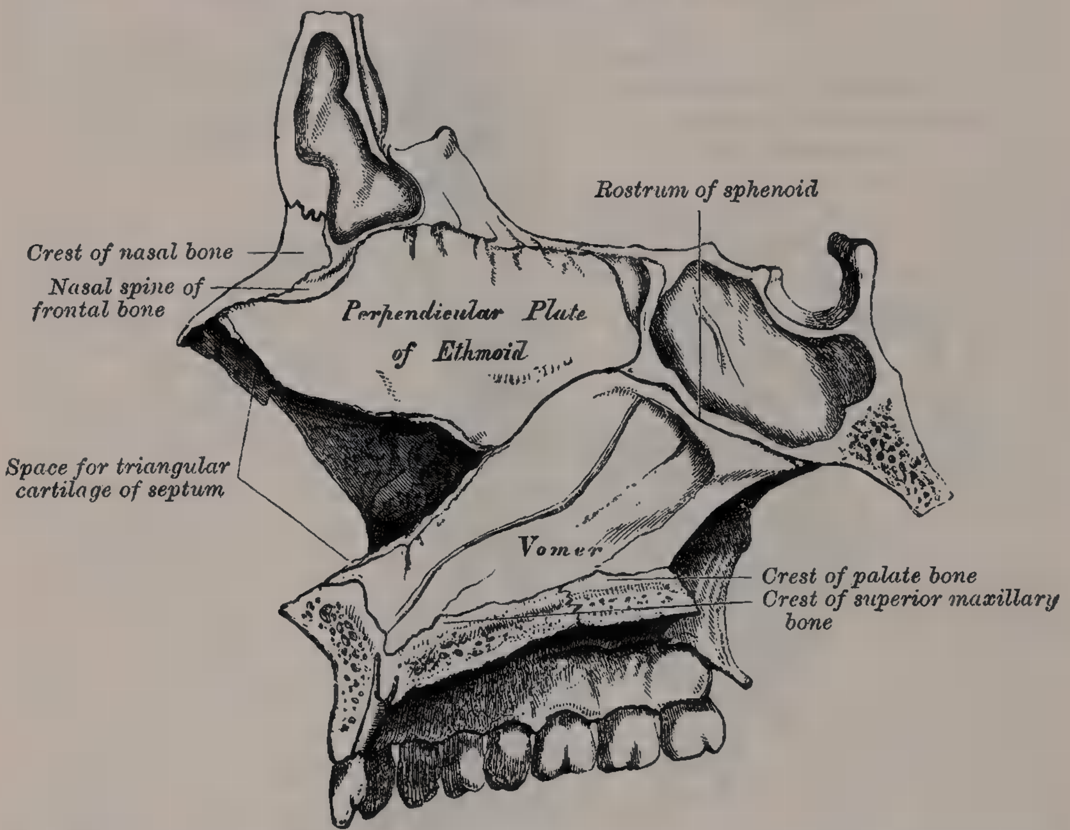


front by the nasal bones and nasal spine of the frontal, which are directed downwards and forwards; in the middle, by the cribriform plate of the ethmoid, which is horizontal; and behind, by the under surface of the body of the sphenoid, and sphenoidal turbinated bones, the ala of the vomer and the sphenoidal process of the palate-bone, which are directed downwards and backwards. This surface presents, from before backwards, the internal aspect of the nasal bones; on their outer side, the suture formed between the nasal bone and the nasal process of the superior maxillary; on their inner side, the elevated crest which receives the nasal spine of the frontal and the perpendicular plate of the ethmoid, and articulates with its fellow of the opposite side; while the surface of the bones is perforated by a few small vascular apertures, and presents the longitudinal groove for the nasal nerve: farther back is the suture, connecting the frontal with the nasal in front, and the ethmoid behind, the olfactory foramina and nasal slit on the under surface of the cribriform plate, and the suture between it and the sphenoid behind: quite posteriorly are seen the sphenoidal turbinated bones, the orifices of the sphenoidal sinuses, and the articulation of the alæ of the vomer with the under surface of the body of the sphenoid.

The **floor** is flattened from before backwards, concave from side to side, and wider in the middle than at either extremity. It is formed in front by the palate process of the superior maxillary; behind, by the palate process of the palate-bone. This surface presents, from before backwards, the anterior nasal spine; behind this, the upper orifices of the anterior palatine canal; internally, the elevated crest which articulates with the vomer; and behind, the suture between the palate and superior maxillary bones, and the posterior nasal spine.

The **inner wall**, or septum (fig. 269), is a thin vertical partition, which separates the nasal fossæ from one another; it is occasionally perforated, so that the fossæ communicate, and it is frequently deflected considerably to one side.* It is formed, in front, by the crest of the nasal bones and nasal spine of the frontal; in the middle, by the perpendicular plate of the ethmoid; behind, by the vomer and rostrum of the sphenoid; below, by the crest of the superior maxillary and palate bones. It presents, in front, a large, triangular notch, which receives the septal cartilage of the nose; and behind, the grooved edge of the vomer. Its

Fig. 269.—Inner wall of nasal fossæ, or septum of nose.



surface is marked by numerous vascular and nervous canals and the groove for the naso-palatine nerve, and is traversed by sutures connecting the bones of which it is formed.

The **outer wall** (fig. 268) is formed, in front, by the nasal process of the superior maxillary and by the lachrymal bone; in the middle, by the ethmoid and inner surface of the superior maxillary and inferior turbinated bones; behind, by the vertical plate of the palate-bone, and the internal pterygoid plate of the sphenoid. This surface presents three irregular longitudinal passages, or *meatuses*, termed the superior, middle, and inferior meatuses of the nose. The *superior meatus*, the smallest of the three, is situated at the upper part of each nasal fossa, occupying the middle third of the outer wall. It lies between the superior and middle turbinated bones, and has opening into it two foramina, the *spheno-palatine* at the back of its outer wall, and the *posterior ethmoidal cells* at the front part of the outer wall. The sphenoidal sinus opens into a recess, the *spheno-ethmoidal recess*, which is placed above and behind the superior turbinated bone. The *middle meatus* is situated between the middle and inferior

* See footnote, page 204.

turbinated bones, and extends from the anterior to the posterior end of the inferior turbinated bone. It presents in front the orifice of the *infundibulum*, by which the middle meatus communicates with the frontal sinus and the anterior ethmoidal cells. The middle ethmoidal cells also open into this meatus, while at the centre of the outer wall is the *orifice of the antrum of Highmore*, which in a considerable percentage of skulls is duplicated. The *inferior meatus*, the largest of the three, is the space between the inferior turbinated bone and the floor of the nasal fossa. It extends almost the entire length of the outer wall of the nose, is broader in front than behind, and presents anteriorly the lower *orifice of the canal for the nasal duct.*

The **anterior nares** present a heart-shaped or pyriform opening, whose long axis is vertical, and narrow extremity upwards. This opening in the recent state is much contracted by the cartilages of the nose. It is bounded above by the inferior border of the nasal bone; laterally by the thin, sharp margin which separates the facial from the nasal surface of the superior maxillary bone; and below by the same border, where it slopes inwards to join its fellow of the opposite side at the anterior nasal spine.

The **posterior nares** or **choanæ** are the two posterior oval openings of the nasal fossæ, by which they communicate with the upper part of the pharynx. They are situated below and in front of the basilar process of the occipital bone, and are bounded above by the under surface of the body of the sphenoid and alæ of the vomer; below, by the posterior border of the horizontal plate of the palate-bone; externally, by the inner surface of the internal pterygoid plate; internally, they are separated from each other by the posetrior border of the vomer.

Surface Form.—The various bony prominences or landmarks which are to be easily felt and recognised in the head and face, and which afford the means of mapping out the important structures comprised in this region, are as follows:

1. Supra-orbital arch.
2. Internal angular process.
3. External angular process.
4. Zygomatic arch.
5. Mastoid process.
6. External occipital protuberance.
7. Superior curved line of occipital bone.
8. Parietal eminence.
9. Temporal ridge.
10. Frontal eminence.
11. Superciliary ridge.
12. Nasal bone.
13. Lower margin of orbit.
14. Lower jaw.

1. The *supra-orbital arch* is to be felt throughout its entire extent, covered by the eyebrow. It forms the upper boundary of the circumference or base of the orbit and separates the face from the forehead. It is strong and arched, and terminates internally at the root of the nose, in the *internal angular process*, which articulates with the lachrymal bone. Externally it terminates in the *external angular process* which articulates with the malar bone. This arched ridge is sharper and more defined in its outer than in its inner half, and forms an overhanging process which protects and shields the lachrymal gland. It also protects the eye in its most exposed situation and in the direction from which blows are more likely to descend. At the junction of the inner and middle third of the arch, a slight interruption in the outline may sometimes be felt; this is the *supra-orbital notch.* Generally the notch is converted into a foramen, and the interruption cannot be felt. A line carried from this notch or foramen downwards over the face, between the two bicuspid teeth of the lower jaw, passes over the infra-orbital and the mental foramina, and thus constitutes a guide to the point of exit from the bones of the face of the three largest cutaneous branches of the fifth cranial nerve. The supra-orbital arch varies in prominence in different individuals. It is more marked in the male than in the female, and in some races of mankind than others. In the less civilised races, as the forehead recedes backwards, the supra-orbital arch becomes more prominent and approaches more to the characters of the monkey tribe, in which the supra-orbital arches are very largely developed and acquire additional prominence from the oblique direction of the frontal bone. 2. The *internal angular process* is scarcely to be felt. Its position is indicated by the angle formed by the supra-orbital arch with the nasal process of the superior maxillary bone and the lachrymal bone at the inner side of the orbit. Between the internal angular processes of the two sides is a broad surface which assists in forming the root of the nose, and immediately above this a broad, smooth, somewhat triangular area, the *glabella*, situated between and connecting the superciliary ridges. 3. The *external angular process* is much more strongly marked than the internal, and is plainly to be felt. It is formed by the junction or confluence of the supra-orbital and temporal ridges, and, articulating with the malar bone, it serves to a very considerable extent to support the bones of the face. In carnivorous animals the external angular process does

not articulate with the malar, and therefore this lateral support to the bones of the face is not present. 4. The *zygomatic arch* can be plainly felt throughout its entire length, being situated almost immediately under the skin. It is formed by the malar bone and the zygomatic process of the temporal bone. At its anterior extremity, it is broad and constitutes the prominence of the cheek; the posterior part is narrower, and terminates just in front and a little above the tragus of the external ear: its upper border may be traced backwards, as the posterior root, above the tragus and the external auditory meatus to join the posterior part of the lower temporal ridge, forming the *supramastoid crest.* A spot in this line, immediately in front of the upper border of the tragus and between it and the condyle of the jaw, is known as the *pre-auricular point.* This is an important landmark, since the temporal vessels and the auriculo-temporal nerve cross it, and two inches vertically above it is the lower end of the fissure of Rolando. The lower border is more plainly to be felt than the upper, in consequence of the dense temporal fascia being attached to the latter, which somewhat obscures its outline. Its shape differs very much in individuals and in different races of mankind. In the most degraded type of skull—as, for instance, in the skull of the negro of the Guinea Coast—the malar bones project forwards and not outwards, and the zygoma at its posterior extremity extends farther outwards before it is twisted on itself to be prolonged forwards. This makes the zygomatic arch stand out in bold relief, and affords greater space for the Temporal muscle. In skulls which have a more pyramidal shape, as in the Esquimaux or Greenlander, the malar bones do not project forwards and downwards under the eyes, as in the preceding form, but take a direction outwards, forming with the zygoma a large, rounded sweep or segment of a circle. Thus it happens that if two lines are drawn from the zygomatic arches, touching the temporal ridges, they meet above the top of the head, instead of being parallel, or nearly so, as in the European skull, in which the zygomatic arches are not nearly so prominent. This gives to the face a more or less oval type. 5. Behind the ear is the *mastoid portion of the temporal bone*, plainly to be felt, and terminating below in a nipple-shaped process. Its anterior border can be traced immediately behind the concha, and its apex is about on a level with the lobule of the ear. It is rudimentary in infancy, but gradually develops in childhood, and is more marked in the negro than in the European. 6. The *external occipital protuberance* (*inion*) is always plainly to be felt just at the level where the skin of the neck joins that of the head. At this point the skull is thick for the purposes of safety, while radiating from it are numerous curved arches or buttresses of bone which give to this portion of the skull further security. 7. Running outwards on either side from the external occipital protuberance is an arched ridge of bone, which can be more or less plainly perceived. This is the *superior curved line* of the occipital bone, and gives attachment to some of the muscles which keep the head erect on the spine; accordingly, we find it more developed in the negro tribes, in whom the jaws are much more massive, and therefore require stronger muscles to prevent their extra weight carrying the head forwards. Below this line the surface of bone at the back of the head is obscured by the overlying muscles, except in the middle line, where the external occipital crest can generally be felt at the bottom of the nuchal furrow. Above it, the vault of the cranium is thinly covered with soft structures, so that the form of this part of the head is almost exactly that of the upper portion of the occipital, the parietal, and the frontal bones themselves; and, in bald persons, even the lines of junction of the bones, especially the junction of the occipital and parietal at the lambdoid suture, may be defined as a slight depression, caused by the thickening of the borders of the bones in this situation. 8. In the line of the greatest transverse diameter of the head are generally to be found the *parietal eminences*, one on each side of the middle line; though sometimes these eminences are not situated at the point of the greatest transverse diameter, which is at some other prominent part of the parietal region. Each denotes the point where ossification of the parietal bone began. They are much more prominent and better marked in early life, in consequence of the sharper curve of the bone at this period, so that it describes the segment of a smaller circle. Later in life, as the bone grows, the curve spreads out and forms the segment of a larger circle, and the eminence becomes less distinguishable. In consequence of this sharp curve of the bone in early life, the whole of the vault of the skull has a squarer shape than it has in later life, and this appearance may persist in some rickety skulls. The eminence is more apparent in the negro's skull than in that of the European. This is due to greater flattening of the temporal fossa in the former skull to accommodate the larger Temporal muscle which exists in these races. The parietal eminence is particularly exposed to injury from blows or falls on the head, but fracture is to a certain extent prevented by the shape of the bone, which forms an arch, so that the force of the blow is diffused over the bone in every direction. 9. At the side of the head is the *temporal ridge.* Commencing at the external angular process, it may be felt as a curved ridge, passing upwards and then curving backwards, on the frontal bone, separating the forehead from the temporal fossa. It may then be traced, passing backwards in a curved direction, over the parietal bone, and, though less marked, still generally to be recognised. Finally, the ridge curves downwards and forwards, and terminates in the posterior root of the zygoma. Victor Horsley has shown, in an article on the 'Topography of the Cerebral Cortex,' that

the second temporal ridge (see page 186) can be made out on the living body. 10. The *frontal eminences* vary in prominence in different individuals, and are often not symmetrical on the two sides of the body, one being more pronounced than the other. This is especially noticeable in the skull of the young child or infant, and becomes less marked as age advances. The prominence of the frontal eminences depends more upon the general shape of the whole bone than upon the size of the protuberances themselves. As the skull is more highly developed in consequence of increased intellectual capacity, so the frontal bone becomes more upright, and the frontal eminences stand out in bolder relief. Thus they may be considered as affording, to a certain extent, an indication of the development of the hemispheres of the brain beneath, and of the mental powers of the individual. They are not so much exposed to injury as the parietal eminences. In falls forward the upper extremities are involuntarily thrown out, and break the force of the fall, and thus shield the frontal bone from injury. 11. Below the frontal eminences on the forehead are the *superciliary ridges*, which denote the position of the frontal sinuses, and vary in different individuals, being, as a rule, small in the female, absent in children, and sometimes unusually prominent in the male, when the frontal sinuses are largely developed. The degree of prominence of the superciliary ridges is not, however, necessarily related to the size of the sinuses, for sometimes large sinuses are present in cases where there is but little elevation of the ridges, and in other cases strongly marked ridges may exist, with little formation of air-spaces. They commence on either side of the glabella, and at first present a rounded form, which gradually fades away at their outer ends. 12. The *nasal bones* form the prominence of the nose. They vary much in size and shape, and to them is due the varieties in the contour of this organ and much of the character of the face. Thus, in the Mongolian or Ethiopian they are flat, broad, and thick at their base, giving to these tribes the flattened nose by which they are characterised, and differing very decidedly from the Caucasian, in whom the nose, owing to the shape of the nasal bones, is narrow, elevated at the bridge, and elongated downwards. At the root of the nose, and a little below the glabella, is the fronto-nasal suture (*nasion*). Beneath it, the nasal bones are thin and connected with the cartilages of the nose, and the angle or arch formed by their union serves to throw out the bridge of the nose, and is much more marked in some individuals than others. 13. The *lower margin of the orbit*, formed by the superior maxillary bone and the malar bone, is plainly to be felt throughout its entire length. It is continuous internally with the nasal process of the superior maxillary bone, which forms the inner boundary of the orbit. At the point of junction of the lower margin of the orbit with the nasal process is to be felt a little tubercle, which can be plainly perceived by running the finger along the bone in this situation. This tubercle serves as a guide to the position of the lachrymal sac, which is situated above and behind it. 14. The outline of the *lower jaw* is to be felt throughout its entire length. Just in front of the tragus of the external ear, and below the zygomatic arch, the condyle can be made out. When the mouth is opened, this prominence of bone can be perceived advancing out of the glenoid fossa on to the eminentia articularis, and receding again when the mouth is closed. From the condyle the posterior border of the ramus can be felt extending down to the angle. A line drawn from the condyle to the angle would indicate the exact position of this border. From the angle to the symphysis of the chin, the lower, rounded border of the body of the bone is plainly to be felt. At the point of junction of the two halves of the bone is a well-marked, triangular eminence, the *mental process*, which forms the prominence of the chin.

Surgical Anatomy.—An arrest in the ossifying process may give rise to deficiencies or gaps; or to fissures, which are of importance from a medico-legal point of view, as they are liable to be mistaken for fractures. The fissures generally extend from the margin towards the centre of the bone, but gaps may be found in the middle, as well as at the edges. In course of time they may become covered with a thin lamina of bone.

Occasionally a protrusion of the brain or its membranes may take place through one of these gaps in an imperfectly developed skull, or through one of the sutures, owing to non-closure. When the protrusion consists of membranes only, and is filled with cerebro-spinal fluid, it is called a *meningocele*; when the protrusion consists of brain as well as membranes, it is termed an *encephalocele*; and when the protruded brain is a prolongation from one of the ventricles, and is distended by a collection of fluid from an accumulation in the ventricle, it is termed an *hydrencephalocele.* This latter condition is most commonly met with at the root of the nose, where a protrusion of the anterior horn of the lateral ventricle takes place through a deficiency of the fronto-nasal suture. These malformations are usually found in the middle line, and most frequently at the back of the head, the protrusion taking place through the fissures which separate the centres of ossification from which the tabular portion of the occipital bone is originally developed (see page 185). They generally occur through the upper part of the vertical fissure, which is the last to ossify, but not uncommonly through the lower part, when the foramen magnum may be incomplete. More rarely these protrusions have been met with in other situations than those two above mentioned, both through normal fissures, as the sagittal, lambdoid, and other sutures, and also through abnormal gaps and deficiencies at the sides, and even at the base of the skull.

The chief function of the skull is to protect the brain and its appendages from any form of violence to which they may be subjected. We find, therefore, that those portions of the skull which are most exposed to external violence are thicker than others, which are shielded from injury by overlying muscles. Thus, the skull-cap is thick and dense, whereas the squamous portion of the temporal bone, being protected by the temporal muscle and the inferior occipital fossæ, being shielded by the muscles at the back of the neck, are thin and fragile. Fracture of the skull is further prevented by its elasticity, by its rounded shape, and its construction of a number of secondary elastic arches, each made up of a single bone. The manner in which vibrations are transmitted through the bones of the skull is also of importance as regards its protective mechanism, at all events as far as the base is concerned. In the vault, the bones being of a fairly equal thickness and density, vibrations are transmitted in a uniform manner in all directions. But, owing to the varying thickness and density of the bones forming the base, this is not so; and therefore we find in this situation special buttresses which serve to carry the vibrations in certain definite directions. At the front of the skull, on either side is the ridge which separates the anterior from the middle fossa of the base; and behind, the ridge or buttress which separates the middle from the posterior fossa; and if any violence is applied to the vault, the vibrations would be carried along these buttresses to the sella turcica, where they meet. This part has been termed the 'centre of resistance,' and here there is a special protective mechanism to guard the brain. The subarachnoid space is dilated, and an increased quantity of cerebro-spinal fluid acts as a water-cushion to shield the brain from injury. In like manner, when violence is applied to the base of the skull, as in falls upon the feet, the vibrations are carried backwards through the occipital crest, and forwards through the basilar process and body of the sphenoid to the vault of the skull.

Fractures of the skull are best considered as affecting either the vault or the base. Fractures of the vault may, and generally do, involve the whole thickness of the bone; but sometimes one table may be fractured without any corresponding injury to the other. Thus, the outer table of the skull may be splintered and driven into the diploë, or in the frontal or mastoid regions into the frontal or mastoid cells, without any injury to the internal table. And, on the other hand, the internal table has been fractured, and portions of it depressed and driven inwards, without any fracture of the outer table. As a rule, in fractures of the skull, the inner table is more splintered and comminuted than the outer, and this is due to several causes. It is thinner and more brittle; the force of the violence as it passes inwards becomes broken up, and is more diffused by the time it reaches the inner table; the bone being in the form of an arch bends as a whole and spreads out, and thus presses the particles together on the convex surface of the arch, i.e. the outer table, and forces them asunder on the concave surface or inner table; and, lastly, there is nothing firm under the inner table to support it and oppose the force. Fractures of the vault may be simple fissures, or starred and comminuted fractures, and these may be depressed or elevated. These latter cases of fracture with elevation of the fractured portion are uncommon, and can only be produced by direct wound. In comminuted fracture, a portion of the skull is broken into several pieces, the lines of fracture radiating from a centre where the chief impact of the blow was felt; if depressed, a fissure circumscribes the radiating lines, enclosing a portion of skull. If this area is circular it is termed a 'pond' fracture, and would in all probability have been caused by a round instrument, as a life preserver or hammer; if elliptical in shape it is termed a 'gutter' fracture, and would owe its shape to the instrument which had produced it, as a poker.

Fractures of the base of the skull may be produced by *indirect* or *direct* violence. I. In the former class of cases the violence is applied to the vertex or some part of the cranial convexity, as when a person falls from a height on to his head and a fracture of the base results. The mechanism of this form of fracture was formerly explained by the doctrine of *contre-coup*, i.e. that the force was transmitted from one side of the skull to the other; but this idea is now completely exploded, and there are at the present day two theories as the mode of causation of these fractures, both probably being responsible for a certain number of cases. (*a*) Aran's theory of *irradiation* holds that all fractures of the base are produced by a fissure, which starts from the point of injury and radiates to the base. There can be little doubt that many cases of fracture of the base, especially of the middle fossæ, are caused in this way; but it is insufficient to explain all, since instances have been met with of fracture of the base of the skull in which there has been no fracture of the vault. (*b*) To explain these cases, another theory, known as the *compression* or *bursting* theory, has been suggested. If a hollow, elastic sphere is compressed, from above downwards, it will bulge laterally, and, if the compression is sufficient, it will eventually burst in the situation where it bulges. Now, the skull is an elastic sphere, and when compression is applied to it, its diameter will be reduced along the line of greatest pressure and will therefore be increased in other directions, and may increase to such an extent that bursting may result. In a hollow elastic sphere of uniform thickness, the bulging and subsequent bursting take place at the equatorial line midway between the two points of compression; but the skull is not of uniform thickness, and therefore the bulging and subsequent bursting take place at the weakest part.

II. Direct violence applied to the base of the skull may cause fracture in several

different ways: by the impact of the vertebral column against the condyles of the occipital bone, in falls on the buttocks or feet; by the condyle of the lower jaw being driven against the glenoid fossa, in blows or falls on the chin; by the thrust of a pointed instrument through the orbit or nose; by gunshot wounds through the mouth; and by falls or a stab on the back of the head, fracturing the occipital bone.

In the majority of cases of fracture of the base, the fracture is compound. In the anterior fossa, if the fissure extends across the cribriform plate, the nasal mucous membrane is usually torn and the fracture rendered compound into the nose; or the fissure may extend into the sphenoidal or ethmoid sinuses and thus open up a communication between the fracture and the external air. In the middle fossa, the fracture often opens up the tympanic cavity, and if the membrana tympani is torn, the fracture is compound; or if it runs across the pituitary fossa, the mucous membrane of the roof of the naso-pharynx is generally torn and the fracture rendered compound.

The most common place for fracture of the base to occur is through the middle fossa, and here the fissure usually takes a fairly definite course. Starting from the point struck, which is generally somewhere in the neighbourhood of the parietal eminence, it runs downwards through the parietal and squamous portion of the temporal bone and across the petrous portion of this bone, frequently traversing and implicating the internal auditory meatus, to the middle lacerated foramen. From this it may pass across the body of the sphenoid, through the pituitary fossa, to the middle lacerated foramen of the other side, and may indeed travel round the whole cranium, so as to completely separate the anterior from the posterior part. The course of the fracture should be borne in mind, as it explains the symptoms to which fracture in this region may give rise: thus, if the fissure pass across the internal auditory meatus, injury to the facial and auditory nerves may result, with consequent facial paralysis and deafness; or the tubular prolongation of the arachnoid around these nerves in the meatus may be torn and thus permit of the escape of the cerebro-spinal fluid should there be a communication between the internal ear and the tympanum together with rupture of the membrana tympani, as is frequently the case: again, if the fissure passes across the pituitary fossa and the muco-periosteum covering the under surface of the body of the sphenoid is torn, blood will find its way into the pharynx and be swallowed, and after a time vomiting of blood will result. Fractures of the anterior fossa, involving the bones forming the roof of the orbit and nasal fossa, are generally the result of blows on the forehead; but fracture of the cribriform plate of the ethmoid may be a complication of fracture of the nasal bone. When the fracture implicates the roof of the orbit, the blood finds its way into this cavity, and, travelling forwards, appears as a subconjunctival ecchymosis. If the roof of the nasal fossa be fractured, the blood escapes from the nose. In rare cases there may be also escape of cerebro-spinal fluid from the nose, where the dura mater and arachnoid have been torn. In fractures of the posterior fossa, extravasation of blood may appear at the nape of the neck.

Diseases of the Skull.—Owing to the fact that the pericranium does not play an important part in the nutrition and regeneration of the skull, as does the periosteum in the long bones, it is advisable to discuss *inflammatory* diseases of the skull, as affecting the bones and the membrane covering them together, under the term *osteomyelitis.* This is generally caused by septic infection of a scalp wound, exposing and bruising the bone, or in compound fractures, and is termed *septic osteomyelitis.* Occasionally it may occur independently of injury, and then follows the same course, and is due to the same causes, as acute infective osteomyelitis in the long bones.

The most common chronic diseases of the skull are due to syphilis and tubercle. In *acquired syphilis* the disease usually occurs as *nodes*, which arise most commonly in the pericranium, but may also arise in the diploë, or more rarely on the inner surface of the skull. The formation of gummata under the periosteum generally leads to *caries*, which may be either limited if the gumma is localised, or widespread if the gumma is diffuse. The caries is often complicated by *necrosis*, for a condition of sclerosis is frequently set up in the surrounding bone, and the vessels in the Haversian canals become compressed and the vitality of the bone interfered with; hence we often find a central necrosing area surrounded by a zone of caries. A common result of syphilitic disease of the skull is the production of large, hard masses of bone on its surface, which gives it a tuberculated appearance; in other cases, the skull presents a curious worm-eaten appearance: this is due to the fact that the osteogenetic powers of the periosteum are small and the formation of bone on the surface slight. In *hereditary syphilis*, in addition to the formation of gummata, which are usually of the subperiosteal variety, atrophic or hypertrophic changes may take place. In the atrophic cases, the bone becomes abnormally thin, or even perforated, generally where there is pressure, as from the pillow or nurse's arm. Hence they are usually met with in the parietal bones or vertical plate of the occiput. In the hypertrophic cases, a deposit of porous bone takes place around the anterior fontanelle in the parietal and frontal bones; these deposits are separated by the coronal and sagittal sutures, and give to the skull an appearance like a 'hot cross bun.' They are known as *Parrot's nodes*, and such a skull has received the name of *natiform*, from its fancied resemblance to the buttocks.

Tuberculous disease sometimes occurs in the bones of the skull, and is plainly differentiated from syphilitic disease by the fact that it always commences in the bone itself and only affects the pericranium and dura mater secondarily; and by the fact that it is never accompanied by the formation of bosses or osteophytes, as in syphilis. It may involve the whole thickness of the bone and cause perforation, or it may destroy only the external table and part of the diploë and produce a non-perforating ulcer of the bone. Or, in a third variety, the tuberculous granulation tissue may perforate the internal table of the skull and spread between the bone and dura mater.

The most common tumours of the skull are the osteomata and the sarcomata; but in addition a few cases of hydatid cyst, originating in the diploë, have been recorded. The osteoma is generally the ivory exostosis, though cases of spongy exostosis do occur. Sarcomata of the skull may arise either from the pericranium or the diploë, but it is usually impossible to distinguish clinically between the two. Carcinoma, if it occurs in the skull, is always secondary to cancer in some other part of the body.

Hypertrophic changes occur in the skull in ostitis deformans, acromegaly, leontiasis ossea, and in rickets. In these latter cases the skull becomes enlarged from the formation of a soft, spongy bone, and its shape peculiar: the forehead is high, square and projecting, and the antero-posterior diameter is long, in relation to its transverse diameter. The bones of the face are small and ill-developed, and this gives the appearance of a larger head than actually exists. The bones may become the seat of cranio-tabes, and the anterior fontanelle is long in closing, sometimes not being obliterated till the fifth or sixth year of life.

The mastoid antrum, situated in the mastoid portion of the temporal bone, is sometimes the seat of suppuration from a direct extension backwards from the tympanic cavity. In such cases, the surgeon has to open the antrum in order to give exit to the pus. This he does by introducing his gouge in the suprameatal triangle (see page 192). A line is drawn horizontally through the upper border of the bony external auditory meatus, and a second vertically through the posterior wall of the meatus, and the gouge is applied in the angle where these two lines intersect each other. If the instrument is introduced at a higher level, it will open the cavity of the skull. It is to be carried in the direction of the external auditory canal—inwards, forwards, and a little upwards—for the distance of from 1 to 1½ cm., when the antrum will be reached. In some cases of middle-ear trouble, septic thrombosis of the lateral sinus takes place, and it becomes necessary to trephine and explore the sinus. This is done by applying the trephine at a point an inch behind the centre of the external auditory meatus, and a quarter of an inch above Reid's base-line: that is to say, a line drawn backwards from the lower margin of the orbit through the centre of the external auditory meatus. In cases of abscess of the brain from middle-ear disease, when the abscess is presumably either in the temporo-sphenoidal lobe or the cerebellum, the operation devised by Dean should be performed. The pin of an average-sized trephine is to be introduced an inch and a quarter behind and a quarter of an inch above the centre of the external auditory meatus, and a crown of bone removed. This will expose a part of the lateral sinus, and the dura mater just above it. By slightly enlarging the opening in an upward direction with gouge forceps, the temporo-sphenoidal lobe of the cerebrum can be explored. Should no pus be found here, the opening must be enlarged in a similar manner downwards and backwards. This will expose the whole of the lateral sinus and the dura mater below it and by incising the membrane in this situation, the cerebellum can be explored.

In connection with the bones of the face a common malformation is *cleft palate*. The cleft usually starts posteriorly, and in its most elementary form may consist simply of a bifid uvula; or the cleft may extend through the soft palate; or the posterior part or the whole of the hard palate may be involved, the cleft extending as far forwards as the anterior palatine canal. In the severest forms, the cleft extends through the alveolus and may pass either between the two maxillary bones, or laterally between the pre-maxillary bone and the rest of the upper jaw; that is to say, between the lateral incisor and canine teeth. In some instances, the cleft has been noticed to pass outwards between the central and lateral incisor teeth; and this has induced some anatomists to believe that the pre-maxillary bone is developed from two centres, and not from one, as was stated in the description of the bone. Thus, Albrecht believes that, instead of there being two pre-maxillary bones, each supporting two incisor teeth, there are four bones, two on either side of the median line, and each one carrying one tooth. The mesial segment, bearing a central incisor, is called an *endo-gnathion*; the lateral segment, bearing the lateral incisor, is called a *meso-gnathion*; and the rest of the maxilla is termed the *exo-gnathion*. When a cleft palate is lateral, it may affect one or both sides. If the latter, the central part is frequently displaced forwards and may be united to the septum of the nose, the deficiency in the alveolus being complicated with a cleft in the lip (hare-lip). On examining a cleft palate in which the alveolus is not implicated, the cleft will generally appear to be in the mesial line, but occasionally is unilateral and in some cases bilateral. To understand this it must be borne in mind that three processes are concerned in the formation of the palate—the two palatal processes of the superior maxilla, which grow in horizontally and unite in the middle line; and the ethmo-vomerine process, which grows

downwards from the base of the skull and fronto-nasal process to unite with the palatal process in the mesial line. In those cases where the palatal processes fail to unite with each other and with the mesial process, the cleft of the palate is median: where one palatal process unites with the mesial septum, the other failing to do so, the appearance of the cleft in the palate is unilateral. The right process is the one which usually joins, and the cleft is therefore on the left side. In some cases where the palatal processes fail to meet in the middle, the ethmo-vomerine process grows downwards into the cleft and thus gives the appearance of a bilateral cleft. Occasionally there may be a hole in the middle line of the hard palate, the anterior part of the hard and the soft palate being perfect. But this is rare, because, as a rule, the union of the various processes progresses from before backwards; and therefore the posterior part of the palate is more frequently involved than the anterior.

The bones of the face are sometimes fractured as the result of direct violence. The two most commonly broken are the nasal bone and the inferior maxilla, and of these, the latter is by far the most frequently fractured of all the bones of the face. Fracture of the *nasal* bone is for the most part transverse, and takes place about half an inch from the free margin. The broken portion may be displaced backwards or more generally to one side by the force which produced the lesion, as there are no muscles here which can cause displacement. The *malar* bone is probably never broken alone—that is to say, unconnected with a fracture of the other bones of the face. The *zygomatic arch* is occasionally fractured, and when this occurs from direct violence, as is usually the case, the fragments may be displaced inwards. Fractures of the *superior maxilla* may vary much in degree, from the chipping off of a portion of the alveolar arch, to an extensive comminution of the whole bone from severe violence, as the kick of a horse. The most common situation for a fracture of the *inferior maxillary bone* is in the neighbourhood of the canine tooth, as at this spot the jaw is weakened by the deep socket for the fang of this tooth; it is next most frequently fractured at the angle; then at the symphysis, and finally the neck of the condyle or the coronoid process may be broken. Occasionally a double fracture may occur, one in either half of the bone. The fractures are usually compound, from laceration of the mucous membrane covering the gums. The displacement is mainly the result of the same violence as produced the injury, but may be further increased by the action of the muscles passing from the neighbourhood of the symphysis to the hyoid bone.

The superior and inferior maxillary bones are both of them frequently the seat of necrosis; though the disease more often affects the lower than the upper jaw, probably on account of the greater supply of blood to the latter. It may be the result of periostitis, from tooth irritation, injury, or the action of some specific poison, as syphilis, or from salivation by mercury; it sometimes occurs in children after attacks of the exanthematous fevers, and a special form occurs from the action of the fumes of phosphorus in persons engaged in the manufacture of matches.

Tumours attack the jaw-bones not infrequently, and these may be either innocent or malignant: in the upper jaw cysts may occur in the antrum, constituting the so-called dropsy of the antrum; or, again, cysts may form in either jaw in connection with the teeth: either cysts connected with the roots of fully developed teeth, the 'dental cyst;' or cysts connected with imperfectly developed teeth, the 'dentigerous cyst.' Solid innocent tumours include the fibroma, the chondroma, and the osteoma. Of malignant tumours there are two classes, the sarcoma and the epithelioma. The sarcomata are of various kinds, the spindle-celled and round-celled of a very malignant character, and the myeloid sarcoma principally affecting the alveolar margin of the bone. Of the epitheliomata we find the squamous variety spreading to the bone from the palate or gum, and the cylindrical epithelioma originating in the antrum or nasal fossæ.

Both superior and inferior maxillary bones occasionally require removal for tumours and for some other conditions. In order to remove the upper jaw the patient should be placed in the recumbent position, in a good light, with the head and shoulders just raised. The central incisor tooth, on the affected side, is then extracted. An incision is made, commencing just below the inner canthus of the eye, along the side of the nose, round the ala, and down the middle line of the upper lip into the mouth. A second incision is made from the commencement of the first, along the lower border of the orbit as far as the prominence of the malar bone. The flap thus formed is reflected outwards, so as to expose the bone. All bleeding is now arrested, before proceeding with the operation. The periosteum attached along the lower margin of the orbit is now to be incised, and with the handle of the scalpel the periosteum covering the floor of the orbit is to be raised from the bone; for in all cases it is essential that this fibrous layer should be left intact. The mouth is now widely opened with a gag, and the mucous membrane covering the hard palate incised down to the bone in the middle line, and the soft palate separated from the hard. The surgeon now proceeds to divide the connections of the bone with the other bones of the face, having first separated the ala of the nose from its bony attachment. This is done partly with a narrow saw and partly with cutting bone forceps. They are (1) the junction with the malar bone, the line of section being carried into the spheno-maxillary fissure: (2) the nasal process of the superior maxillary bone; a small portion of

its upper extremity, connected with the nasal bone in front, the lachrymal bone behind, and the frontal bone above, being left: (3) the connection with the bone on the opposite side and with the palate bone in the roof of the mouth. The bone is now firmly grasped with lion-forceps; and by means of a rocking movement upwards and downwards, the remaining attachments of the orbital plate with the ethmoid, and of back of the bone with the palate, broken through. Occasionally, in removing the upper jaw, it will be found that the orbital plate can be saved, and this should always be done if possible. A horizontal saw-cut is to be made just below the infra-orbital foramen, and the bone cut through in this situation.

Removal of one half of the lower jaw is sometimes required. The patient should be placed in a recumbent position, in a good light, with the head and shoulders well raised. The central incisor tooth on the affected side is first extracted. An incision is then made in the middle line, through the lower lip and over the chin, to just below the symphysis of the jaw. From the termination of this the incision is carried outwards, along the lower margin of the bone to its angle. This will necessarily divide the facial artery and vein, which must be at once secured. The incision is now to be carried upwards along the posterior border of the ramus of the bone, to a point a little below the lobule of the ear. The flap thus formed is now raised by dividing the reflection of the mucous membrane from the lip on to it and the muscles attached to its external surface, including the Masseter. The jaw is then divided by sawing the bone through the socket of the extracted tooth. By dividing the bone in this situation, and not through the symphysis, the attachment of the Genio-hyo-glossus to the genial tubercle is preserved, and all danger of the tongue falling backwards and occluding the larynx is prevented. The bone being divided and pulled outwards, the knife is inserted along the inner side of the bone, and the muscles attached to this surface separated from it; in doing this, care must be taken to keep close to the bone, to avoid injuring the submaxillary gland. The anterior part of the bone being thus freed, the surgeon seizes it in his left hand, and by strongly everting it, allows space to divide the Internal pterygoid muscle and the inferior dental vessels and nerve. He now depresses it, so as to bring into view the coronoid process, from which he separates the Temporal muscle. When the tendon of this muscle has been completely divided, the bone can be still further depressed; and this should be done without any eversion, for fear of danger to the internal maxillary artery, which would be brought up into the wound by everting the bone. When the bone is sufficiently depressed, the condyle of the jaw will come into view. The capsular ligament is opened in front with the point of the knife, and the ligamentous tissues on the other side of the joint carefully divided. It is wiser now to abandon the use of the knife, and tear through the External pterygoid muscle and other structures by twisting out the bone. If the knife is used it should be kept closely in contact with the bone, for the danger of wounding the internal maxillary artery in this stage of the operation is very considerable.

The antrum of Highmore occasionally requires tapping for suppuration. This may be done through the socket of a tooth, preferably the first molar, the fangs of which are most intimately connected with the antrum, or through the facial aspect of the bone above the alveolar process. This latter method does not perhaps afford such efficient drainage, but there is less chance of food finding its way into the cavity. The operation may be performed by incising the mucous membrane above the second molar tooth, and driving a trocar or any sharp-pointed instrument into the cavity.

THE THORAX

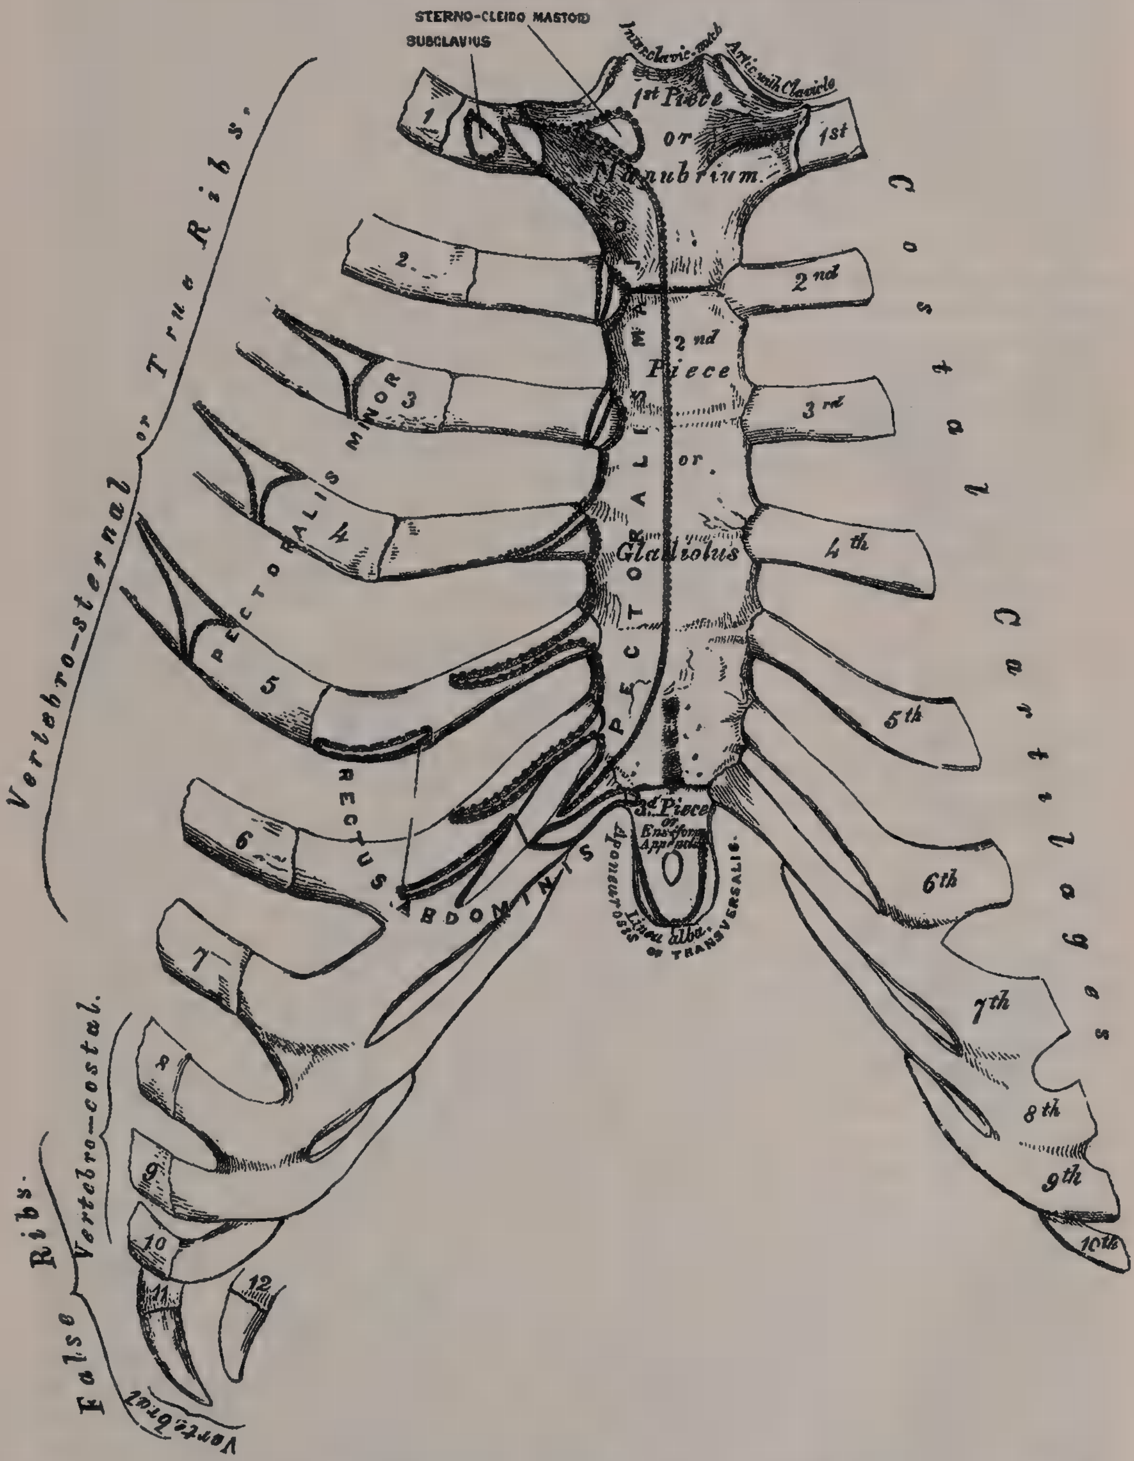
The skeleton of the **Thorax,** or **Chest,** is an osseo-cartilaginous cage, containing and protecting the principal organs of respiration and circulation. It is conical in shape, being narrow above and broad below, flattened from before backwards, and longer behind than in front. It is somewhat reniform on transverse section.

Boundaries.—The *posterior* surface is formed by the twelve dorsal or thoracic vertebræ and the posterior part of the ribs. It is concave from above downwards, and presents on each side of the middle line a deep groove, in consequence of the direction backwards and outwards which the ribs take from their vertebral extremities to their angles. The *anterior* surface is flattened or slightly convex, and inclined forwards from above downwards. It is formed by the sternum and costal cartilages. The *lateral* surfaces are convex; they are formed by the ribs, separated from each other by spaces, the *intercostal spaces.* These spaces are eleven in number, and are occupied by the intercostal muscles and membranes.

The *upper opening* of the thorax is reniform in shape, being broader from side to side than from before backwards. It is formed by the first dorsal vertebra behind, the upper margin of the sternum in front, and the first rib on each side. It slopes downwards and forwards, so that the anterior part of the ring is on a

lower level than the posterior. The antero-posterior diameter is about two inches and the transverse about four. The *lower* opening is formed by the twelfth dorsal vertebra behind, by the eleventh and twelfth ribs at the sides, and in front by the cartilages of the tenth, ninth, eighth, and seventh ribs, which ascend on either side and form an angle, the *subcostal angle*, from the apex of which the ensiform cartilage projects. It is wider transversely than from before backwards. It

FIG. 270.—Anterior surface of sternum and costal cartilages.



slopes obliquely downwards and backwards; so that the cavity of the thorax is much deeper behind than in front. The Diaphragm closes in the opening, forming the floor of the thorax.

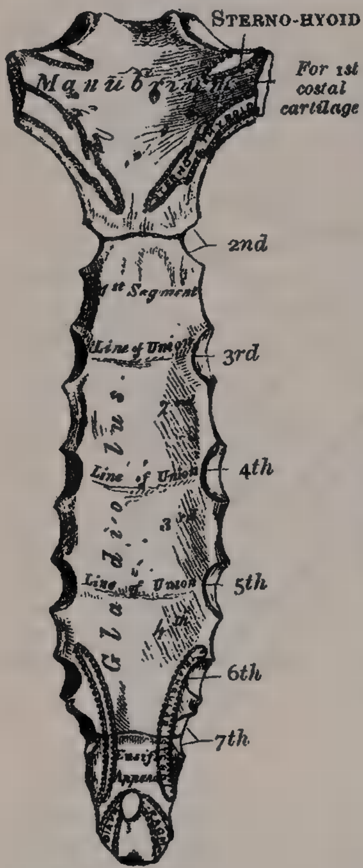
In the female, the thorax differs from that of the male as follows: 1. Its general capacity is less. 2. The sternum is shorter. 3. The upper margin of the sternum is on a level with the lower part of the body of the third dorsal vertebra,

whereas in the male it is on a level with the lower part of the body of the second dorsal vertebra. 4. The upper ribs are more movable, and so allow a greater enlargement of the upper part of the thorax than in the male.

The Sternum

The **Sternum** (στέρνον, the chest) (figs. 270, 271) is a flat, narrow bone, situated in the median line of the front of the chest, and consisting, in the adult, of three portions. It has been likened to an ancient sword: the upper piece, representing the handle, is termed the *manubrium*; the middle and largest piece, which represents the chief part of the blade, is termed the *gladiolus*; and the inferior piece, which is likened to the point of the sword, is termed the *ensiform process* or *xiphoid appendix*. In its natural position its inclination is oblique from above, downwards and forwards. It is slightly convex in front and concave behind, broad above, becoming narrowed at the point where the first and second pieces are connected; after which it again widens a little, and is pointed at its extremity. Its average length in the adult is about seven inches, being rather longer in the male than in the female.

Fig. 271.—Posterior surface of sternum.



The **Manubrium** (*presternum*) is of a somewhat triangular form, broad and thick above, narrow below at its junction with the middle piece. Its *anterior surface*, convex from side to side, concave from above downwards, is smooth, and affords attachment on each side to the Pectoralis major and sternal origin of the Sterno-cleido-mastoid muscles. In well-marked bones the ridges limiting the attachment of these muscles are very distinct. Its *posterior surface*, concave and smooth, affords attachment on each side to the Sterno-hyoid and Sterno-thyroid muscles. The *superior border*, the thickest, presents at its centre the *presternal notch*; and on each side an oval articular surface, directed upwards, backwards, and outwards, for articulation with the sternal end of the clavicle. The *inferior border* presents an oval, rough surface, covered in the recent state with a thin layer of cartilage, for articulation with the second portion of the bone. The *lateral borders* are marked above by a depression for the first costal cartilage, and below by a small facet, which, with a similar facet on the upper angle of the middle portion of the bone, forms a notch for the reception of the costal cartilage of the second rib. These articular surfaces are separated by a narrow, curved edge, which slopes from above downwards and inwards.

The **Gladiolus** (*mesosternum*), considerably longer, narrower, and thinner than the first piece, is broader below than above. Its *anterior surface* is nearly flat, directed upwards and forwards, and marked by three transverse ridges which cross the bone opposite the third, fourth, and fifth articular depressions.* At the junction of the third and fourth pieces is occasionally seen an orifice, the *sternal foramen*, of varying size and form. This surface affords attachment on each side to the sternal origin of the Pectoralis major. The *posterior surface*, slightly concave, is also marked by three transverse lines; but they are less distinct than those in front: this surface affords attachment below, on each side, to the Triangularis sterni muscle, and occasionally presents the posterior opening of the sternal foramen. The *superior border* has an oval surface

* Patterson (*The Human Sternum*, 1904), who examined 524 specimens, points out that these ridges are altogether absent in 26·7 per cent.; that in 69 per cent. a ridge exists opposite the third costal attachment; in 39 per cent., opposite the fourth; and in 4 per cent. only, opposite the fifth.

for articulation with the manubrium. The *inferior border* is narrow, and articulates with the ensiform appendix. Each *lateral border*, at its superior angle, has a small facet, which, with a similar facet on the manubrium, forms a cavity for the cartilage of the second rib; below this are four angular depressions which receive the cartilages of the third, fourth, fifth, and sixth ribs, while the inferior angle has a small facet, which, with a corresponding one on the ensiform appendix, forms a notch for the cartilage of the seventh rib. These articular depressions are separated by a series of curved interarticular intervals, which diminish in length from above downwards, and correspond to the intercostal spaces. Most of the cartilages belonging to the true ribs, as will be seen from the foregoing description, articulate with the sternum at the lines of junction of its primitive component segments. This is well seen in many of the lower animals, where the separate parts of the bone remain ununited longer than in man. In this respect a striking analogy exists between the mode of connection of the ribs with the vertebral column, and the connection of the costal cartilages with the sternum.

The **Ensiform Process** or **Xiphoid Appendix** (*metasternum*) is the smallest of the three pieces: it is thin and elongated in form, cartilaginous in structure in youth, but more or less ossified at its upper part in the adult. Its *anterior surface* affords attachment to the chondro-xiphoid ligament and a small part of the Rectus abdominis; its *posterior surface*, to some of the fibres of the Diaphragm and Triangularis sterni muscles; its *lateral borders*, to the aponeurosis of the abdominal muscles. Above, it articulates with the lower end of the gladiolus, and at each superior angle presents a facet for the lower half of the cartilage of the seventh rib; below, by its pointed extremity, it gives attachment to the linea alba. This portion of the sternum varies much in appearance, being sometimes pointed, broad and thin, sometimes bifid, or perforated by a round hole, occasionally curved, or deflected considerably to one or the other side.

Structure.—The bone is composed of delicate, highly vascular cancellous tissue, covered by a thin layer of compact bone, which is thickest in the manubrium, between the articular facets for the clavicles.

Development.—The cartilaginous sternum originally consists of two bars, situated one on either side of the mesial plane and connected with the cartilages of the nine upper ribs of its own side. These two bars fuse with each other along the middle line, and the bone, including the ensiform appendix, is developed by *six* centres: one for the first piece or manubrium, four for the second piece or gladiolus, and one for the ensiform appendix (fig. 272). Up to the middle of fœtal life the sternum is entirely cartilaginous, and when ossification takes place the ossific granules are deposited in the middle of the intervals between the articular depressions for the costal cartilages, in the following order: in the manubrium and first piece of the gladiolus, during the sixth month; in the second and third pieces of the gladiolus, during the seventh month; in its fourth piece, within the first year, or between the first and second years after birth; and in the ensiform appendix, between the fifth and eighteenth years, by a single centre which makes its appearance at the upper part, and proceeds gradually downwards. To these may be added the occasional existence, as described by Breschet, of two small episternal centres, which make their appearance one on each side of the presternal notch. They are probably vestiges of the episternal bone of the monotremata and lizards.* It occasionally happens that some of the segments are formed from more than one centre, the number and position of which vary (fig. 274). Thus, the first piece may have two, three, or even six centres. When two are present, they are generally situated one above the other, the upper one being the larger; † the second piece has seldom more than one; the third, fourth, and fifth pieces are often formed from two centres placed laterally, the irregular union of which will serve to explain the rare occurrence of the sternal foramen (fig. 275), or of the vertical fissure which occasionally intersects this part of the bone,

* Out of 141 sterna between the ages of birth and sixteen years, Patterson (*op. cit.*) found the fourth or lowest centre for the gladiolus present only in 38 cases, i.e. 26·9 per cent.

† Sir George Humphry states that this is 'probably the more complete condition.'

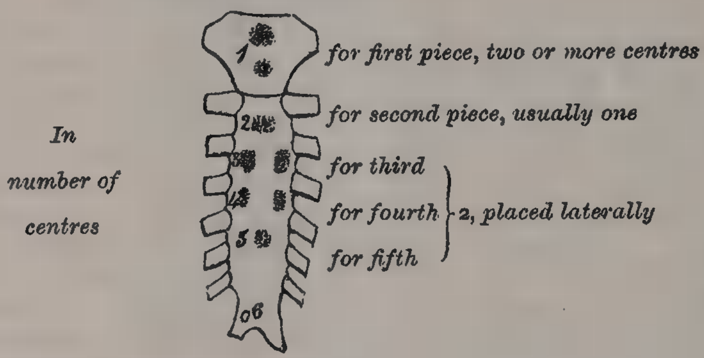

FIG. 275.

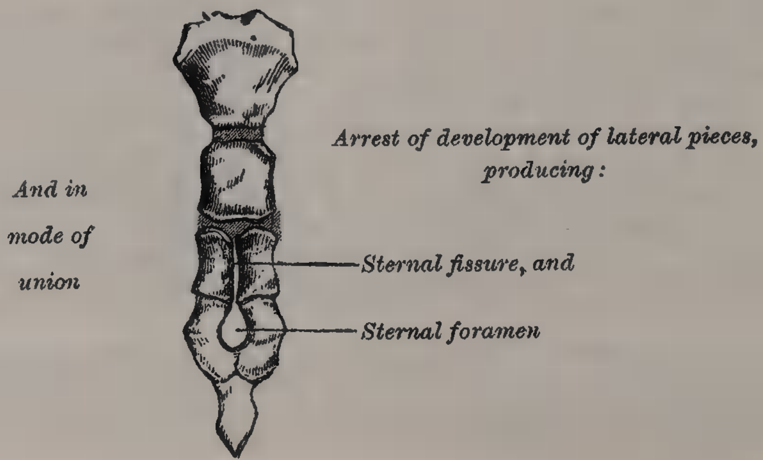
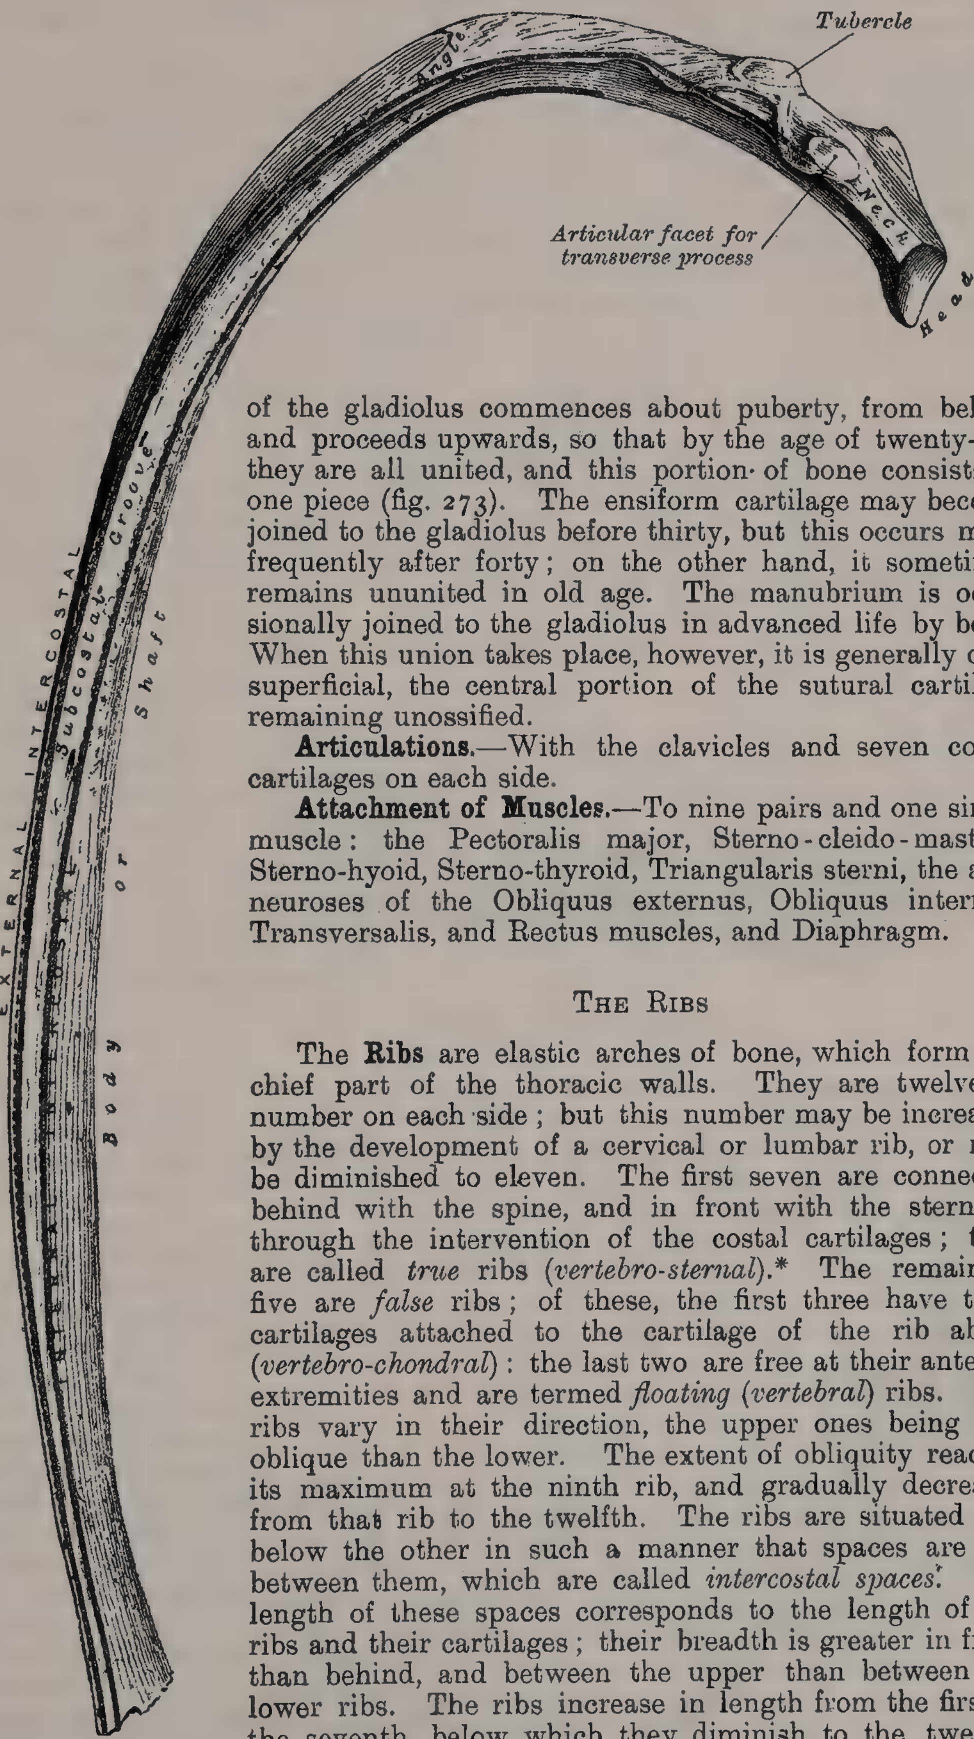


and which is further explained by the manner in which the cartilaginous matrix, in which ossification takes place, is formed. Union of the various centres

Fig. 276.—A central rib of left side.



of the gladiolus commences about puberty, from below, and proceeds upwards, so that by the age of twenty-five they are all united, and this portion of bone consists of one piece (fig. 273). The ensiform cartilage may become joined to the gladiolus before thirty, but this occurs more frequently after forty; on the other hand, it sometimes remains ununited in old age. The manubrium is occasionally joined to the gladiolus in advanced life by bone. When this union takes place, however, it is generally only superficial, the central portion of the sutural cartilage remaining unossified.

Articulations.—With the clavicles and seven costal cartilages on each side.

Attachment of Muscles.—To nine pairs and one single muscle: the Pectoralis major, Sterno-cleido-mastoid, Sterno-hyoid, Sterno-thyroid, Triangularis sterni, the aponeuroses of the Obliquus externus, Obliquus internus, Transversalis, and Rectus muscles, and Diaphragm.

The Ribs

The **Ribs** are elastic arches of bone, which form the chief part of the thoracic walls. They are twelve in number on each side; but this number may be increased by the development of a cervical or lumbar rib, or may be diminished to eleven. The first seven are connected behind with the spine, and in front with the sternum, through the intervention of the costal cartilages; they are called *true* ribs (*vertebro-sternal*).* The remaining five are *false* ribs; of these, the first three have their cartilages attached to the cartilage of the rib above (*vertebro-chondral*): the last two are free at their anterior extremities and are termed *floating* (*vertebral*) ribs. The ribs vary in their direction, the upper ones being less oblique than the lower. The extent of obliquity reaches its maximum at the ninth rib, and gradually decreases from that rib to the twelfth. The ribs are situated one below the other in such a manner that spaces are left between them, which are called *intercostal spaces*. The length of these spaces corresponds to the length of the ribs and their cartilages; their breadth is greater in front than behind, and between the upper than between the lower ribs. The ribs increase in length from the first to the seventh, below which they diminish to the twelfth.

* Sometimes the eighth rib cartilage articulates with the sternum; this condition occurs more frequently on the right than on the left side.

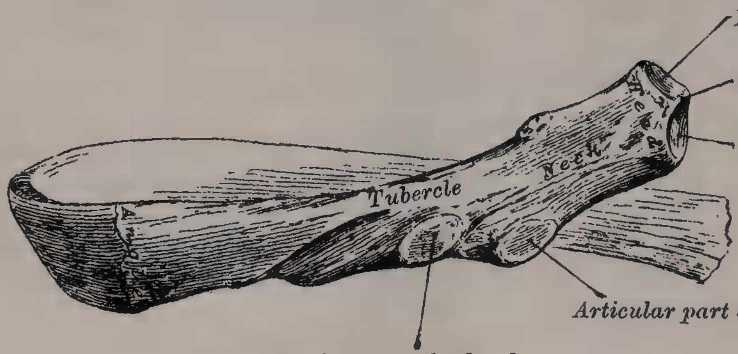
In breadth they decrease from above downwards; in the upper ten the greatest breadth is at the sternal extremity.

Common Characters of the Ribs (fig. 276).—A rib from the middle of the series should be taken in order to study the common characters of these bones.

Each rib presents two extremities, a posterior or vertebral, an anterior or sternal, and an intervening portion—the body or shaft.

The **posterior** or **vertebral extremity** presents for examination a head, neck, and tuberosity. The **head** (fig. 277) is marked by a kidney-shaped articular surface, divided by a horizontal ridge into two facets for articulation with the depression formed by the junction of the bodies of two contiguous dorsal vertebræ; the upper facet is small, the inferior one of larger size; the ridge separating them serves for the attachment of the interarticular ligament. The **neck** is the flattened portion of the rib which extends outwards from the head; it is about an inch long, and is placed in front of the transverse process of the lower of the two vertebræ with which the head articulates. Its *anterior surface* is flat and smooth, its *posterior* rough, for the attachment of the middle costo-transverse ligament, and perforated by numerous foramina, the direction of which is less constant than those found on the inner surface of the shaft. Of its two borders the *superior* presents a rough crest for the attachment of the anterior costo-transverse ligament; its *inferior border* is rounded. On the posterior surface of the neck, just where it joins the shaft, and nearer the lower than the upper border, is an eminence—the **tubercle**; it consists of an articular and a non-articular portion. The *articular portion*, the more internal and inferior of

Fig. 277.—Vertebral extremity of a rib. External surface.



the two, presents a small, oval surface for articulation with the extremity of the transverse process of the lower of the two vertebræ to which the head is connected. The *non-articular portion* is a rough elevation, which affords attachment to the posterior costo-transverse ligament. The tubercle is much more prominent in the upper than in the lower ribs.

The **shaft** is thin and flat, so as to present two surfaces, an external and an internal; and two borders, a superior and an inferior. The *external surface* is convex, smooth, and marked, at its back part, a little in front of the tuberosity, by a prominent line, directed obliquely from above downwards and outwards; this gives attachment to a tendon of the Ilio-costalis muscle, or of one of its accessory portions, and is called the *angle*. At this point the rib is bent in two directions. If the rib is laid upon its lower border, it will be seen that the portion of the shaft in front of the angle rests upon this border, while the portion of the shaft behind the angle is bent inwards and at the same time tilted upwards. The interval between the angle and the tuberosity increases gradually from the second to the tenth rib. The portion of bone between these two parts is rounded, rough, and irregular, and serves for the attachment of the Longissimus dorsi muscle. The portion of bone between the tubercle and sternal extremity is also slightly twisted upon its own axis, the external surface looking downwards behind the angle and a little upwards in front of it. This surface presents, towards its sternal extremity, an oblique line, the *anterior angle*. The *internal surface* is concave, smooth, directed a little upwards behind the angle, a little downwards in front of it, and is marked by a ridge which commences at the lower extremity of the head; this ridge is strongly marked as far as the inner side of the angle, and gradually

becomes lost at the junction of the anterior with the middle third of the bone. The interval between it and the inferior border presents a groove, *subcostal*, for the intercostal vessels and nerve. At the back part of the bone, this groove belongs to the inferior border, but just in front of the angle, where it is deepest and broadest, it corresponds to the internal surface. The superior edge of the groove is rounded; it serves for the attachment of the Internal intercostal muscle. The inferior edge corresponds to the lower margin of the rib, and gives attachment to the External intercostal muscle. Within the groove are seen the orifices of numerous small foramina, which traverse the wall of the shaft obliquely from before backwards. The *superior border*, thick and rounded, is marked by an external and an internal lip, more distinct behind than in front, which serve for the attachment of the External and Internal intercostal muscles. The *inferior border*, thin and sharp, has attached to it the External intercostal muscle. The **anterior** or **sternal extremity** is flattened, and presents a porous, oval, concave depression, into which the costal cartilage is received.

Peculiar Ribs

The ribs which require especial consideration are five in number—viz. the first, second, tenth, eleventh, and twelfth.

The **first rib** (fig. 278) is one of the shortest and the most curved of all the ribs; it is broad and flat, its surfaces looking upwards and downwards, and its borders inwards and outwards. The *head* is of small size, rounded, and presents only a single articular facet for articulation with the body of the first dorsal vertebra. The *neck* is narrow and rounded. The *tuberosity*, thick and prominent, rests on the outer border. There is no angle, but in this situation the rib is slightly bent, with the convexity of the bend upwards, so that the head of the bone is directed downwards. The *upper surface* of the shaft is marked by two shallow depressions, separated from each other at the inner border of the rib by a small rough surface, the *scalene tubercle*, for the attachment of the Scalenus anticus muscle—the groove in front of it transmitting the subclavian vein, that behind it the subclavian artery. Between the groove for the subclavian artery and the tuberosity is a second rough surface for the attachment of the Scalenus medius muscle. The *under surface* is smooth, and destitute of a subcostal groove. The *outer border* is convex, thick, and rounded, and at its posterior part gives attachment to the first serration of the Serratus magnus; the *inner* is concave, thin, and sharp, and marked about its centre by the scalene tubercle. The *anterior extremity* is larger and thicker than any of the other ribs.

The **second rib** (fig. 279) is much longer than the first, but bears a very considerable resemblance to it in the direction of its curvature. The non-articular portion of the tuberosity is occasionally only feebly marked. The *angle* is slight, and situated close to the tuberosity, and the shaft is not twisted, so that both ends touch any plane surface upon which it may be laid; but there is a similar though smaller bend, with its convexity upwards, to that found in the first rib. The shaft is not horizontal, like that of the first rib; its *outer surface*, which is convex, looking upwards and a little outwards. It presents, near the middle, a rough eminence for the attachment of the lower part of the first and the whole of the second digitation of the Serratus magnus; behind and above which is attached the Scalenus posticus. The *inner surface*, smooth and concave, is directed downwards and a little inwards: it presents a short subcostal groove towards its posterior part.

The **tenth rib** (fig. 280) has only a single articular facet on its head.

The **eleventh** and **twelfth ribs** (figs. 281 and 282) have each a single articular facet on the head, which is of rather large size; they have no neck or tuberosity, and are pointed at the extremity. The eleventh has a slight angle and a shallow subcostal groove. The twelfth has neither, and is much shorter than the eleventh, and the head has a little inclination downwards. Sometimes the twelfth rib is even shorter than the first.

Structure.—The ribs consist of highly vascular cancellous tissue, enclosed in a thin, compact layer.

Development.—Each rib, with the exception of the last two, is developed by *three* centres: one each for the shaft, the head, and the tubercle. The last

two ribs have only *two* centres, that for the tubercle being wanting. Ossification commences in the shaft at a very early period, before its appearance in the vertebræ. The epiphysis of the head, which is of a slightly angular shape, and that for the tubercle, of a lenticular form, make their appearance between the sixteenth and twentieth years, and are not united to the rest of the bone until about the twenty-fifth year.

Peculiar ribs.

Attachment of Muscles.—To nineteen : the Internal and External intercostals, Scalenus anticus, Scalenus medius, Scalenus posticus, Pectoralis minor, Serratus magnus, Obliquus externus, Quadratus lumborum, Diaphragm, Latissimus dorsi, Serratus posticus superior, Serratus posticus inferior, Ilio-costalis, Musculus accessorius ad ilio-costalem, Longissimus dorsi, Cervicalis ascendens, Levatores costarum, and Infracostales.

The Costal Cartilages

The **Costal Cartilages** (fig. 270, page 253) are bars of white, hyaline cartilage, which serve to prolong the ribs forward to the front of the chest, and contribute very materially to the elasticity of its walls. The first seven are connected with the sternum, the next three with the lower border of the cartilage of the preceding rib. The cartilages of the last two ribs have pointed extremities, which terminate in free ends in the walls of the abdomen. Like the ribs, the costal cartilages vary in their length, breadth, and direction. They increase in length from the first to the seventh, then gradually diminish to the last. Their breadth, as well as that of the intervals between them, diminishes from the first to the last. They are broad at their attachment to the ribs, and taper towards their sternal extremities, excepting the first two, which are of the same breadth throughout, and the sixth, seventh, and eighth, which are enlarged where their margins are in contact. In direction they also vary: the first descends a little, the second is horizontal, the third ascends slightly, while all the rest follow the course of the ribs for a short extent, and then ascend to the sternum or preceding cartilage. Each costal cartilage presents two surfaces, two borders, and two extremities. The *anterior surface* is convex, and looks forwards and upwards: that of the first gives attachment to the costo-clavicular ligament and the Subclavius muscle; that of the second, third, fourth, fifth, and sixth, at their sternal ends, to the Pectoralis major.* The others are covered by, and give partial attachment to, some of the great flat muscles of the abdomen. The *posterior surface* is concave, and directed backwards and downwards, the first giving attachment to the Sterno-thyroid, the third to the sixth inclusive to the Triangularis sterni, and the six or seven inferior ones to the Transversalis muscle and the Diaphragm. Of the two borders, the *superior* is concave, the *inferior* convex: they afford attachment to the Internal intercostal muscles, the upper border of the sixth giving attachment to the Pectoralis major muscle. The contiguous borders of the sixth, seventh, and eighth, and sometimes the ninth and tenth, costal cartilages present small, smooth, oblong-shaped facets at the points where they articulate. Of the two extremities, the *outer* one is continuous with the osseous tissue of the rib to which it belongs. The *inner* extremity of the first is continuous with the sternum; the six succeeding ones have rounded extremities, which are received into shallow concavities on the lateral margins of the sternum. The inner extremities of the eighth, ninth, and tenth costal cartilages are pointed, and are connected with the cartilage above. Those of the eleventh and twelfth are free and pointed.

The costal cartilages are most elastic in youth, those of the false ribs being more so than those of the true. In old age they become of a deep yellow colour, and are prone to calcify.

Attachment of Muscles.—To nine: the Subclavius, Sterno-thyroid, Pectoralis major, Internal oblique, Transversalis, Rectus, Diaphragm, Triangularis sterni, and Internal intercostals.

Surface Form.—The bones of the chest are to a very considerable extent covered by muscles, so that in the strongly developed muscular subject they are for the most part concealed. In the emaciated subject, on the other hand, the ribs, especially in the lower and lateral regions, stand out as prominent ridges with the sunken, intercostal spaces between them.

In the middle line, in front, the superficial surface of the sternum is to be felt throughout its entire length, at the bottom of a deep median furrow situated between the two great Pectoral muscles and called the *sternal furrow*. These muscles overlap the anterior surface somewhat, so that the whole of the sternum in its entire width is not subcutaneous, and this overlapping is greater opposite the centre of the bone than above and below, so that the furrow is wide at its upper and lower part, but narrower in the middle. The centre of the upper border of the sternum is visible, constituting the *presternal notch*, and is in the same horizontal plane as the lower border of the body of the second dorsal vertebra; the lateral parts of this border are obscured by the tendinous origins of the Sterno-mastoid muscles, which present themselves as oblique tendinous cords, which narrow and deepen the notch. Lower down on the subcutaneous surface a well-defined transverse ridge, the *angle of Ludovic*, is always to be felt. This denotes the line of junction of the manubrium and body of the bone; it lies in the same horizontal plane as

* The first and seventh occasionally give origin to the same muscle.

the body of the fifth dorsal vertebra, and is a useful guide to the second costal cartilage, and thus to the identity of any given rib. The second rib being found, through its costal cartilage, it is easy to count downwards and find any other. From the middle of the sternum the furrow spreads out, and, exposing more of the surface of the bone, terminates at the junction of the body of the bone with the ensiform cartilage, on the same level as the intervertebral cartilage between the ninth and tenth dorsal vertebræ. Immediately below this is the *infrasternal notch*; between the points of junction of the seventh costal cartilages to the sternum, and below the notch, is a triangular depression, the *epigastric fossa*, or pit of the stomach (scrobiculus cordis), bounded laterally by the cartilages of the seventh ribs; in it the ensiform cartilage can be felt. The sternum in its vertical diameter presents a general convexity forwards, the most prominent point of which is at the joint between the manubrium and gladiolus.

On each side of the sternum the costal cartilages and ribs on the front of the chest are partially obscured by the great Pectoral muscle; through which, however, they are to be felt as ridges, with yielding intervals between them, corresponding to the intercostal spaces. Of these spaces, the one between the second and third ribs is the widest, the next two somewhat narrower, and the remainder, with the exception of the last two, comparatively narrow.

The lower border of the Pectoralis major muscle corresponds to the fifth rib, and below this, on the front of the chest, the broad, flat outline of the ribs, as they begin to ascend, and the more rounded outline of the costal cartilages, are often visible. The lower boundary of the front of the thorax, the *abdomino-thoracic arch*, which is most plainly seen by bending the body backwards, is formed by the ensiform cartilage and the cartilages of the seventh, eighth, ninth, and tenth ribs, and the extremities of the eleventh and twelfth ribs or their cartilages.

On each side of the chest, from the axilla downwards, the flattened external surfaces of the ribs may be defined in the form of oblique ridges, separated by depressions corresponding to the intercostal spaces. They are, however, covered by muscles, which, when strongly developed, obscure their outline to a certain extent. Nevertheless, the ribs, with the exception of the first, can generally be followed over the front and sides of the chest without difficulty. The first rib, being almost completely covered by the clavicle and scapula, can only be distinguished in a small portion of its extent. At the back, the angles of the ribs form a slightly marked oblique line, on each side of and some distance from the vertebral spines. This line diverges somewhat as it descends, and external to it is a broad, convex surface, caused by the projection of the ribs beyond their angles. Over this surface, except where covered by the scapula, the individual ribs can be distinguished.

For clinical purposes and convenience of description, the surface of the chest has been mapped out by arbitrary lines into certain definite areas. Of these lines, some are vertical and others transverse. On the front of the chest the most important vertical lines are the *mid-sternal*, which run down the median line of the sternum and the *mammary*, which runs vertically downwards from a point midway between the centre of the presternal notch and the tip of the acromion process. This line, if prolonged, will cross Poupart's ligament at a point midway between the anterior superior spine of the ilium and the symphysis pubis. The transverse lines are also two in number, and are drawn across the front of the chest at the levels of the junction of the third and sixth costal cartilages to the sternum. These lines divide the front of the thorax on either side into the following regions. Above the upper transverse line, the space to the inner side of the mid-clavicular line is the *upper sternal* region, and to the outer side the *infraclavicular* region. The space between the two transverse lines to the inner side of the mid-clavicular line is the *lower sternal* region; and that to the outer side of the same line, the *mammary* region. The space below the lower transverse line is the *inframammary* region. The lower transverse line, if continued on to the lateral area of the thorax, divides this surface into an *axillary* region above the line and an *infra-axillary* region below the line. This lateral area is bounded in front and behind by two vertical lines—that in front, the *anterior axillary line*, being drawn from the anterior fold of the axilla; and that behind, the *posterior axillary line*, from the posterior fold of the axilla. By some, this lateral area of the thorax is further divided by a *mid-axillary* line, drawn downwards from the apex of the axilla. On the posterior aspect of the thorax the *scapular line* is drawn vertically through the inferior aspect of the scapula.

Surgical Anatomy.—Malformations of the sternum present nothing of surgical importance beyond the fact that abscesses of the mediastinum may sometimes escape through the sternal foramen. Fracture of the sternum is by no means common, owing, no doubt, to the elasticity of the ribs and their cartilages which support it like so many springs. When broken, it is frequently associated with fracture of the spine, and may be caused by forcibly bending the body either backwards; or forwards until the chin becomes impacted against the top of the sternum. It may also be fractured by direct violence or by muscular action. The fracture usually occurs in the upper half of the body of the bone. Dislocation of the gladiolus from the manubrium also takes place, and is sometimes described as a fracture.

The bone being subcutaneous is frequently the seat of gummatous tumours and not

uncommonly is affected with caries. Occasionally the bone, and especially its ensiform appendix, becomes altered in shape and driven inwards by the pressure, in workmen, of tools against their chest.

The ribs are frequently broken, though from their connections and shape they are able to withstand great force, yielding under the injury and recovering themselves like a spring. The middle ones of the series are the most liable to fracture. The first and to a less extent the second, being protected by the clavicle, are rarely fractured; and the eleventh and twelfth on account of their loose and floating condition enjoy a like immunity. The fracture generally occurs from indirect violence, from forcible compression of the chest wall, and the bone then gives way at its weakest part, i.e. just in front of the angle. But the ribs may also be broken by direct violence, when the bone gives way and is driven inwards at the point struck, or they may be broken by muscular action. It seems probable, however, that in these latter cases the bone has undergone some atrophic changes. Fracture of the ribs is frequently complicated with some injury to the viscera contained within the thorax or upper part of the abdominal cavity, and this is most likely to occur in fractures from direct violence.

Fracture of the costal cartilages may also take place, though it is a comparatively rare injury.

The thorax is frequently found to be altered in shape in certain diseases.

In *rickets*, the ends of the ribs, where they join the costal cartilages, become enlarged, giving rise to the so-called 'rickety rosary.' Outside these enlargements the softened ribs sink in, so as to present a groove passing downwards and outwards on each side of the sternum. This bone is forced forwards by the bending of the ribs, and the antero-posterior diameter of the chest is increased. The ribs from the second to the eighth are the ones affected, the lower ones being prevented from falling in by the presence of the liver, stomach, and spleen; and when the liver and spleen are enlarged, as they sometimes are in rickets, the lower ribs may be pushed outwards, causing a transverse groove (Harrison's sulcus) just above the costal arch. This deformity is known under the name of 'pigeon-breast,' and is primarily due to some chronic obstruction to the entry of air into the thorax, though it is more prone to occur in the softened bones of rickety children than in the healthy, where the resistance of the thoracic walls is greater. The *phthisical chest* is often long and narrow, flattened from before backwards, and with great obliquity of the ribs and projection of the scapulæ. In *pulmonary emphysema* the chest is enlarged in all its diameters, and presents on section an almost circular outline. It has received the name of the 'barrel-shaped chest.' In severe cases of *lateral curvature of the spine*, the thorax becomes much distorted. In consequence of the rotation of the bodies of the vertebræ, which takes place in this disease, the ribs opposite the convexity of the dorsal curve become extremely convex behind, being thrown out and bulging, and at the same time flattened in front, so that the two ends of the same rib are almost parallel. Coincident with this the ribs on the opposite side, on the concavity of the curve, are sunk and depressed behind, and bulging and convex in front. In addition to this the ribs often become welded together by bony material.

The chest walls are sometimes unduly rigid, owing to excessive deposit of calcareous matter in the bones and costal cartilages. This is usually found in old age, but occasionally in the young, and interferes more or less with the respiratory movements. Not infrequently the ribs are the seat of a tuberculous periostitis, leading to necrosis. The disease is usually situated on the internal surface of the rib; and hence the best treatment is to excise the portion of the rib which is the seat of the disease, when a carious cavity containing a sequestrum will be found on its internal surface.

In cases of empyema the chest requires opening to evacuate the pus. There is considerable difference of opinion as to the best position for doing this. Probably the best place in most cases will be found to be between the fifth and sixth ribs, in or a little in front of the mid-axillary bone. This is the last part of the cavity to be closed by the expansion of the lung; it is not thickly covered by soft parts; the space between the two ribs is sufficiently great to allow of the introduction of a fair-sized drainage tube, and the opening is in a dependent position, when the patient is confined to bed, as he usually inclines towards the affected side, so as to allow the sound lung the freest possible play, and this position permits of efficient drainage.

THE EXTREMITIES

The extremities, or limbs, are those long, jointed appendages of the body which are connected to the trunk by one end, and free in the rest of their extent. They are *four* in number: an *upper* or *thoracic pair*, connected with the thorax through the intervention of the shoulder, and subservient mainly to prehension; and a *lower pair*, connected with the pelvis, intended for support and locomotion. Both pairs of limbs are constructed after one common type, so that they present numerous analogies; while, at the same time, certain differences are observed

between the upper and lower pair, dependent on the peculiar offices they have to perform.

The bones by which the upper and lower limbs are attached to the trunk are named respectively the *shoulder* and *pelvic girdles*, and they are constructed on the same general type, though presenting certain modifications relating to the different uses to which the upper and lower limbs are respectively applied. The *shoulder girdle* is formed by the scapulæ and clavicles, and is imperfect in front and behind. In front, however, the girdle is completed by the upper end of the sternum, with which the inner extremities of the clavicles articulate. Behind, the girdle is widely imperfect, and the scapulæ are connected to the trunk by muscles only. The *pelvic girdle* is formed by the innominate bones, and is completed in front, through the symphysis pubis, at which the two innominate bones articulate with each other. It is imperfect behind, but the intervening gap is filled in by the upper part of the sacrum. The pelvic girdle therefore presents, with the sacrum, a complete ring, comparatively fixed, and presenting an arched form which confers upon it a solidity manifestly intended for the support of the trunk, and in marked contrast to the lightness and mobility of the shoulder girdle.

With regard to the morphology of these girdles, it will be noticed that they each consist of a dorsal and a ventral section: the dorsal section of the upper extremity is the scapula; of the lower, the ilium, and these two parts coincide. The ventral section, in the lower extremity, divides into two branches: one, anterior, is the os pubis; the other, posterior, is the ischium; in the upper extremity the arrangement is not quite so clear, the posterior branch of the ventral section is generally believed to be the coracoid process and corresponds to the ischium, and the anterior division by some is regarded as concurring with the precoracoid of reptiles and amphibia: which would thus be the homologue of the os pubis. The clavicle is looked upon as of secondary or dermic origin, and as having no representative in the lower limb. Others believe that the clavicle is analogous to the ventral anterior segment of the shoulder girdle, and therefore is the representative of the os pubis.

THE UPPER EXTREMITY

The bones of the upper extremity consist of those of the shoulder girdle, of the arm, the forearm, and the hand.

THE SHOULDER GIRDLE

The Shoulder Girdle consists of two bones, the clavicle and the scapula.

The Clavicle (figs. 283, 284)

The **Clavicle** (clavis, *a key*), or collar-bone, forms the anterior portion of the shoulder girdle. It is a long bone, curved somewhat like the italic letter *f*, and placed nearly horizontally at the upper and anterior part of the thorax, immediately above the first rib. It articulates by its inner extremity with the upper border of the sternum, and by its outer extremity with the acromion process of the scapula; serving to sustain the upper extremity in the various positions which it assumes, while, at the same time, it allows of great latitude of motion in the arm.* It presents a double curvature, when looked at in front; the convexity being forwards at the sternal end, and the concavity at the scapular end. Its outer third is flattened from above downwards, and extends, in the natural position of the bone, from a point opposite the coracoid process to the acromion. Its inner two-thirds are of a prismatic form, and extend from the sternum to a point opposite the coracoid process of the scapula.

* The clavicle acts especially as a fulcrum to enable the muscles to give lateral motion to the arm. It is accordingly absent in those animals whose fore limbs are used only for progression, but is present for the most part in those animals whose anterior extremities are clawed and used for prehension, though in some of them—as, for instance, in a large number of the carnivora—it is merely a rudimentary bone suspended among the muscles, and not articulating either with the scapula or sternum.

External or **Flattened Portion.**—The *outer third* is flattened from above downwards, so as to present two surfaces, an upper and a lower; and two borders, an anterior and a posterior. The *upper surface* is flattened, rough, marked by impressions for the attachment of the Deltoid in front, and the Trapezius behind; between these two impressions, externally, a small portion of the bone is subcutaneous. The *under surface* is flattened. At its posterior border, a little external to the point where the prismatic joins with the flattened portion, is a rough eminence, the *conoid tubercle*; this, in the natural position of the bone, surmounts the coracoid process of the scapula, and gives attachment to the conoid ligament. From this tubercle, an oblique line, rarely a depression, passes forwards and outwards to near the outer end of the anterior border; it is called the *oblique line*, or *trapezoid ridge*, and affords attachment to the trapezoid ligament. The *anterior border* is concave, thin, and rough, and gives attachment to the Deltoid; it occasionally presents, at its inner end, at the commencement of the deltoid impression, a tubercle, the *deltoid tubercle*, which is sometimes to be felt in the living subject. The *posterior border* is convex, rough, broader than the anterior, and gives attachment to the Trapezius.

Fig. 283.—Left clavicle. Superior surface.

Sternal extremity *Acromial extremity*

Fig. 284.—Left clavicle. Inferior surface.

Articulation with sternum

Internal or **Prismatic Portion.**—The prismatic portion forms the *inner two-thirds* of the bone. It is curved so as to be convex in front, concave behind, and is marked by three borders, separating three surfaces. The *anterior border* is continuous with the anterior margin of the flat portion. Its outer portion is smooth, and corresponds to the interval between the attachment of the Pectoralis major and Deltoid muscles; at the inner half of the clavicle it forms the lower boundary of an elliptical space for the attachment of the clavicular portion of the Pectoralis major, and approaches the posterior border of the bone. The *superior border* is continuous with the posterior margin of the flat portion, and separates the anterior from the posterior surface. Smooth and rounded externally, it becomes rough towards the inner third for the attachment of the Sterno-mastoid muscle, and terminates at the upper angle of the sternal extremity. The *posterior* or *subclavian border* separates the posterior from the inferior surface, and extends from the conoid tubercle to the rhomboid impression. It forms the posterior boundary of the groove for the Subclavius muscle, and gives attachment to a layer of cervical fascia, enveloping the Omo-hyoid muscle. The *anterior surface* is included between the superior and anterior borders. Its inner part is directed forwards and upwards; its outer part looks still more upwards, and becomes continuous with the superior

surface of the flat portion. Externally, it is smooth, convex, nearly subcutaneous, being covered only by the Platysma; but, corresponding to the inner half of the bone, it is divided by a more or less prominent line into two parts: a lower portion, elliptical in form, rough, and slightly convex, for the attachment of the Pectoralis major; and an upper part, which is rough, for the attachment of the Sterno-cleido-mastoid. Between the two muscular impressions is a small, subcutaneous interval. The *posterior* or *cervical surface* is smooth, flat, and looks backwards towards the root of the neck. It is limited, above, by the superior border; below, by the subclavian border; internally, by the margin of the sternal extremity; externally, it is continuous with the posterior border of the flat portion. It is concave from within outwards, and is in relation, by its lower part, with the suprascapular vessels. This surface, at the junction of the inner and outer curves, is also in close relation with the brachial plexus and subclavian vessels. It gives attachment, near the sternal extremity, to part of the Sterno-hyoid muscle; and presents, at or near the middle, a foramen, directed obliquely outwards, which transmits the chief nutrient artery of the bone. Sometimes there are two foramina on the posterior surface, or one on the posterior, and another on the inferior surface. The *inferior* or *subclavian surface* is bounded, in front, by the anterior border; behind, by the subclavian border. It is narrow internally, but gradually increases in width externally, and is continuous with the under surface of the flat portion. Commencing at the sternal extremity may be seen a small facet for articulation with the cartilage of the first rib. This is continuous with the articular surface at the sternal end of the bone. External to this is a broad, rough surface, the *rhomboid impression*, rather more than an inch in length, for the attachment of the costo-clavicular (rhomboid) ligament. The remaining part of this surface is occupied by a longitudinal groove, broad and smooth externally, narrow and more uneven internally; it gives attachment to the Subclavius muscle, and, by its margins, to the costo-coracoid membrane, which splits to enclose the muscle. Not infrequently this groove is subdivided into two parts by a longitudinal line, which gives attachment to the intermuscular septum of the Subclavius muscle.

The **inner** or **sternal extremity** of the clavicle is triangular in form, directed inwards, and a little downwards and forwards; and presents an articular facet, concave from before backwards, convex from above downwards, which articulates with the sternum through the intervention of an interarticular fibro-cartilage; the circumference of the articular surface is rough, for the attachment of numerous ligaments. The posterior border of this surface is prolonged backwards so as to increase the size of the articular facet; the upper border gives attachment to the interarticular fibro-cartilage, and the lower border is continuous with the costal facet on the inner end of the inferior or subclavian surface, which articulates with the cartilage of the first rib.

The **outer** or **acromial extremity**, directed outwards and forwards, presents a small, flattened, oval facet, which looks obliquely downwards, for articulation with the acromion process of the scapula. The circumference of the articular facet is rough, especially above, for the attachment of the acromio-clavicular ligaments.

Peculiarities of the Bone in the Sexes and in Individuals.—In the female, the clavicle is generally shorter, thinner, less curved, and smoother than in the male. In those persons who perform considerable manual labour, which brings into constant action the muscles connected with this bone, it becomes thicker and more curved, and its ridges for muscular attachment become prominently marked. The right clavicle is generally longer, thicker, and rougher than the left.

Structure.—The shaft, as well as the extremities, consists of cancellous tissue, invested in a compact layer much thicker in the middle than at either end. The clavicle is highly elastic, by reason of its curves. From the experiments of Ward, it has been shown that it possesses sufficient longitudinal elastic force to project its own weight nearly two feet on a level surface, when a smart blow is struck on it; and sufficient transverse elastic force, opposite the centre of its anterior convexity, to throw its own weight about a foot. This extent of elastic power must serve to moderate very considerably the effect of concussions received upon the point of the shoulder.

Development.—By *two* centres: one for the shaft, and one for the sternal extremity. The centre for the shaft appears very early, before any other bone;

according to Béclard, as early as the thirtieth day. The centre for the sternal end makes its appearance about the eighteenth or twentieth year, and unites with the rest of the bone about the twenty-fifth year.

Articulations.—With the sternum, scapula, and cartilage of the first rib.

Attachment of Muscles. — To six: the Sterno-cleido-mastoid, Trapezius, Pectoralis major, Deltoid, Subclavius, and Sterno-hyoid.

Surface Form.—The clavicle can be felt throughout its entire length, even in persons who are very fat. Commencing at the inner end, the enlarged sternal extremity, where the bone projects above the upper margin of the sternum, can be felt, forming with the sternum and the rounded tendon of the Sterno-mastoid a V-shaped notch, the *presternal notch.* Passing outwards, the shaft of the bone can be defined immediately under the skin, with its convexity forwards in the inner two-thirds, the surface partially obscured above and below by the attachments of the Sterno-mastoid and Pectoralis major muscles. In the outer third it forms a gentle curve backwards, and terminates at the outer end in a somewhat enlarged extremity which articulates with the acromial process of the scapula. The direction of the clavicle is almost, if not quite, horizontal when the arm is lying quietly by the side, though in well-developed subjects it may incline a little upwards at its outer end. Its direction is, however, very changeable with the varying movements of the shoulder-joint. The clavicle inclines backwards, so that its outer or acromial extremity is on a plane posterior to its sternal end. This causes the shoulder to be thrown backwards away from the thorax; and if a solution of continuity of the bone takes place, the point of the shoulder is carried forwards and inwards, having lost the buttress-like action of the bone.

Surgical Anatomy.—The clavicle is more frequently broken than any other bone in the body. This is due to the fact that it is much exposed to violence, and is the only bony connection between the upper limb and the trunk, acting as a buttress, which keeps the point of the shoulder away from the thorax. The bone, moreover, is slender, and is very superficial. It may be broken by direct or indirect violence, or by muscular action. The most common cause is, however, from indirect violence, as the result of force applied to the hand or shoulder, and the bone then gives way at the junction of its outer with its inner two-thirds: that is to say, at the junction of the two curves, for this is its weakest part. The fracture is generally oblique, and the displacement of the outer fragment is downwards, forwards, and inwards. The deformity is mainly due to the weight of the arm acting upon the fragment, when the buttress-like action of the bone is gone, assisted by the muscles which pass from the thorax to the upper extremity. The inner fragment, as a rule, is little displaced. Beneath the bone the main vessels of the upper limb and the great nerve-cords of the brachial plexus lie on the first rib and are liable to be wounded in fracture; especially in fracture from direct violence, when the force of the blow drives the broken ends inwards. Fortunately the Subclavius muscle is interposed between the structures and the clavicle, and this often protects them from injury.

The clavicle is not uncommonly the seat of sarcomatous tumours, rendering the operation of excision of the entire bone necessary. This is an operation of considerable difficulty and danger. It is best performed by exposing the bone freely, disarticulating at the acromial end, and turning it inwards. The removal of the outer part is comparatively easy, but resection of the inner part is fraught with difficulty, the main danger being the risk of wounding the great veins which are in relation with its under surface.

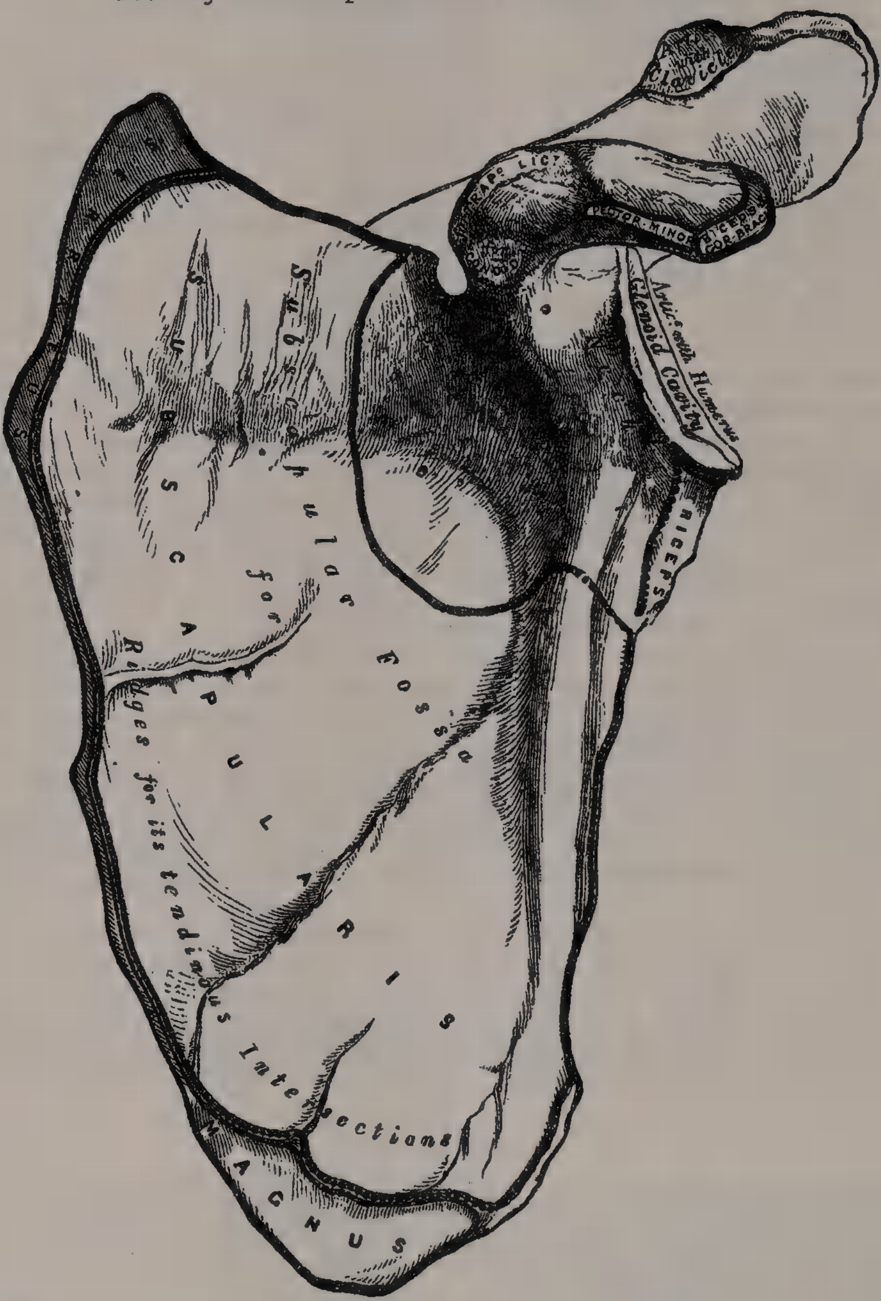
The Scapula

The **Scapula** (*σκαπάνη, a spade*) forms the back part of the shoulder girdle. It is a large, flat bone, triangular in shape, situated at the posterior aspect and side of the thorax, between the second and seventh or sometimes the eighth ribs, its internal border or base being about an inch from, and nearly but not quite parallel with, the spinous processes of the vertebræ, so that it is rather closer to them above than below. It presents for examination two surfaces, three borders, and three angles.

The **anterior surface,** or **venter** (fig. 285), presents a broad concavity, the *subscapular fossa.* It is marked, in the inner two-thirds, by several oblique ridges, which pass from behind outwards and upwards; the outer third is smooth. The oblique ridges give attachment to the tendinous intersections, and the surfaces between them to the fleshy fibres, of the Subscapularis muscle. The outer third of the fossa, which is smooth, is covered by, but does not afford attachment to, the fibres of this muscle. The venter is separated from the internal border by smooth, triangular areas at the superior and inferior angles, and in the interval between these by a narrow ridge which is often deficient. These triangular areas

and the intervening ridge afford attachment to the Serratus magnus muscle. The subscapular fossa presents a transverse depression at its upper part, where the bone appears to be bent on itself, forming a considerable angle, called the *subscapular angle*, thus giving greater strength to the body of the bone from its arched form; while the summit of the arch serves to support the spine and acromion process. It is in this situation that the fossa is deepest; so that the

FIG. 285.—Left scapula. Anterior surface, or venter.



thickest part of the Subscapularis muscle lies in a line perpendicular to the plane of the glenoid cavity, and must consequently operate most effectively on the head of the humerus, which is contained in that cavity.

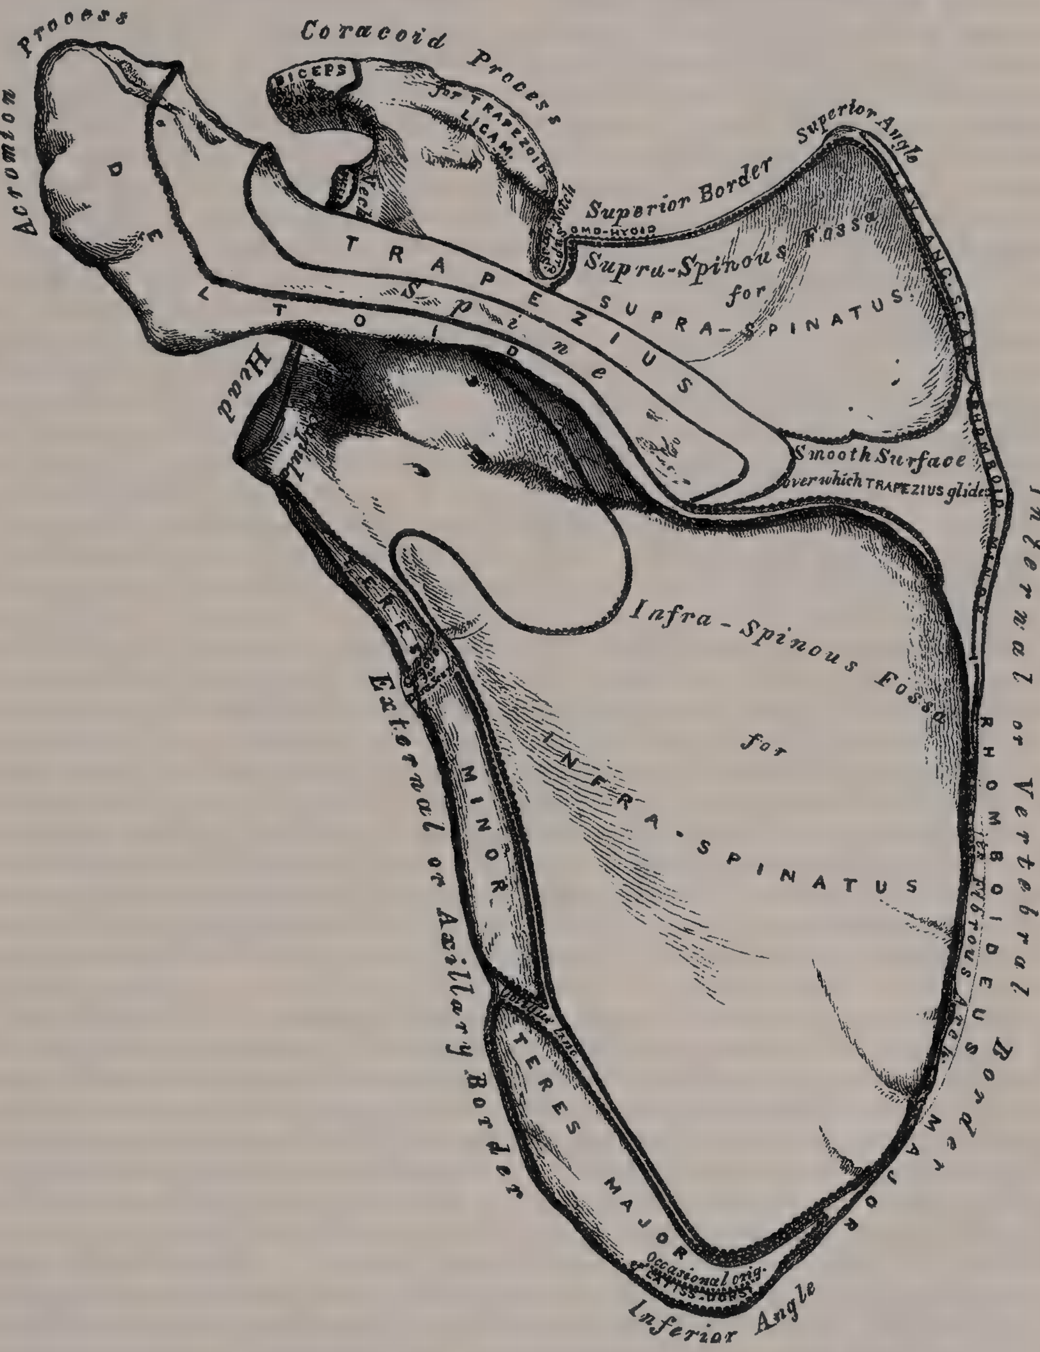
The **posterior surface**, or **dorsum** (fig. 286), is arched from above downwards, alternately concave and convex from side to side. It is subdivided unequally into two parts by the *spine*; the portion above the spine is called the *supraspinous fossa*, and that below it the *infraspinous fossa*.

The *supraspinous fossa*, the smaller of the two, is concave, smooth, and broader at the vertebral than at the humeral extremity. It affords attachment by its inner two-thirds to the Supraspinatus muscle.

The *infraspinous fossa* is much larger than the preceding; towards its

vertebral margin a shallow concavity is seen at its upper part; its centre presents a prominent convexity, while towards the axillary border is a deep groove which runs from the upper towards the lower part. The inner two-thirds of this surface affords attachment to the Infraspinatus muscle; the outer third is only covered by it, without giving origin to its fibres. This surface is marked near the axillary border by an elevated ridge, which runs from the lower part of the

FIG. 286.—Left scapula. Posterior surface, or dorsum.



glenoid cavity, downwards and backwards to the posterior border, about an inch above the inferior angle. The ridge serves for the attachment of a strong aponeurosis, which separates the Infraspinatus from the two Teres muscles. The surface of bone between this line and the axillary border is narrow in the upper two-thirds of its extent, and is crossed near its centre by a groove for the passage of the dorsalis scapulæ vessels; it affords attachment to the Teres minor. Its lower third presents a broader, somewhat triangular surface, which gives origin to the Teres major, and over which the Latissimus dorsi glides; frequently the latter muscle takes origin by a few fibres from this part. The broad and narrow portions of bone above alluded to are separated by an oblique line, which

runs from the axillary border, downwards and backwards, to meet the elevated ridge: to it is attached the aponeurosis which separates the two Teres muscles from each other.

The **Spine** is a prominent plate of bone, which crosses obliquely the inner four-fifths of the dorsum of the scapula at its upper part, and separates the supra- from the infra-spinous fossa: it commences at the vertebral border by a smooth, triangular surface over which the tendon of insertion of the lower part of the Trapezius glides, separated from the bone by a bursa; and, gradually becoming more elevated as it passes outwards, terminates in the acromion process, which overhangs the shoulder-joint. The spine is triangular, and flattened from above downwards, its apex corresponding to the vertebral border, its base (which is directed outwards) to the neck of the scapula. It presents two surfaces and three borders. Its *superior surface* is concave, assists in forming the supraspinous fossa, and affords attachment to part of the Supraspinatus muscle. Its *inferior surface* forms part of the infraspinous fossa, gives origin to part of the Infraspinatus muscle, and presents near its centre the orifice of a nutrient canal. Of the three borders, the *anterior* is attached to the dorsum of the bone; the *posterior*, or *crest of the spine*, is broad, and presents two lips and an intervening rough interval. To the superior lip is attached the Trapezius, to the extent shown in the figure. A rough tubercle is generally seen occupying that portion of the spine which receives the tendon of insertion of the lower part of this muscle. To the inferior lip, throughout its whole length, is attached the Deltoid. The interval between the lips is also partly covered by the tendinous fibres of these muscles. The *external border*, or *base*, the shortest of the three, is slightly concave; its edge, thick and round, is continuous above with the under surface of the acromion process, below with the neck of the scapula. The narrow portion of bone external to this border, and separating it from the glenoid cavity, is called the *great scapular notch*, and serves to connect the supra- and infra-spinous fossæ.

The **Acromion Process**, so called from forming the summit of the shoulder (*ἄκρον, a summit; ὦμος, the shoulder*), is a large and somewhat triangular or oblong process, flattened from behind forwards, directed at first a little outwards, and then curving forwards and upwards, so as to overhang the glenoid cavity. Its *upper surface*, directed upwards, backwards, and outwards, is convex, rough, and gives attachment to some fibres of the Deltoid, and in the rest of its extent it is subcutaneous. Its *under surface* is smooth and concave. Its *outer border* is thick and irregular, and presents three or four tubercles for the tendinous origins of the Deltoid muscle. Its *inner margin*, shorter than the outer, is concave, gives attachment to a portion of the Trapezius muscle, and presents about its centre a small, oval surface for articulation with the acromial end of the clavicle. Its *apex*, which corresponds to the point of meeting of these two borders in front, is thin, and has attached to it the coraco-acromial ligament.

Borders.—Of the three borders of the scapula, the *superior* is the shortest and thinnest; it is concave, and extends from the superior angle to the base of the coracoid process. At its outer part is a deep, semicircular notch, the *suprascapular*, formed partly by the base of the coracoid process. This notch is converted into a foramen by the transverse ligament, and serves for the passage of the suprascapular nerve; sometimes this foramen is entirely surrounded by bone. The adjacent margin of the superior border affords attachment to the Omo-hyoid muscle. The *external*, or *axillary*, *border* is the thickest of the three. It commences above at the lower margin of the glenoid cavity, and inclines obliquely downwards and backwards to the inferior angle. Immediately below the glenoid cavity is a rough impression (the *infraglenoid tubercle*), about an inch in length, which affords attachment to the long head of the Triceps muscle; in front of this is a longitudinal groove, which extends as far as its lower third, and affords origin to part of the Subscapularis muscle. The inferior third of this border, which is thin and sharp, serves for the attachment of a few fibres of the Teres major behind and of the Subscapularis in front. The *internal*, or *vertebral*, *border*, also named the *base*, is the longest of the three, and extends from the superior to the inferior angle of the bone. It is arched, intermediate in thickness between the superior and the external borders, and the portion of it above the spine is bent considerably outwards, so as to form an obtuse angle with the lower part. The vertebral border presents an anterior lip, a posterior lip, and an

intermediate space. The *anterior lip* affords attachment to the Serratus magnus; the *posterior lip*, to the Supraspinatus above the spine, the Infraspinatus below; the interval between the two lips, to the Levator anguli scapulæ above the triangular surface at the commencement of the spine, the Rhomboideus minor to the edge of that surface; the Rhomboideus major being attached by means of a fibrous arch, connected above to the lower part of the triangular surface at the base of the spine, and below to the lower part of the posterior border.

Angles.—Of the three angles, the *superior*, formed by the junction of the superior and internal borders, is thin, smooth, rounded, somewhat inclined outwards, and gives attachment to a few fibres of the Levator anguli scapulæ muscle. The *inferior* angle, thick and rough, is formed by the union of the vertebral and axillary borders, its outer surface affording attachment to the Teres major and frequently to a few fibres of the Latissimus dorsi. The *anterior* angle is the thickest part of the bone, and forms what is called the *head* of the scapula. The head presents a shallow, pyriform, articular surface, the *glenoid cavity* (*γλήνη, a socket*), whose longest diameter is from above downwards, and its direction outwards and forwards. It is broader below than above; at its apex is a slight impression (the *supraglenoid tubercle*), to which is attached the long tendon of the Biceps muscle. It is covered with cartilage in the recent state; and its margins, slightly raised, give attachment to a fibro-cartilaginous structure, the *glenoid ligament*, by which its cavity is deepened. The *neck* of the scapula is the slightly depressed surface which surrounds the head; it is more distinct on the posterior than on the anterior surface, and below than above. In the latter situation it has, arising from it, a thick prominence, the coracoid process.

The **Coracoid Process**, so called from its fancied resemblance to a crow's beak (*κόραξ, a crow*), is a thick, curved process of bone, which arises by a broad base from the upper part of the neck of the scapula; it is directed at first upwards and inwards; then, becoming smaller, it changes its direction, and passes forwards and outwards. The ascending portion, flattened from before backwards, presents in front a smooth, concave surface, over which passes the Subscapularis muscle. The horizontal portion is flattened from above downwards; its upper surface is convex and irregular, and gives attachment to the Pectoralis minor; its under surface is smooth; its inner border is rough, and gives attachment to the Pectoralis minor; its outer border is also rough for the coraco-acromial ligament, while the apex is embraced by the conjoined tendon of origin of the short head of the Biceps and of the Coraco-brachialis and gives attachment to the costo-coracoid ligament. At the inner side of the root of the coracoid process is a rough impression for the attachment of the conoid ligament; and running from it obliquely forwards and outwards, on to the upper surface of the horizontal portion, an elevated ridge for the attachment of the trapezoid ligament.

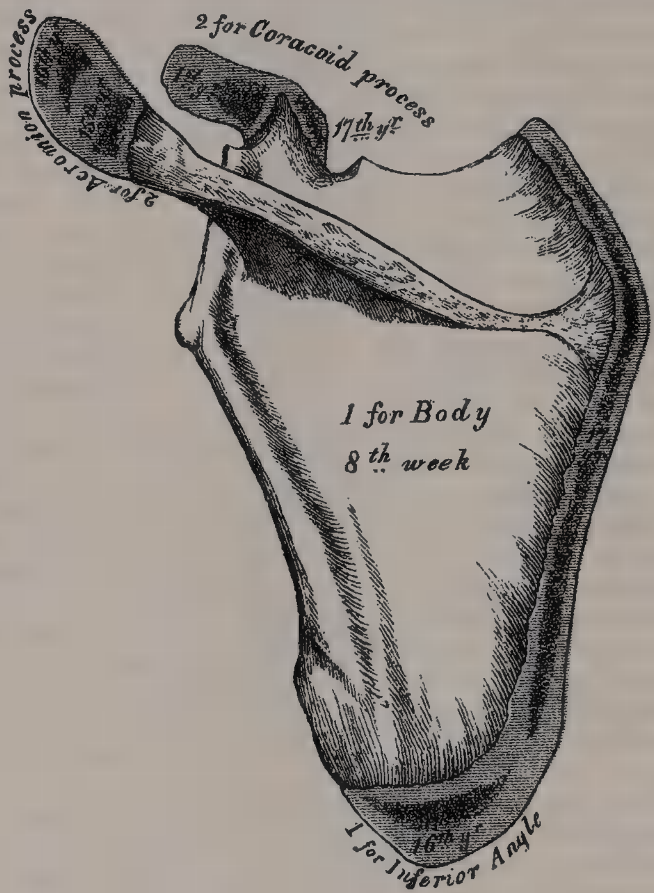
Structure.—In the head, processes, and all the thickened parts of the bone, the scapula is composed of cancellous tissue, while in the rest of its extent it is composed of a thin layer of dense, compact tissue. The central part of the supraspinous fossa and the upper part of the infraspinous fossa, but especially the former, are usually so thin as to be semi-transparent; occasionally the bone is found wanting in this situation, and the adjacent muscles come into contact.

Development (fig. 287).—By *seven* or more centres: one for the body, two for the coracoid process, two for the acromion, one for the vertebral border, and one for the inferior angle.

Ossification of the body of the scapula commences about the second month of fœtal life, by the formation of an irregular quadrilateral plate of bone, immediately behind the glenoid cavity. This plate extends so as to form the chief part of the bone, the spine growing up from its posterior surface about the third month. At birth, a large part of the scapula is osseous, but the glenoid cavity, coracoid and acromion processes, the posterior border, and inferior angle are cartilaginous. From the fifteenth to the eighteenth month after birth, ossification takes place in the middle of the coracoid process, which as a rule becomes joined with the rest of the bone about the fifteenth year. Between the fourteenth and twentieth years, ossification of the remaining centres takes place in quick succession, and usually in the following order: first, in the root of the coracoid process, in the form of a broad scale; secondly, near the base of the acromion process; thirdly, in the inferior angle and contiguous part of the posterior

border; fourthly, near the extremity of the acromion; fifthly, in the posterior border. The acromion process, besides being ossified from two separate nuclei, has its base formed by an extension into it of the centre of ossification which belongs to the spine, the extent of which varies in different cases. The two separate nuclei unite, and then join with the extension from the spine. The upper third of the glenoid cavity is ossified from a separate centre (subcoracoid), which makes its appearance between the tenth and eleventh years and joins between sixteen and eighteen. Further, an epiphysial plate appears for the lower part of the glenoid cavity, while the tip of the coracoid process frequently presents a separate nucleus. These various epiphyses are joined to the bone by the twenty-fifth year. Sometimes failure of union between the acromion process and spine occurs, the junction being effected by fibrous tissue, or by an

FIG. 287.—Plan of the development of the scapula. By seven centres.



imperfect articulation; in some cases of supposed fracture of the acromion with ligamentous union, it is probable that the detached segment was never united to the rest of the bone.

Articulations.—With the humerus and clavicle.

Attachment of Muscles.—To seventeen: to the anterior surface, the Subscapularis; posterior surface, Supraspinatus, Infraspinatus, Teres minor, Teres major; spine, Trapezius, Deltoid; superior border, Omo-hyoid; vertebral border, Serratus magnus, Levator anguli scapulæ, Rhomboideus minor and major; axillary border, Triceps; apex of glenoid cavity, long head of the Biceps; coracoid process, short head of the Biceps, Coraco-brachialis, Pectoralis minor; and to the inferior angle occasionally a few fibres of the Latissimus dorsi.

Surface Form.—The only parts of the scapula which are truly subcutaneous are the spine and acromion process, but, in addition to these, the coracoid process, the internal or vertebral border and inferior angle, and, to a less extent, the axillary border, may be defined. The acromion process and spine of the scapula are easily felt throughout their entire length, forming, with the clavicle, the arch of the shoulder. The acromion can be ascertained to be connected to the clavicle at the acromio-clavicular joint by running the finger along

it, its position being often indicated by an irregularity or bony outgrowth from the clavicle close to the joint. The acromion can be felt forming the point of the shoulder, and from this can be traced backwards to join the spine of the scapula. The place of junction is denoted by a prominence, which is sometimes called the acromial angle. From here the spine can be felt as a distinct ridge of bone, marked on the surface as an oblique depression, which becomes less and less distinct and terminates a little external to the spinous processes of the vertebræ. Its termination is indicated by a slight dimple in the skin, on a level with the interval between the third and fourth dorsal spines. Below this point the vertebral border of the scapula may be traced, running downwards and outwards, and thus diverging from the vertebral spines, to the inferior angle of the bone, which can be recognised, although covered by the Latissimus dorsi muscle. From this angle the axillary border can usually be traced through its thick muscular covering, forming, with the muscles, the posterior fold of the axilla. The coracoid process may be felt about an inch below the junction of the middle and outer third of the clavicle. Here it is covered by the anterior border of the Deltoid, and lies a little to the outer side of a slight depression, which corresponds to the interval between the Pectoralis major and Deltoid muscles. When the arms are hanging by the side, the upper angle of the scapula corresponds to the upper border of the second rib or the interval between the first and second dorsal spines, the inferior angle to the upper border of the eighth rib or the interval between the seventh and eighth dorsal spines.

Surgical Anatomy.—Fractures of the body of the scapula are rare, owing to the mobility of the bone, the thick layer of muscles by which it is encased on both surfaces, and the elasticity of the ribs on which it rests. Fracture of the neck of the bone is also uncommon. The most frequent course of the fracture is from the suprascapular notch to the infra-glenoid tubercle, and it derives its principal interest from its simulation to a subglenoid dislocation of the humerus. The diagnosis can be made by noting the alteration in the position of the coracoid process. A fracture of the neck external to and not including the coracoid process is said to occur, but it is exceedingly doubtful whether such an accident ever takes place. The acromion process is more frequently broken than any other part of the bone, and there is sometimes, in young subjects, a separation of the epiphysis. It is believed that many of the cases of supposed fracture of the acromion, with fibrous union, which have been found on post-mortem examination are really cases of imperfectly united epiphysis. The coracoid process is occasionally broken off, either from direct violence or, perhaps rarely, from muscular action.

Tumours of various kinds grow from the scapula. Of the innocent form of tumours probably the osteomata are the most common. When this tumour grows from the venter of the scapula, as it sometimes does, it is of the compact variety, such as usually grows from membrane-formed bones, as the bones of the skull. This would appear to afford evidence that this portion of the bone is formed from membrane, and not like the rest of the bone from cartilage. Sarcomatous tumours sometimes grow from the scapula and may necessitate removal of the bone, with or without amputation of the upper limb. The bone may be excised by a T-shaped incision, and the flaps being reflected, the removal is commenced from the posterior or vertebral border, so that the subscapular vessels which lie along the axillary border are among the last structures divided, and can be at once secured.

THE ARM

The **Arm** is that portion of the upper extremity which is situated between the shoulder and the elbow. Its skeleton consists of a single bone, the humerus.

The Humerus

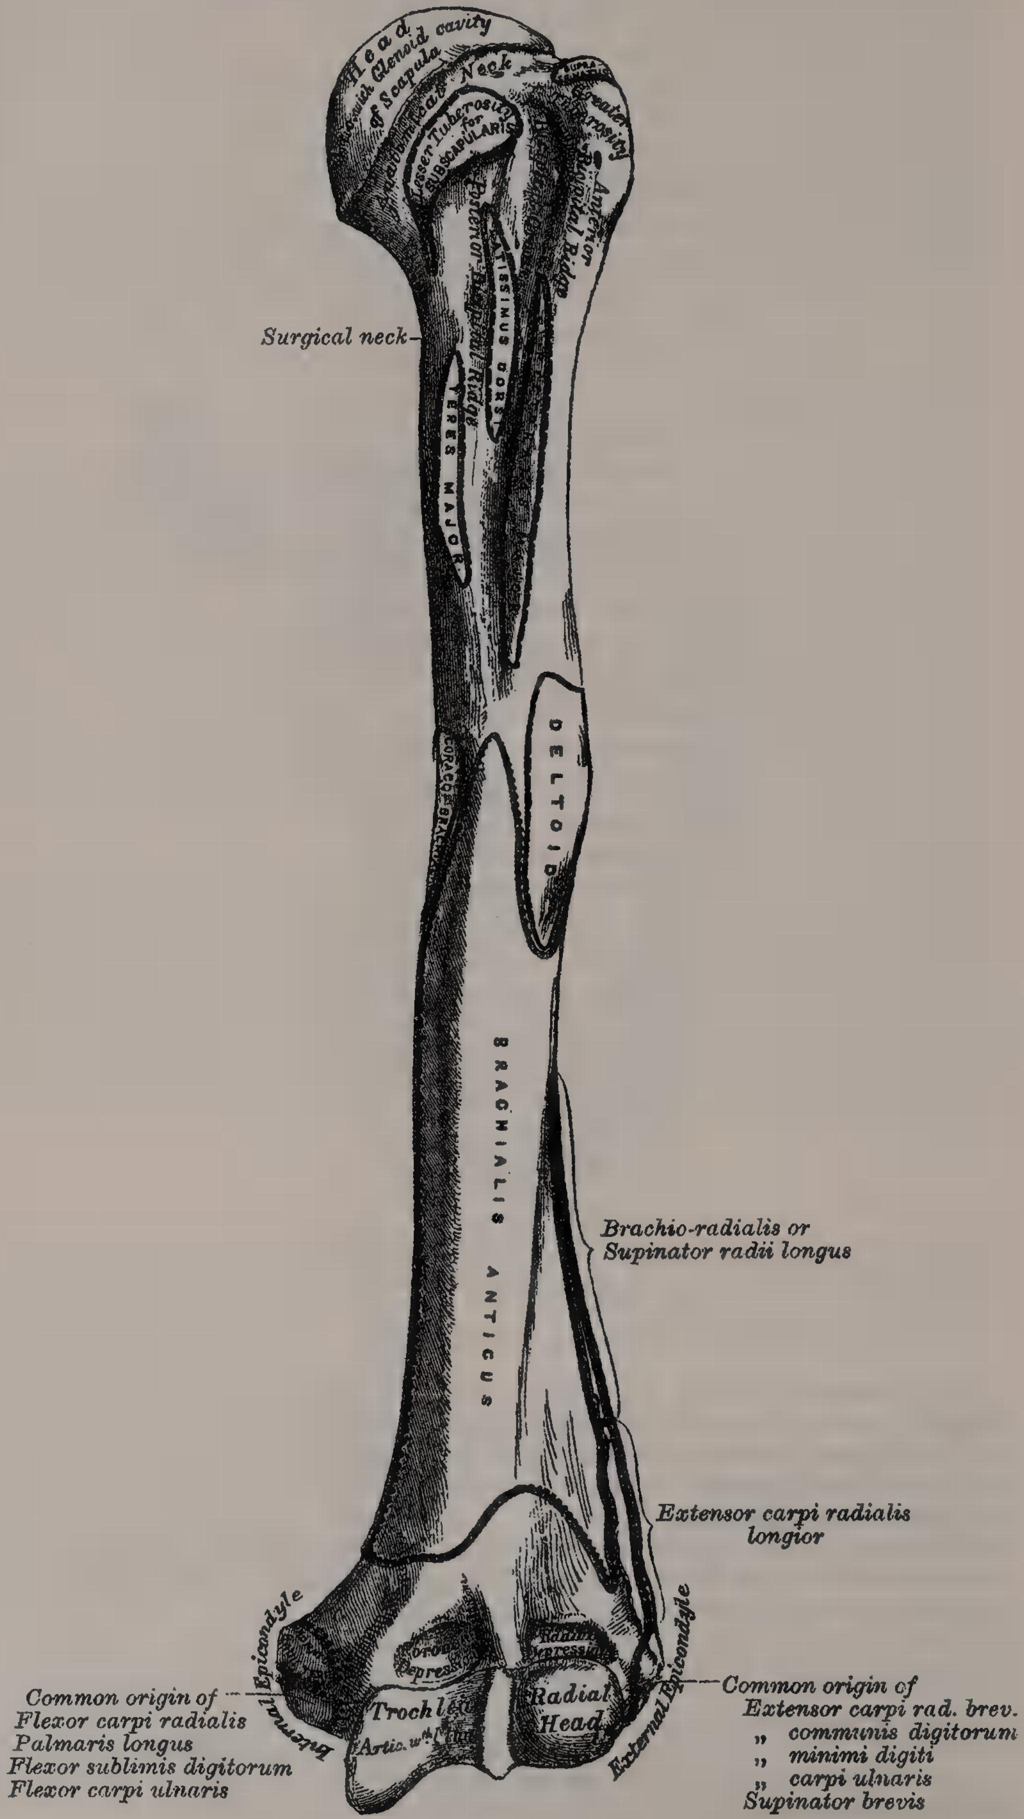
The **Humerus** is the longest and largest bone of the upper extremity; it presents for examination a shaft and two extremities.

The **Upper Extremity** consists of a large, rounded *head*, joined to the shaft by a constricted portion, called the *neck*, and two other eminences, the *greater* and *lesser tuberosities* (fig. 288).

The **head**, nearly hemispherical in form,* is directed upwards, inwards, and a little backwards, and articulates with the glenoid cavity of the scapula; its surface is smooth, and coated with cartilage in the recent state. The circumference of its articular surface is slightly constricted, and is termed the *anatomical neck*, in contradistinction to the constriction which exists below the tuberosities. The

* Though the head is nearly hemispherical in form, its margin, as Humphry has shown, is by no means a true circle. Its greatest measurement is, from the top of the bicipital groove in a direction downwards, inwards, and backwards. Hence it follows that the greatest elevation of the arm can be obtained by rolling the articular surface in this direction—that is to say, obliquely upwards, outwards, and forwards.

Fig. 288.—Left humerus. Anterior view



latter is called the *surgical neck*, from its being frequently the seat of fracture. It should be remembered, however, that fracture of the *anatomical neck* does sometimes, though rarely, occur.

The **anatomical neck** is obliquely directed, forming an obtuse angle with the shaft. It is more distinctly marked in the lower half of its circumference than in the upper half, where it presents a narrow groove, separating the head from the tuberosities. Its circumference affords attachment to the capsular ligament, and is perforated by numerous vascular foramina.

The **greater tuberosity** is situated on the outer side of the head and lesser tuberosity. Its upper surface is rounded and marked by three flat impressions, separated by two slight ridges: the superior impression gives insertion to the tendon of the Supraspinatus; the middle to the Infraspinatus; the inferior one, and the shaft of the bone below it, to the Teres minor. The outer surface of the great tuberosity is convex, rough, and continuous with the outer side of the shaft.

The **lesser tuberosity** is more prominent, although smaller, than the greater: it is situated in front of the head, and is directed inwards and forwards. Its summit presents a prominent impression for the insertion of the tendon of the Subscapularis muscle. The tuberosities are separated from one another by a deep groove, the *bicipital groove*, which lodges the long tendon of the Biceps muscle, and transmits a branch of the anterior circumflex artery to the shoulder-joint. It commences above between the two tuberosities, passes obliquely downwards and a little inwards, and terminates at the junction of the upper with the middle third of the bone. It is deep and narrow at the commencement, and becomes shallow and a little broader as it descends. Its borders are called, respectively, the anterior and posterior *bicipital ridges*, and form the upper part of the anterior and internal borders of the shaft of the bone. In the recent state it is covered with a thin layer of cartilage, lined by a prolongation of the synovial membrane of the shoulder-joint, and gives insertion to the tendon of the Latissimus dorsi muscle.

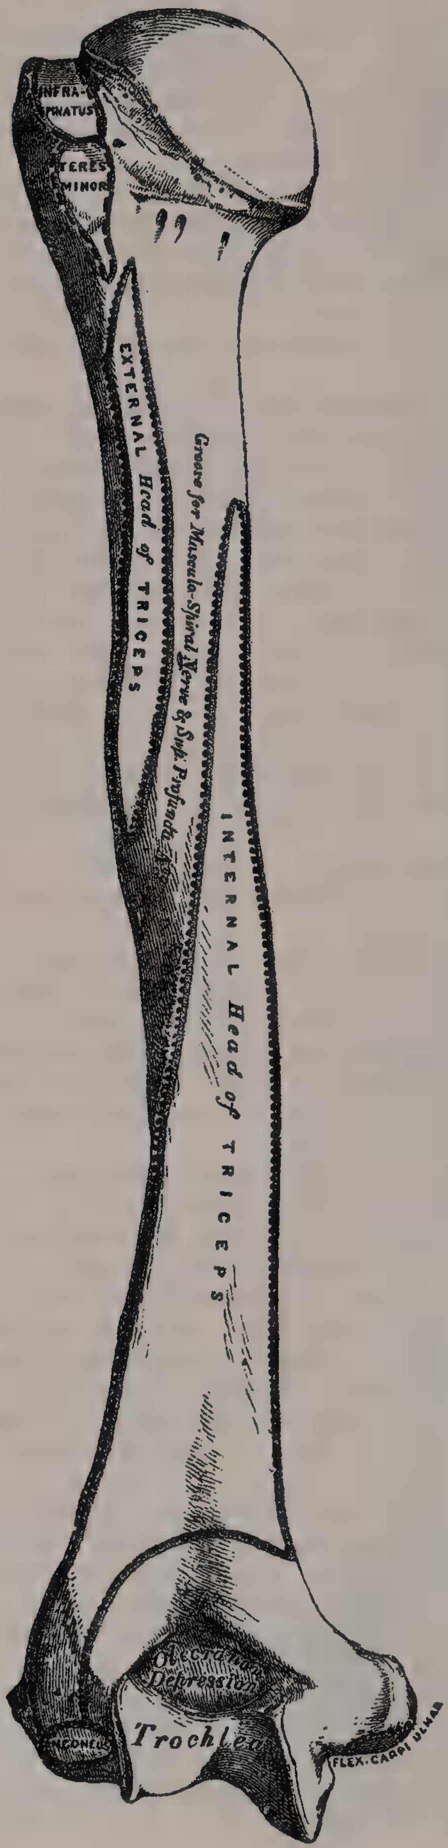
The **Shaft** of the humerus is almost cylindrical in the upper half of its extent, prismatic and flattened below, and presents three borders and three surfaces for examination.

The **anterior border** runs from the front of the great tuberosity above to the coronoid depression below, separating the internal from the external surface. Its upper part is very prominent and rough, and forms the outer lip of the bicipital groove. It is sometimes called the *anterior bicipital* or *pectoral ridge*, and serves for the insertion of the tendon of the Pectoralis major. About its centre it forms the anterior boundary of the rough deltoid impression; below, it is smooth and rounded, affording attachment to the Brachialis anticus.

The **external border** runs from the back part of the greater tuberosity to the external epicondyle, and separates the external from the posterior surface. It is rounded and indistinctly marked in its upper half, serving for the attachment of the lower part of the insertion of the Teres minor, and below this giving origin to the external head of the Triceps muscle; its centre is traversed by a broad but shallow, oblique depression, the *musculo-spiral groove*; its lower part is marked by a prominent, rough margin, a little curved from behind forwards, the *external supracondylar ridge*, which presents an anterior lip for the origin of the Supinator longus (Brachio-radialis) above, and Extensor carpi radialis longior below, a posterior lip for the Triceps, and an intermediate space for the attachment of the external intermuscular septum.

The **internal border** extends from the lesser tuberosity to the internal epicondyle. Its upper third is marked by a prominent ridge, the posterior lip of the bicipital groove, which gives insertion to the tendon of the Teres major. About its centre is a slight impression for the insertion of the Coraco-brachialis, and just below this is seen the entrance of the nutrient canal, directed downwards. Sometimes there is a second canal situated at the commencement of the musculo-spiral groove for a nutrient artery derived from the superior profunda branch of the brachial artery. The inferior third of this border is raised into a slight ridge, the *internal supracondylar ridge*, which becomes very prominent below; it presents an anterior lip for the origin of the Brachialis anticus, a posterior lip for the internal head of the Triceps, and an intermediate space for the attachment of the internal intermuscular septum.

FIG. 289.—Left humerus. Posterior surface.



The **external surface** is directed outwards above, where it is smooth, rounded, and covered by the Deltoid muscle; forwards and outwards below, where it is slightly concave from above downwards, and gives origin to part of the Brachialis anticus muscle. About the middle of this surface is seen a rough, triangular impression for the insertion of the Deltoid muscle; and below it the musculo-spiral groove, directed obliquely from behind, forwards, and downwards, and transmitting the musculo-spiral nerve and superior profunda artery.

The **internal surface**, less extensive than the external, is directed inwards above, forwards and inwards below; at its upper part it is narrow, and forms the floor of the bicipital groove which gives insertion to the tendon of the Latissimus dorsi. The middle part of this surface is slightly rough for the attachment of some of the fibres of the tendon of insertion of the Coraco-brachialis; its lower part is smooth, concave from above downwards, and gives origin to the Brachialis anticus muscle.*

The **posterior surface** (fig. 289) appears somewhat twisted, so that its upper part is directed a little inwards, its lower part backwards and a little outwards. Nearly the whole of this surface is covered by the external and internal heads of the Triceps, the former

* A small, hook-shaped process of bone, the *supracondylar process*, varying from $\frac{1}{10}$ to $\frac{3}{4}$ of an inch in length, is not infrequently found projecting from the inner surface of the shaft of the humerus two inches above the internal epicondyle. It is curved downwards, forwards, and inwards, and its pointed extremity is connected to the internal border, just above the inner epicondyle, by a ligament or fibrous band, which gives origin to a portion of the Pronator radii teres; through the arch completed by this fibrous band the median nerve and brachial artery pass, when these structures deviate from their usual course. Sometimes the nerve alone is transmitted through it, or the nerve may be accompanied by the ulnar artery, in cases of high division of the brachial. A well-marked groove is usually found behind the process, in which the nerve and artery are lodged. This space is analogous to the supracondyloid foramen in many animals, and probably serves in them to protect the nerve and artery from compression during the contraction of the muscles in this region. A detailed account of this process is given by Struthers, in his *Anatomical and Physiological Observations*, p. 202. According to J. Wood, an accessory portion of the Coraco-brachialis muscle is frequently connected with this process (*Journal of Anat. and Phys.* No. 1. Nov. 1866, p. 47).

of which arises from its upper and outer part, the latter from its inner and back part, the two being separated by the musculo-spiral groove.

The **Lower Extremity** is flattened from before backwards, and curved slightly forwards; it terminates below in a broad, articular surface, which is divided into two parts by a slight ridge. Projecting on either side are the external and internal epicondyles. The articular surface extends a little lower than the epicondyles, and is curved slightly forwards, so as to occupy the more anterior part of the bone; its greatest breadth is in the transverse diameter, and it is obliquely directed, so that its inner extremity occupies a lower level than the outer. The outer portion of the articular surface presents a smooth, rounded eminence, which has received the name of the *capitellum*, or *radial head* of the humerus; it articulates with the cup-shaped depression on the head of the radius, and is limited to the front and lower part of the bone, not extending as far back as the other portion of the articular surface. On the inner side of this eminence is a shallow groove, in which is received the inner margin of the head of the radius. Above the front part of the capitellum is a slight depression, the *radial fossa*, which receives the anterior border of the head of the radius, when the forearm is flexed. The inner portion of the articular surface, the *trochlea*, presents a deep depression between two well-marked borders. This surface is convex from before backwards, concave from side to side, and occupies the anterior, lower, and posterior parts of the bone. The external border, less prominent than the internal, separates it from the groove which articulates with the margin of the head of the radius. The internal border is thicker, more prominent, and consequently of greater length, than the external. The grooved portion of the articular surface fits accurately within the greater sigmoid cavity of the ulna; it is broader and deeper on the posterior than on the anterior aspect of the bone, and is inclined obliquely from behind forwards, and from without inwards. Above the front part of the trochlear surface is a smaller depression, the *coronoid fossa*, which receives the coronoid process of the ulna during flexion of the forearm. Above the back part of the trochlear surface is a deep, triangular depression, the *olecranon fossa*, in which the summit of the olecranon process is received in extension of the forearm. These fossæ are separated from one another by a thin, transparent lamina of bone, which is sometimes perforated, forming the *supratrochlear foramen*; their margins afford attachment to the anterior and posterior ligaments of the elbow-joint, and they are lined, in the recent state, by the synovial membrane of this articulation. The articular surfaces, in the recent state, are covered with a thin layer of cartilage. The external epicondyle is a small, tubercular eminence, less prominent than the internal, curved a little forwards, and giving attachment to the external lateral ligament of the elbow-joint, and to a tendon common to the origin of some of the Extensor and Supinator muscles. The internal epicondyle, larger and more prominent, and therefore more liable to fracture, than the external, is directed a little backwards: it gives attachment to the internal lateral ligament, to the Pronator radii teres, and to a tendon common to the origin of some of the Flexor muscles of the forearm. The ulnar nerve runs in a groove at the back of the internal condyle. These epicondyles are directly continuous above with the external and internal supracondylar ridges.

Structure.—The extremities consist of cancellous tissue, covered with a thin, compact layer; the shaft is composed of a cylinder of compact tissue, thicker at the centre than at the extremities, and hollowed out by a large medullary canal, which extends along its whole length.

Development (fig. 290).—By *eight* centres: one for the shaft, one for the head, one for each tuberosity, one for the radial head, one for the trochlear portion of the articular surface, and one for each epicondyle. The nucleus for the shaft appears near the centre of the bone in the eighth week, and soon extends towards the extremities. At birth the humerus is ossified nearly in its whole length, only the extremities remaining cartilaginous. During the first year, sometimes before birth, ossification commences in the head of the bone, and during the third year the centre for the great tuberosity, and during the fifth that for the lesser tuberosity, make their appearance. By the sixth year the centres for the head and tuberosities have increased in size and become joined, so as to form a single large epiphysis, which fuses with the shaft about the twentieth year.

The lower end of the humerus is developed in the following manner: At the end of the second year ossification commences in the capitellum, and from this point extends inwards, so as to form the chief part of the articular end of the bone, the centre for the inner part of the trochlea not appearing until about the age of twelve. Ossification commences in the internal epicondyle about the fifth year, and in the external one about the thirteenth or fourteenth year. About the sixteenth or seventeenth year, the outer epicondyle and both portions of the articulating surface (having already joined) unite with the shaft, and at the eighteenth year the inner epicondyle becomes joined to it.

Fig. 290.—Plan of the development of the humerus. By seven centres.

Articulations.—With the glenoid cavity of the scapula, and with the ulna and radius.

Attachment of Muscles.—To twenty-four: to the greater tuberosity, the Supraspinatus, Infraspinatus, and Teres minor; to the lesser tuberosity, the Subscapularis; to the anterior bicipital ridge, the Pectoralis major; to the posterior bicipital ridge, the Teres major; to the bicipital groove, the Latissimus dorsi; to the shaft, the Deltoid, Coraco-brachialis, Brachialis anticus, external and internal heads of the Triceps; to the internal epicondyle, the Pronator radii teres, and common tendon of the Flexor carpi radialis, Palmaris longus, Flexor sublimis digitorum, and Flexor carpi ulnaris; to the external supracondylar ridge, the Supinator longus and Extensor carpi radialis longior; to the external epicondyle, the common tendon of the Extensor carpi radialis brevior, Extensor communis digitorum, Extensor minimi digiti, Extensor carpi ulnaris, and Supinator brevis; to the back of the external epicondyle, the Anconeus.

Surface Form.—The humerus is almost entirely clothed by the muscles which surround it, and the only parts of this bone which are strictly subcutaneous are small portions of the internal and external epicondyles. In addition to these, the tuberosities and a part of the head of the bone can be felt under the skin and muscles by which they are covered. Of these the greater tuberosity forms the most prominent bony point of the shoulder, extending beyond the acromion process and covered by the Deltoid muscle. It influences materially the surface form of the shoulder. It is best felt while the arm is lying loosely by the side; if the arm be raised, it recedes from under the finger. The lesser tuberosity, directed forwards and inwards, is to be felt to the inner side of the greater tuberosity, just below the acromio-clavicular joint. Between the two tuberosities lies the bicipital groove. This can be defined by placing the finger, and making firm pressure, just internal to the greater tuberosity; then, by rotating the humerus, the groove will be felt to pass under the finger as the bone is rotated. With the arm abducted from the side the lower part of the head of the bone is to be felt by pressing deeply in the axilla. On each side of the elbow-joint, and just above it, the internal and external epicondyles of the bone are to be felt. Of these the internal is the more prominent, but the internal supracondylar ridge, passing upwards from it, is much less marked than the external, and, as a rule, is not to be felt. Occasionally, however, we find along this border the hook-shaped process mentioned above. The external epicondyle is to be seen most plainly during semiflexion of the forearm, and its position is indicated by a depression between the attachment of the adjacent muscles. From it is to be felt a strong bony ridge running up the outer border of the shaft of the bone. This is the external supracondylar ridge; it is concave forwards, and corresponds with the curved direction of the lower extremity of the humerus.

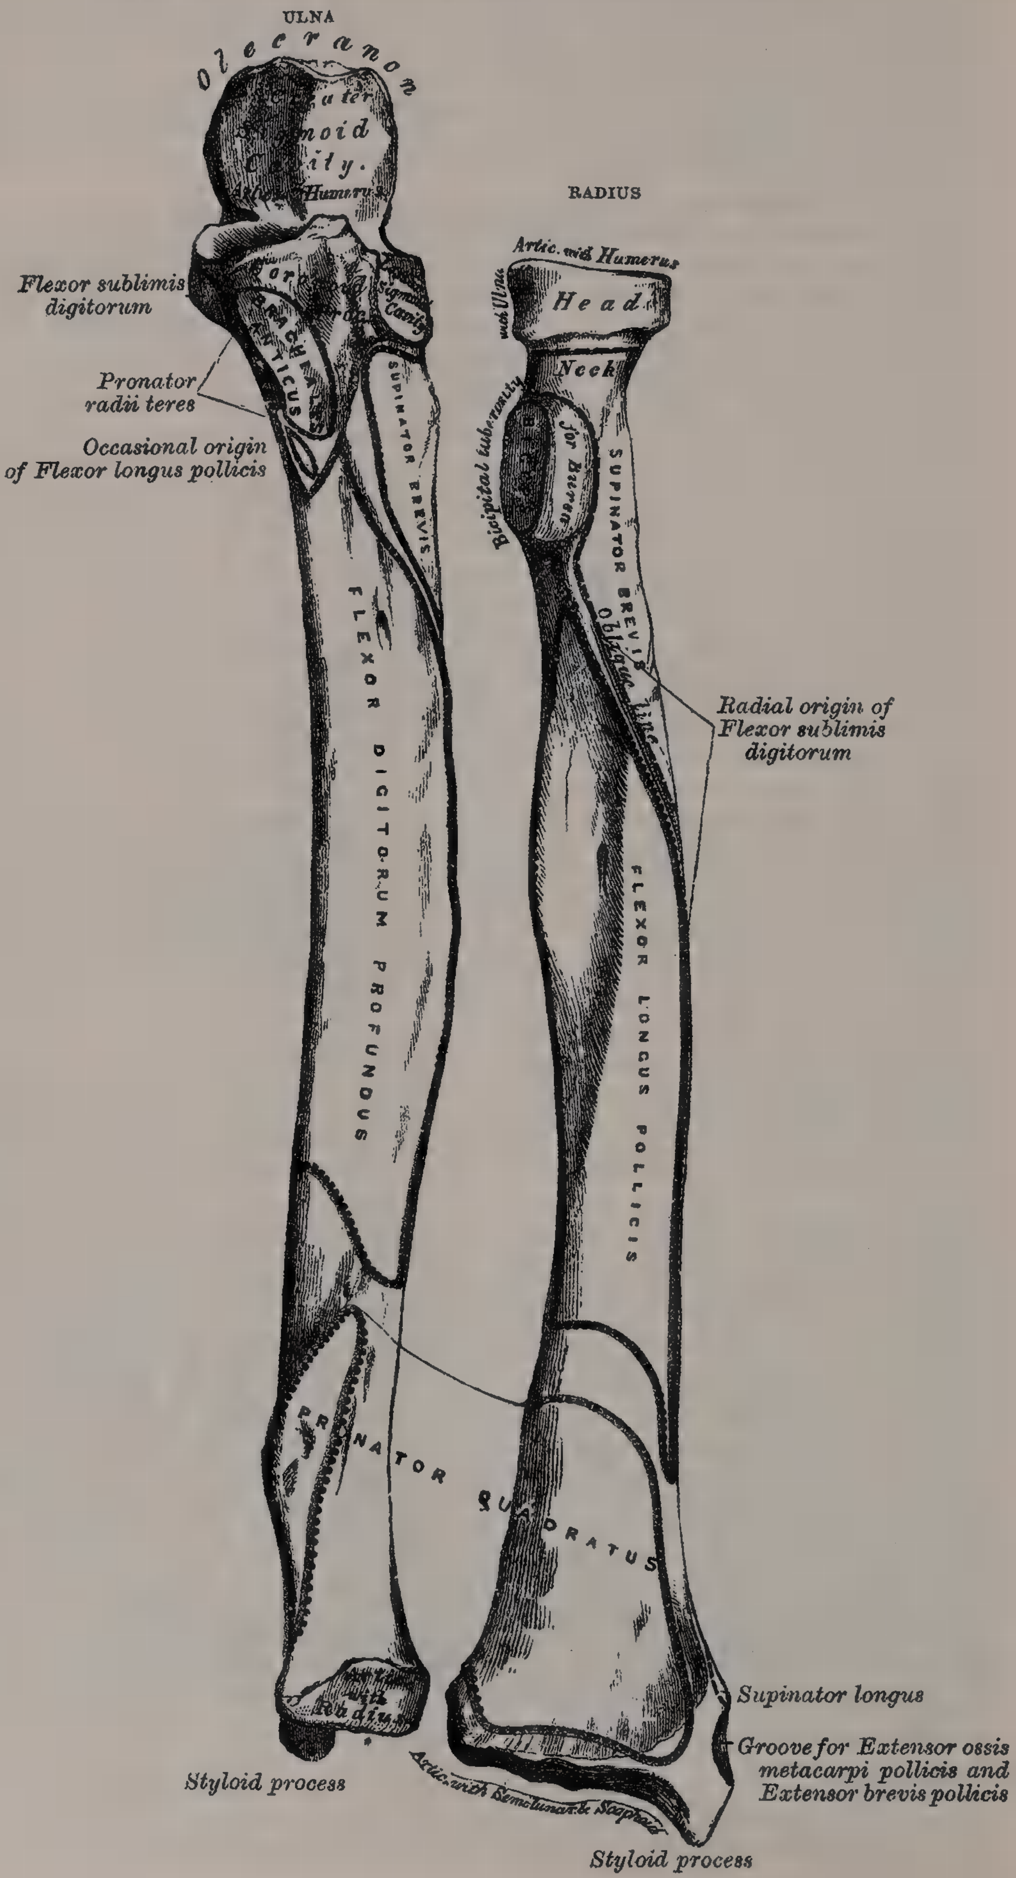
Surgical Anatomy.—There are several points of surgical interest connected with the humerus. First, as regards its development. The upper end, though the first to ossify, is the last to join the shaft, and the length of the bone is mainly due to growth from the upper epiphysial line. Hence, in cases of amputation of the arm in young subjects, the humerus continues to grow considerably, and the end of the bone which immediately after the operation was covered with a thick cushion of soft tissue begins to project, thinning the soft parts and rendering the stump conical. This may necessitate the removal of a couple of inches or so of the bone, and even after this operation a recurrence of the conical stump may take place.

There are several points of surgical interest in connection with fractures. First, as regards their causation; the bone may be broken by direct or indirect violence like the other long bones, but, in addition to this, it is probably more frequently fractured by muscular action than any other of this class of bone in the body. It is usually the shaft, just below the insertion of the Deltoid, which is thus broken. The accident has been known to happen from throwing a stone, and again in an apparently healthy adult, from cutting a piece of hard 'cake tobacco' on a table. In this latter case there was no disease of the bone that could be discovered. Fractures of the upper end may take place through the anatomical neck, through the surgical neck, or separation of the greater tuberosity may occur. Fracture of the anatomical neck is a very rare accident; in fact, it is doubted by some whether it ever occurs. These fractures are usually considered to be intracapsular, but they are probably partly within and partly without the capsule, as the lower part of the capsule is inserted some little distance below the anatomical neck, while the upper part is attached to it. They may be impacted or non-impacted. In most cases there is little or no displacement on account of the capsule, in whole or in part, remaining attached to the lower fragment. But occasionally a very remarkable alteration in position takes place; the upper fragment turns on its own axis, so that the cartilaginous surface of the head rests against the upper end of the lower fragment. When the fractured end is entirely separated from all its surroundings, its vascular supply must be entirely cut off, and one would expect it, theoretically, to necrose. But this must be exceedingly rare, for Gurlt was unable to find a single authenticated case recorded. Separation of the upper epiphysis of the humerus sometimes occurs in the young subject, and is marked by a characteristic deformity, by which the lesion may be at once recognised. This consists in the presence of an abrupt projection at the front of the joint some short distance below the coracoid process, caused by the upper end of the lower fragment. In fractures of the shaft of the humerus the lesion may take place at any point, but appears to be more common in the lower than the upper part of the bone. The points of interest in connection with these fractures are: (1) that the musculo-spiral nerve may be injured as it lies in the groove on the bone, or may become involved in the callus which is subsequently thrown out; and (2) the frequency of non-union. The latter is believed to be more common in the humerus than in any other bone, and various causes have been assigned for it. It would seem most probably to be due to the difficulty that there is in fixing the shoulder-joint and the upper fragment, and possibly the elbow-joint and lower fragment also. Other causes which have been assigned for the non-union are: (1) that in attempting passive motion of the elbow-joint to overcome any rigidity which may exist, the movement does not take place at the articulation but at the seat of fracture; or that the patient, in consequence of the rigidity of the elbow, in attempting to flex or extend the forearm, moves the fragment and not the joint. (2) The presence of small portions of muscular tissue between the broken ends. (3) Want of support to the elbow, so that the weight of the arm tends to drag the lower fragment away from the upper. An important distinction to make in fractures of the lower end of the humerus, is between those that involve the joint and those which do not; the former are always serious, as they may lead to impairment of the utility of the limb. They include the T-shaped fracture and oblique fractures which involve the articular surface. The fractures which do not involve the joint are the transverse above the epicondyles, and the so-called epitrochlear fracture, where the tip of the internal epicondyle is broken off, generally from direct violence.

Under the head of separation of the epiphysis two separate injuries have been described. One where the whole of the four ossific centres which form the lower extremity of the bone are separated from the shaft; and secondly, where the articular portion is alone separated, the two epicondyles remaining attached to the shaft of the bone. The epiphysial line between the shaft and lower end runs across the bone just above the tips of the epicondyles, a point to be borne in mind in performing the operation of excision.

Tumours originating from the humerus are of frequent occurrence. A not uncommon place for a chondroma to grow from is the shaft of the bone somewhere in the neighbourhood of the insertion of the Deltoid. Sarcomata frequently grow from this bone.

FIG. 291.—Bones of the left forearm. Anterior surface.



THE FOREARM

The **Forearm** is that portion of the upper extremity which is situated between the elbow and wrist. Its skeleton is composed of two bones, the ulna and the radius.

The Ulna

The **Ulna** (figs. 291, 292), so called from its forming the elbow (ὠλένη), is a long bone, prismatic in form, placed at the inner side of the forearm, parallel with the radius. It is the larger and longer of the two bones. Its upper extremity, of great thickness and strength, forms a large part of the articulation of the elbow-joint; it diminishes in size from above downwards, its lower extremity being very small, and excluded from the wrist-joint by the interposition of an interarticular fibro-cartilage. It is divisible into a shaft and two extremities.

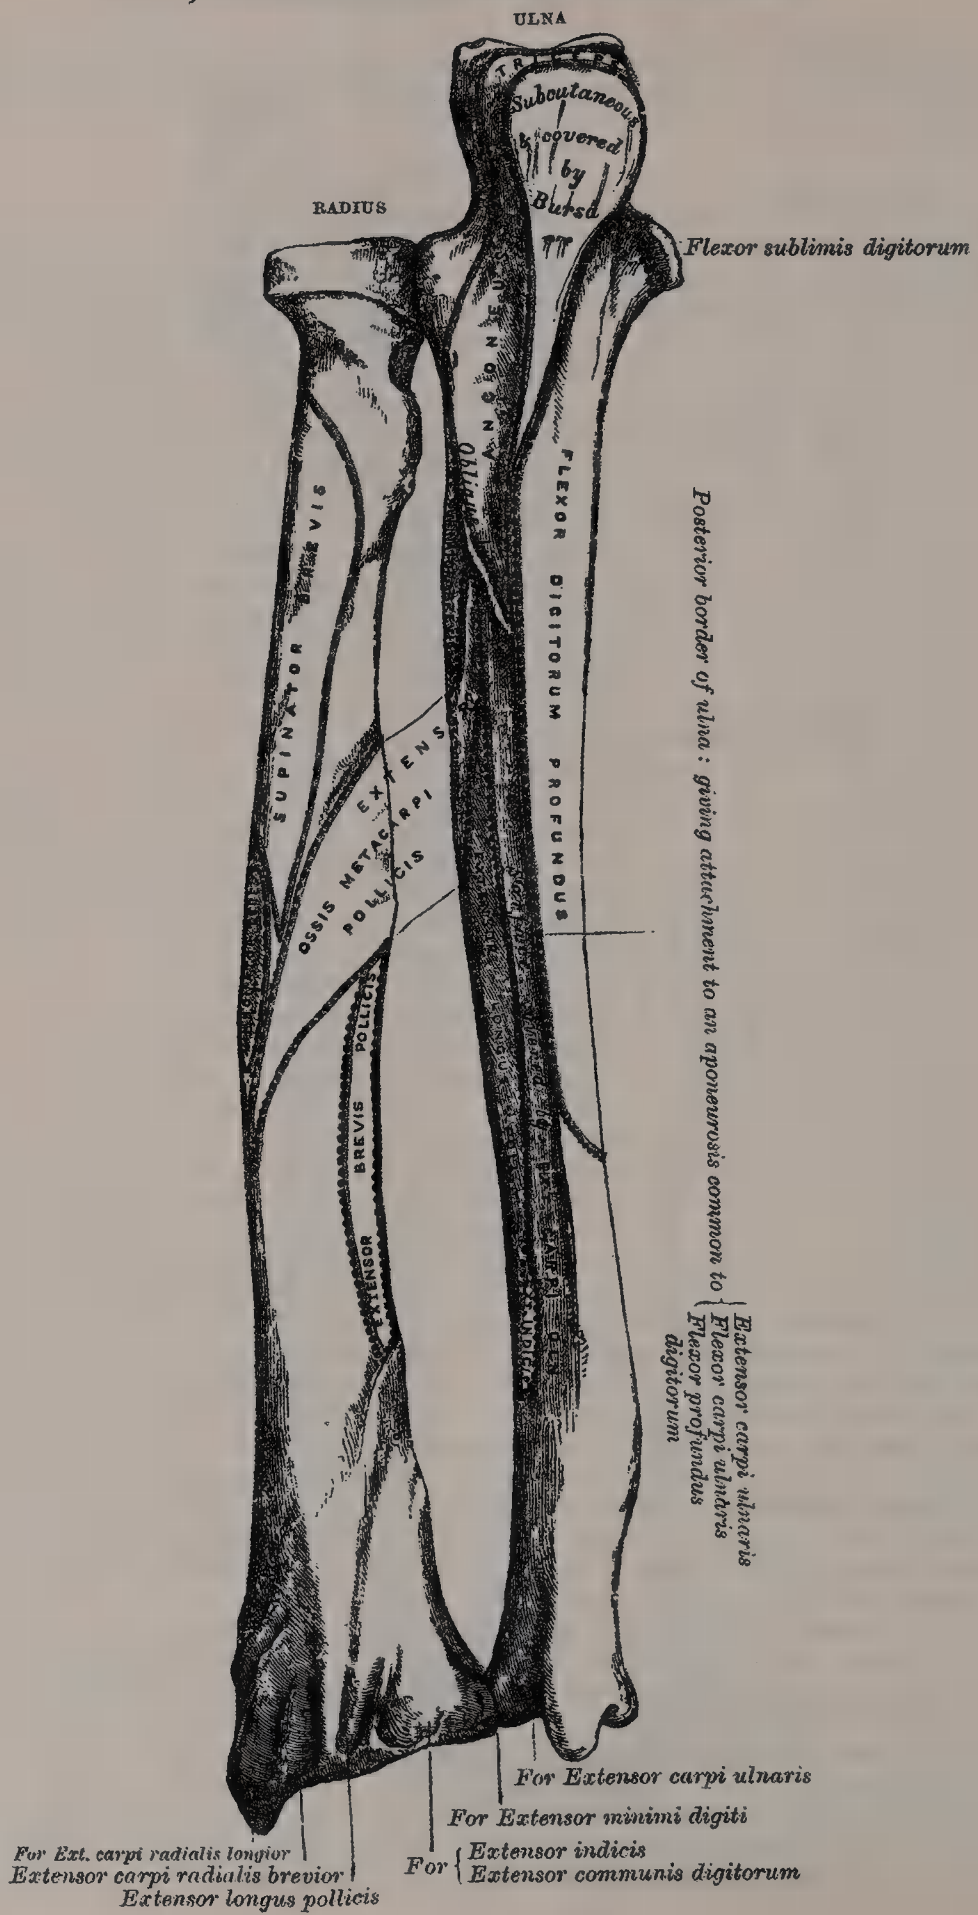
The **Upper Extremity,** the strongest part of the bone, presents for examination two large, curved processes, the olecranon process and the coronoid process; and two concave, articular cavities, the greater and lesser sigmoid cavities.

The **Olecranon Process** (*ὠλένη, elbow*; *κρανίον, head*) is a large, thick, curved eminence, situated at the upper and back part of the ulna. It is curved forwards at the summit so as to present a prominent tip which is received into the olecranon fossa in extension of the forearm; its base being contracted where it joins the shaft. This is the narrowest part of the upper end of the ulna, and, consequently, the most usual seat of fracture. The posterior surface of the olecranon, directed backwards, is triangular, smooth, subcutaneous, and covered by a bursa. Its upper surface is of quadrilateral form, marked behind by a rough impression for the insertion of the Triceps muscle; and in front, near the margin, by a slight transverse groove for the attachment of part of the posterior ligament of the elbow-joint. Its anterior surface is smooth, concave, covered with cartilage in the recent state, and forms the upper and back part of the great sigmoid cavity. The lateral borders present a continuation of the same groove that was seen on the margin of the superior surface; they serve for the attachment of ligaments —viz. the back part of the internal lateral ligament internally, the posterior ligament externally. From its inner border a part of the Flexor carpi ulnaris arises; while to the outer border is attached the Anconeus.

The **Coronoid Process** (*κορώνη, anything hooked like a crow's beak*) is a triangular eminence of bone which projects horizontally forwards from the upper and front part of the ulna. Its base is continuous with the shaft, and of considerable strength; so much so that fracture of it is an accident of rare occurrence. Its apex is pointed, slightly curved upwards, and received into the coronoid depression of the humerus in flexion of the forearm. Its upper surface is smooth, concave, and forms the lower part of the greater sigmoid cavity. The under surface is concave, and marked internally by a rough impression for the insertion of the Brachialis anticus. At the junction of this surface with the shaft is a rough eminence, the *tubercle of the ulna,* for the attachment of the oblique ligament. Its outer surface presents a narrow, oblong, articular depression, the *lesser sigmoid* cavity. The inner surface, by its prominent, free margin, serves for the attachment of part of the internal lateral ligament. At the front part of this surface is a small, rounded eminence for the origin of one head of the Flexor sublimis digitorum; behind the eminence, a depression for part of the origin of the Flexor profundus digitorum; and, descending from the eminence, a ridge, which gives origin to one head of the Pronator radii teres. Frequently, the Flexor longus pollicis arises from the lower part of the coronoid process by a rounded bundle of muscular fibres.

The **Greater Sigmoid Cavity,** so called from its resemblance to the old shape of the Greek letter Σ, is a semilunar depression of large size, formed by the olecranon and coronoid processes, and serving for articulation with the trochlear surface of the humerus. About the middle of either lateral border of this cavity is a notch, which contracts it somewhat, and serves to indicate the junction of the two processes of which it is formed. The cavity is concave from above downwards, and divided into two lateral parts by a smooth, elevated ridge which runs from the summit of the olecranon to the tip of the coronoid process. Of these two portions, the internal is the larger, and is slightly concave transversely;

Fig. 292.—Bones of the left forearm. Posterior surface.



the external portion is convex above, slightly concave below. The articular surface, in the recent state, is covered with a thin layer of cartilage.

The **Lesser Sigmoid Cavity** is a narrow, oblong, articular depression on the outer side of the coronoid process, and receives the lateral articular surface of the head of the radius. It is concave from before backwards; and its extremities, which are prominent, serve for the attachment of the orbicular ligament. In the recent state, it is covered with a thin layer of cartilage.

The **Shaft**, at its upper part, is prismatic in form, and curved from behind forwards, and from without inwards, so as to be convex behind and externally; its central part is quite straight; its lower part is rounded, smooth, and bent a little outwards; it tapers gradually from above downwards, and presents for examination three borders, and three surfaces.

The **anterior border** commences above at the prominent inner angle of the coronoid process, and terminates below in front of the styloid process. It is well marked above, smooth and rounded in the middle of its extent, and affords attachment to the Flexor profundus digitorum: its lower fourth, marked off from the rest of the border by the commencement of an oblique ridge on the anterior surface, serves for the origin of the Pronator quadratus. It separates the anterior from the internal surface.

The **posterior border** commences above at the apex of the triangular subcutaneous surface at the back part of the olecranon, and terminates below at the back part of the styloid process; it is well marked in the upper three-fourths, and gives attachment to an aponeurosis which affords a common origin to the Flexor carpi ulnaris, the Extensor carpi ulnaris, and the Flexor profundus digitorum muscles; its lower fourth is smooth and rounded. This border separates the internal from the posterior surface.

The **external** or **interosseous border** commences above by the union of two lines, which converge one from each extremity of the lesser sigmoid cavity, enclosing between them a triangular space for the origin of part of the Supinator brevis; it terminates below at the middle of the head of the ulna. Its two middle fourths are very prominent, its lower fourth is smooth and rounded. This border gives attachment to the interosseous membrane, and separates the anterior from the posterior surface.

The **anterior surface**, much broader above than below, is concave in its upper three-fourths, and affords attachment to the Flexor profundus digitorum; its lower fourth, also concave, is covered by the Pronator quadratus. The lower fourth is separated from the remaining portion of the bone by a prominent ridge, directed obliquely from above downwards and inwards; this ridge (the *oblique* or *Pronator ridge*) marks the extent of origin of the Pronator quadratus. At the junction of the upper with the middle third of the bone is the nutrient canal, directed obliquely upwards and inwards.

The **posterior surface**, directed backwards and outwards, is broad and concave above; somewhat narrower and convex in the middle of its course; narrow, smooth, and rounded below. It presents, above, an oblique ridge, which runs from the posterior extremity of the lesser sigmoid cavity, downwards to the posterior border; the triangular surface above this ridge receives the insertion of the Anconeus muscle, while the upper part of the ridge itself affords attachment to the Supinator brevis. The surface of bone below this is subdivided by a longitudinal ridge, sometimes called the *perpendicular line*, into two parts: the internal part is smooth, and covered by the Extensor carpi ulnaris; the external portion, wider and rougher, gives origin from above downwards to part of the Supinator brevis, the Extensor ossis metacarpi pollicis, the Extensor longus pollicis, and the Extensor indicis muscles.

The **internal surface** is broad and concave above, narrow and convex below It gives origin by its upper three-fourths to the Flexor profundus digitorum muscle: its lower fourth is subcutaneous.

The **Lower Extremity** of the ulna is of small size, and excluded from the articulation of the wrist-joint. It presents for examination two eminences, the outer and larger of which is a rounded, articular eminence, termed the *head* of the ulna; the inner, narrower and more projecting, is a non-articular eminence, the *styloid process*. The *head* presents an articular facet, part of which, of an oval or semilunar form, is directed downwards, and articulates with the upper surface of the interarticular fibro-cartilage which separates it from the wrist-joint; the

remaining portion, directed outwards, is narrow, convex, and received into the sigmoid cavity of the radius. The *styloid process* projects from the inner and back part of the bone, and descends a little lower than the head, terminating in a rounded summit, which affords attachment to the internal lateral ligament of the wrist. The head is separated from the styloid process by a depression for the attachment of the apex of the triangular interarticular fibro-cartilage; and behind, by a shallow groove for the passage of the tendon of the Extensor carpi ulnaris.

Fig. 293.—Plan of the development of the ulna. By three centres.

Structure.—Similar to that of the other long bones.

Development.—By *three* centres: one for the shaft, one for the inferior extremity, and one for the olecranon (fig. 293). Ossification commences near the middle of the shaft about the eighth week, and soon extends through the greater part of the bone. At birth the ends are cartilaginous. About the fourth year, a separate osseous nucleus appears in the middle of the head, and soon extends into the styloid process. About the tenth year, ossific matter is deposited in the olecranon near its extremity, the chief part of this process being formed from an extension of the shaft of the bone into it. The upper epiphysis is joined to the shaft about the sixteenth year, the lower about the twentieth year.

Articulations. — With the humerus and radius.

Attachment of Muscles.—To fourteen: to the olecranon, the Triceps, Anconeus, and one head of the Flexor carpi ulnaris. To the coronoid process, the Brachialis anticus, Pronator radii teres, Flexor sublimis digitorum, and Flexor profundus digitorum; generally also the Flexor longus pollicis. To the shaft, the Flexor profundus digitorum, Pronator quadratus, Flexor carpi ulnaris, Extensor carpi ulnaris, Anconeus, Supinator brevis, Extensor ossis metacarpi pollicis, Extensor longus pollicis, and Extensor indicis.

Surface Form.—The most prominent part of the ulna on the surface of the body is the olecranon process, which can always be identified at the back of the elbow-joint. When the forearm is flexed, the upper quadrilateral surface can be felt, directed backwards; during extension it recedes into the olecranon fossa, and the contracting fibres of the Triceps prevent its being perceived. At the back of the olecranon is the smooth, triangular, subcutaneous surface, continuous below with the posterior border of the shaft of the bone, and felt in every position of the forearm. During extension, the upper border of the olecranon is slightly above the level of the internal epicondyle, and the process itself is nearer to this epicondyle than the outer one. Running down the back of the forearm, from the apex of the triangular surface which forms the posterior surface of the olecranon, is a prominent ridge of bone, the posterior border of the ulna. This can be made out throughout the entire length of the shaft of the bone, from the olecranon above to the styloid process below. As it passes down the forearm it pursues a sinuous course and inclines to the inner side, so that, though it is situated in the middle of the back of the limb above, it is on the inner side of the wrist at its termination. It becomes rounded off in its lower third, and may be traced below to the small, subcutaneous surface of the styloid process. Internal to this border the lower fourth of the inner surface is to be felt. The styloid process presents itself as a prominent tubercle of bone, continuous above with the posterior subcutaneous border of the ulna, and terminating below in a blunt apex, which lies a little internal, and behind, but on a level with, the wrist-joint. The styloid process is best perceived when the hand is in the same line as the bones of the forearm, and in a position midway between supination and pronation. If the forearm is pronated while the finger is placed on the process, it will be felt to recede, and another prominence of bone will appear just behind and above it. This is the head of the ulna, which articulates with the lower end of the radius and the triangular interarticular fibro-cartilage, and now projects between the tendons of the Extensor carpi ulnaris and the Extensor minimi digiti muscles.

The Radius

The **Radius** (radius, *a ray*, or *spoke of a wheel*) is situated on the outer side of the forearm, lying side by side with the ulna, which exceeds it in length and size (figs. 291, 292). Its upper end is small, and forms only a slight part of the elbow-joint; but its lower end is large, and forms the chief part of the wrist. It is a long bone, prismatic in form, slightly curved longitudinally, and, like other long bones, has a shaft and two extremities.

The **Upper Extremity** presents a head, neck, and tuberosity. The *head* is of a cylindrical form, depressed on its upper surface into a shallow cup which articulates with the capitellum or radial head of the humerus. In the recent state it is covered with a layer of cartilage, which is thinnest at its centre. Around the circumference of the head is a smooth, articular surface, broad internally where it articulates with the lesser sigmoid cavity of the ulna; narrow in the rest of its circumference, where it rotates within the orbicular ligament. It is coated with cartilage in the recent state. The head is supported on a round, smooth, and constricted portion of bone, called the *neck*, which presents, behind, a slight ridge, for the insertion of part of the Supinator brevis. Beneath the neck, at the inner and front aspect of the bone, is a rough eminence, the *bicipital tuberosity*. Its surface is divided into two parts by a vertical line—a posterior, rough portion, for the insertion of the tendon of the Biceps muscle; and an anterior, smooth portion, on which a bursa is interposed between the tendon and the bone.

The **Shaft** of the bone is prismoid in form, narrower above than below, and slightly curved, so as to be convex outwards. It presents three surfaces, separated by three borders.

The **anterior border** extends from the lower part of the tuberosity above, to the anterior part of the base of the styloid process below. It separates the anterior from the external surface. Its upper third is very prominent; and from its oblique direction, downwards and outwards, has received the name of the *oblique line* of the radius. It gives insertion, externally, to the Supinator brevis; internally, there arises from it the Flexor longus pollicis, and between these the Flexor sublimis digitorum. The middle third of the anterior border is indistinct and rounded. Its lower fourth is sharp, prominent, affords insertion to the Pronator quadratus and gives attachment to the posterior annular ligament of the wrist; it terminates in a small tubercle, into which is inserted the tendon of the Supinator longus.

The **posterior border** commences above, at the back part of the neck of the radius, and terminates below, at the posterior part of the base of the styloid process; it separates the posterior from the external surface. It is indistinct above and below, but well marked in the middle third of the bone.

The **internal** or **interosseous border** commences above, at the back part of the tuberosity, where it is rounded and indistinct; it becomes sharp and prominent as it descends, and at its lower part divides into two ridges, which pass to the anterior and posterior margins of the sigmoid cavity. To the posterior of the two ridges the lower part of the interosseous membrane is attached, while the triangular surface between the ridges gives insertion to part of the Pronator quadratus. This border separates the anterior from the posterior surface, and has the interosseous membrane attached to it throughout the greater part of its extent.

The **anterior surface** is concave in its upper three-fourths, and gives origin to the Flexor longus pollicis muscle; it is broad and flat in its lower fourth, and gives insertion to the Pronator quadratus. A prominent ridge limits the attachment of the Pronator quadratus below, and between this and the inferior border is a triangular rough surface for the attachment of the anterior ligament of the wrist-joint. At the junction of the upper and middle third of this surface is the nutrient foramen, which is directed obliquely upwards.

The **posterior surface** is round, convex, and smooth in the upper third of its extent, and covered by the Supinator brevis muscle. Its middle third is broad, slightly concave, and gives origin to the Extensor ossis metacarpi pollicis above, the Extensor brevis pollicis below. Its lower third is broad, convex, and covered by the tendons of the muscles, which subsequently run in the grooves on the lower end of the bone.

The **external surface** is round and convex throughout its entire extent. Its upper third gives insertion to the Supinator brevis muscle. About its

centre is seen a rough ridge, for the insertion of the Pronator radii teres muscle. Its lower part is narrow, and covered by the tendons of the Extensor ossis metacarpi pollicis and Extensor brevis pollicis muscles.

The **Lower Extremity** of the radius is large, of quadrilateral form, and provided with two articular surfaces—one at the extremity, for articulation with the carpus, and one at the inner side of the bone, for articulation with the ulna. The carpal articular surface is triangular, concave, smooth, and divided by a slight antero-posterior ridge into two parts. Of these, the external is of a triangular form, and articulates with the scaphoid bone; the inner, quadrilateral, articulates with the semilunar. The articular surface for the ulna is called the *sigmoid cavity* of the radius; it is narrow, concave, smooth, and articulates with the head of the ulna. These two articular surfaces are separated from each other by a prominent ridge, to which is attached the base of the triangular fibro-cartilage; a structure which serves to separate the carpal joint from the inferior radio-ulnar articulation. The circumference of this end of the bone presents three surfaces—an anterior, external, and posterior. The *anterior surface*, rough and irregular, affords attachment to the anterior ligament of the wrist-joint. The *external surface* is prolonged obliquely downwards into a strong, conical projection, the *styloid process*, which gives attachment by its base to the tendon of the Supinator longus, and by its apex to the external lateral ligament of the wrist-joint. The outer surface of this process is marked by a flat groove, which runs obliquely downwards and forwards, and gives passage to the tendons of the Extensor ossis metacarpi pollicis, and the Extensor brevis pollicis. The *posterior surface* is convex, affords attachment to the posterior ligament of the wrist, and is marked by three grooves. Proceeding from without inwards, the first groove is broad, but shallow, and subdivided into two by a slight ridge: the outer of these two transmits the tendon of the Extensor carpi radialis longior, the inner the tendon of the Extensor carpi radialis brevior. The second, which is near the centre of the bone, is a deep but narrow groove, bounded on its outer side by a sharply defined ridge; it is directed obliquely from above, downwards and outwards, and transmits the tendon of the Extensor longus pollicis. The third, lying most internally, is a broad groove, for the passage of the tendons of the Extensor indicis and Extensor communis digitorum.

Fig. 294.—Plan of the development of the radius. By three centres.

Structure.—Similar to that of the other long bones.

Development (fig. 294).—By *three* centres: one for the shaft, and one for each extremity. That for the shaft makes its appearance near the centre of the bone, during the eighth week of fœtal life. About the end of the second year, ossification commences in the lower end; and at the fifth year, in the upper end. At the age of seventeen or eighteen the upper epiphysis becomes joined to the shaft; the lower epiphysis becoming united during the twentieth year.

Articulations.—With four bones: the humerus, ulna, scaphoid, and semilunar.

Attachment of Muscles.—To nine: to the tuberosity, the Biceps; to the oblique ridge, the Supinator brevis, Flexor sublimis digitorum, and Flexor longus pollicis; to the shaft (its anterior surface), the Flexor longus pollicis and Pronator quadratus; (its posterior surface), the Extensor ossis metacarpi pollicis and Extensor brevis pollicis; (its outer surface), the Pronator radii teres; and to the styloid process, the Supinator longus.

Surface Form.—Below, and a little in front of, the posterior surface of the external condyle a part of the head of the radius may be felt, covered by the orbicular and external lateral ligaments. There is in this situation a little dimple in the skin, which is most visible when the arm is extended, and which marks the position of the head of the bone. If the finger is placed on this dimple, and the semiflexed forearm pronated and supinated, the head of the bone will be distinctly perceived rotating in the lesser sigmoid cavity. The upper half of the shaft of the radius cannot be felt, as it is surrounded by the fleshy bellies of the muscles arising from the external condyle. The lower half of the shaft can be readily examined, though covered by tendons and muscles and not strictly subcutaneous. If traced downwards, the shaft will be felt to terminate in a lozenge-shaped, convex surface on the outer side of the base of the styloid process. This is the only subcutaneous part of the bone, and from its lower extremity the apex of the styloid process will be felt bending inwards towards the wrist. About the middle of the posterior aspect of the lower extremity of the bone is a well-marked ridge, the *dorsal radial tubercle*, best perceived when the hand is slightly flexed on the wrist. It forms the outer boundary of the oblique groove on the posterior surface of the bone, through which the tendon of the Extensor longus pollicis runs, and serves to keep that tendon in its place.

Surgical Anatomy.—Cases of congenital absence, either partial or complete, of both radius and ulna, have been recorded. Absence of the radius is not uncommonly accompanied by absence of the thumb. The two bones of the forearm are more often broken together, than is either the radius or ulna separately. It is therefore convenient to consider the fractures of both bones in the first instance and subsequently to mention the principal fractures which take place in each bone. These fractures may be produced by either direct or indirect violence, though more commonly by direct violence. When indirect force is applied to the forearm the radius as a rule alone gives way, though both bones may suffer. The fracture from indirect force generally takes place somewhere about the middle of the bones, fracture from direct violence may occur at any part, more often, however, in the lower half of the bones. The fracture is usually transverse, but may be more or less oblique. A point of interest in connection with these fractures is the tendency that there is for the two bones to unite across the interosseous membrane; the limb should therefore be put up in a position midway between supination and pronation, which is not only the most comfortable position, but also separates the bones most widely from each other and therefore diminishes the risk of the bones becoming united across the interosseous membrane. The splints, anterior and posterior, which are applied in these cases should be rather wider than the limb, so as to prevent any lateral pressure on the bones. In these cases there is a greater liability to gangrene from the pressure of the splints than in other parts of the body. This is no doubt due principally to two causes: (1) the flexion of the forearm compressing to a certain extent the brachial artery and retarding the flow of blood to the limb; and (2) the superficial position of the two main arteries of the forearm in a part of their course, and their liability to be compressed by the splints. The special fractures of the ulna are: (1) fracture of the olecranon. This is usually caused by direct violence, as in falls on the elbow with the forearm flexed, but occasionally by muscular action by the sudden contraction of the Triceps. The most common place for the fracture to occur is at the constricted portion where the olecranon joins the shaft of the bone, and the fracture may be either transverse or oblique; but any part may be broken, and even a thin shell may be torn off. Fractures from direct violence are occasionally comminuted. The displacement is sometimes very slight, owing to the fibrous structures around the process not being torn. (2) Fracture of the coronoid process may occur as a complication of dislocation backwards of the bones of the forearm, but it is doubtful if it ever occurs as an uncomplicated injury. (3) Fractures of the shaft of the ulna may occur at any part, but usually take place at the middle of the bone or a little below it. They are generally the result of direct violence, but may occur as a complication of dislocation of the radius. (4) The styloid process may be knocked off by direct violence. Fractures of the radius consist of (1) fracture of the head of the bone; this for the most part takes place in conjunction with some other lesion, but may occur as an uncomplicated injury. (2) Fracture of the neck may also take place, but is usually complicated with other injury. (3) Fractures of the shaft of the radius are very common, and may take place at any part of the bone. They may be caused either by direct or indirect violence. In fractures of the upper third of the shaft of the bone—that is to say, above the insertion of the Pronator radii teres—the displacement is very great. The upper fragment is strongly supinated by the Biceps and Supinator brevis, and flexed by the Biceps; while the lower fragment is pronated and drawn towards the ulna by the two pronators. If such a fracture is put up in the ordinary position, midway between supination and pronation, the fracture will unite with the upper fragment in a position of supination, and the lower one in the mid-position, and thus considerable impairment of the movements of the hand will result. The limb should be put up with the forearm supinated. (4) The most important fracture of the radius is that of the lower end (Colles's fracture). The fracture is transverse, and generally takes place about an inch from the lower extremity. It is caused by falls on the palm of the hand, and is an injury of advanced life, occurring more

Fig. 295.—Bones of the left hand. Dorsal surface.

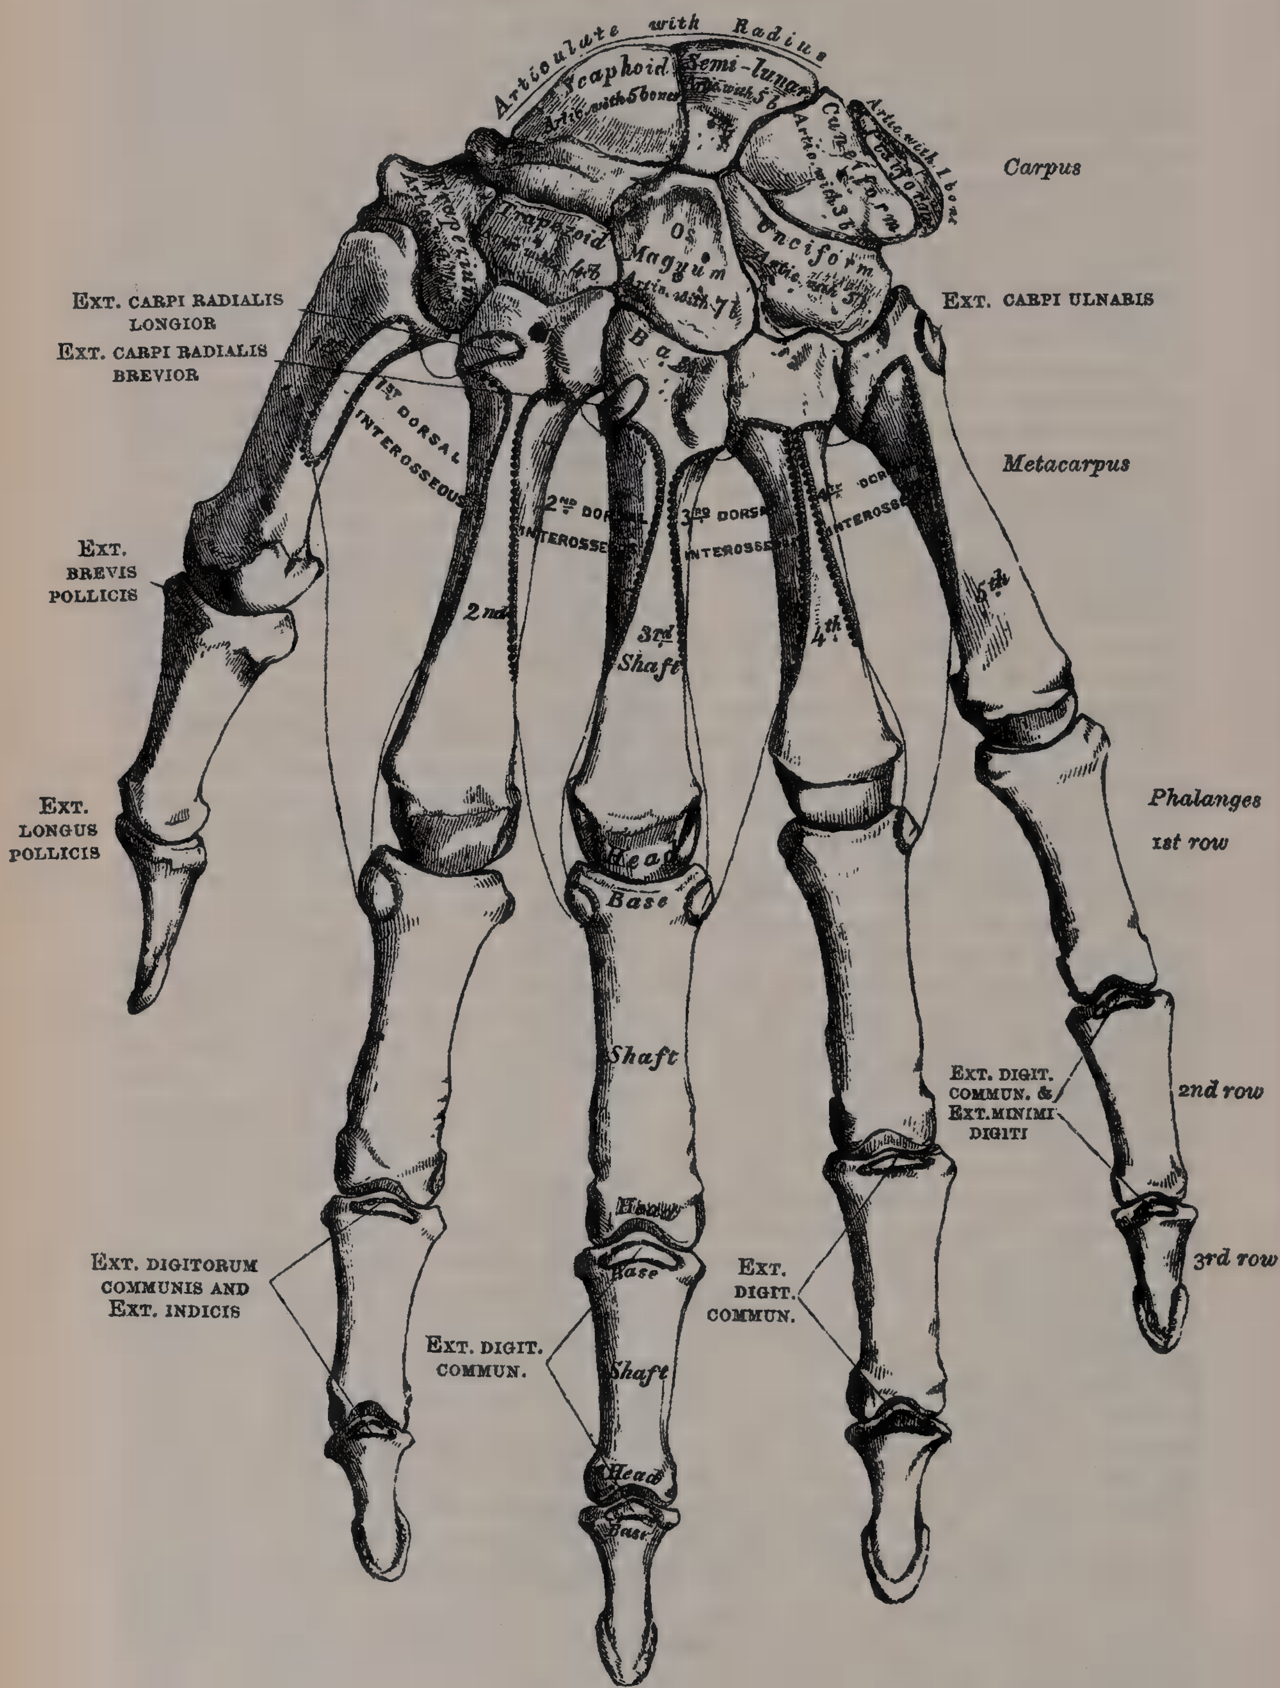


FIG. 296.—Bones of the left hand. Palmar surface.

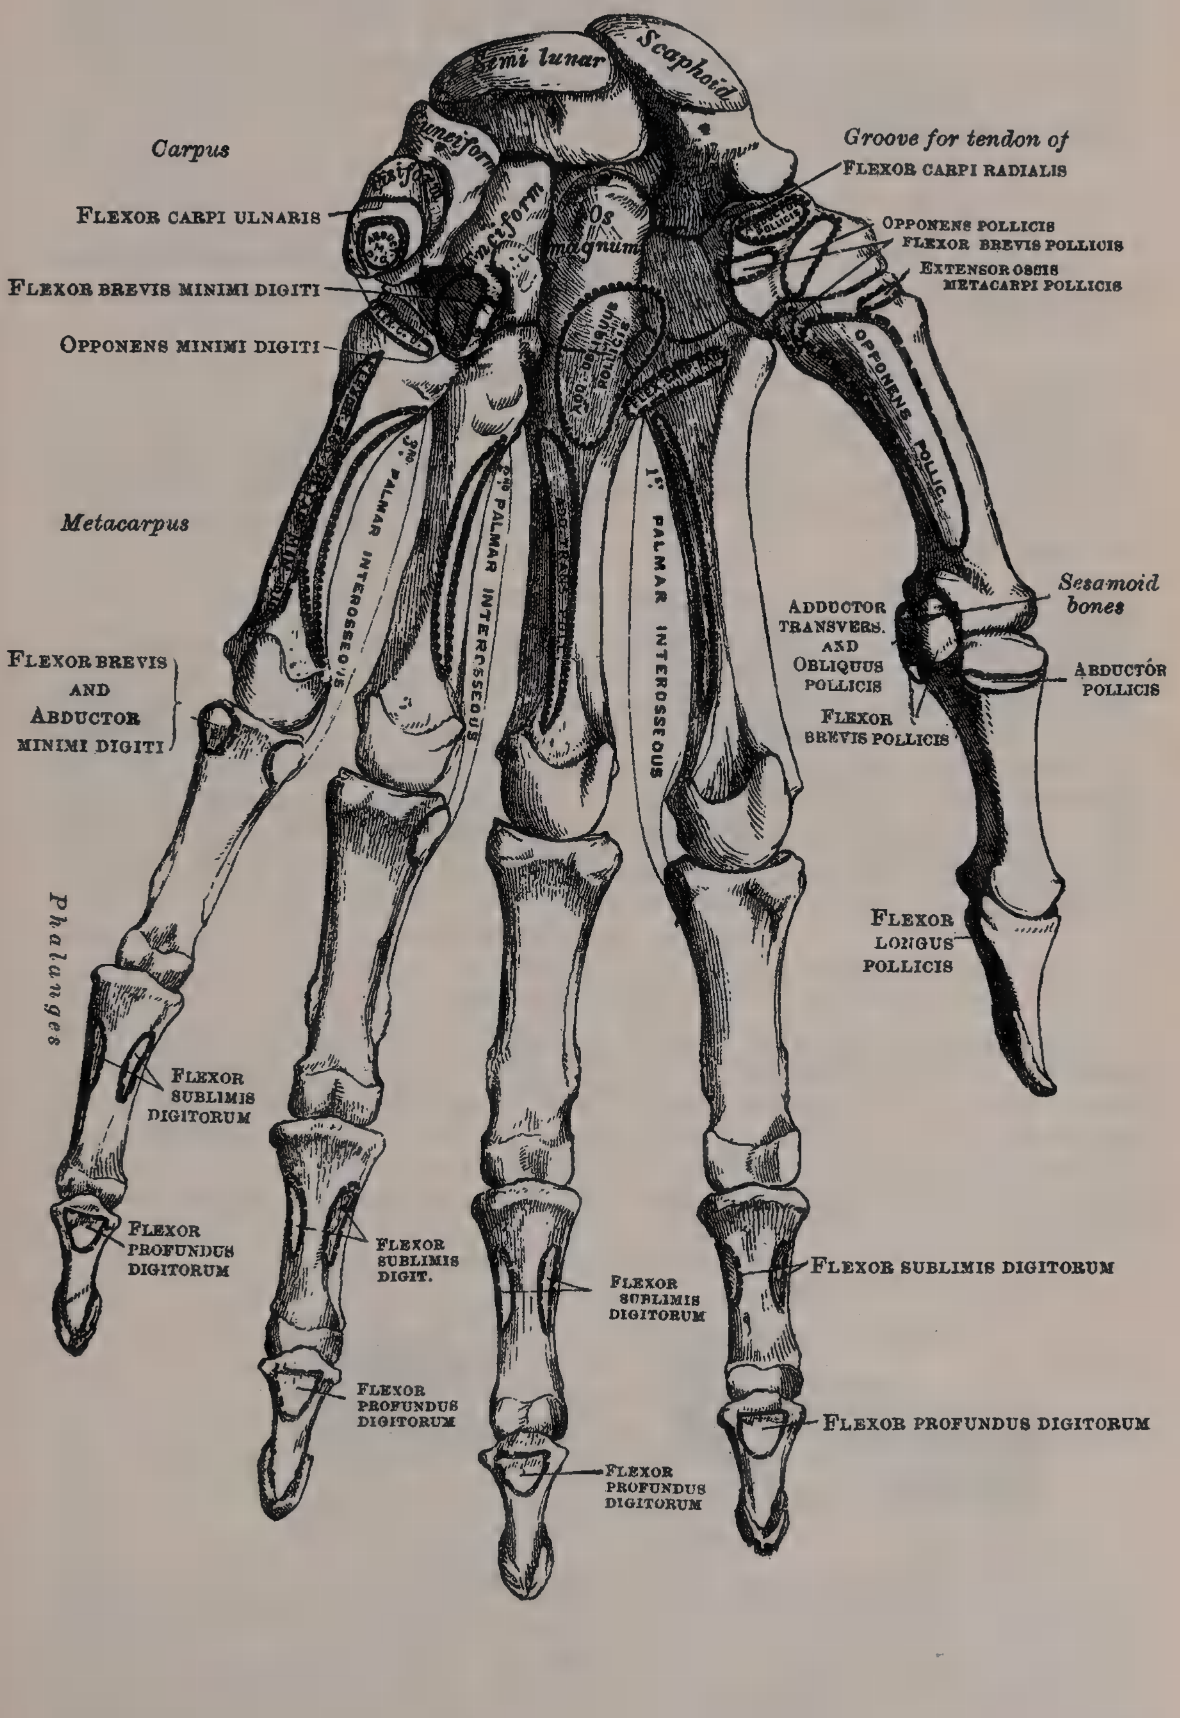


frequently in the female than in the male. In consequence of the manner in which the fracture is caused, the upper fragment becomes driven into the lower, and impaction is the result; excess of violence may, however, disimpact; the lower fragment becoming split up into two or more pieces, so that no fixation occurs. Separation of the lower epiphysis of the radius may take place in the young. This injury and Colles's fracture may be distinguished from other injuries in this neighbourhood—especially dislocation, with which it is liable to be confounded—by observing the relative positions of the styloid processes of the ulna and radius. In the natural condition of parts, with the arm hanging by the side, the styloid process of the radius is on a lower level than that of the ulna: that is to say, nearer the ground. After fracture or separation of the epiphysis this process is on the same or on a higher level than that of the ulna, whereas it would be unaltered in position in dislocation.

THE HAND

The skeleton of the Hand is subdivided into three segments—the Carpus or wrist bones; the Metacarpus or bones of the palm; and the Phalanges or bones of the digits.

THE CARPUS

The bones of the **Carpus** (καρπός, *the wrist*), eight in number, are arranged in two rows. Those of the upper row, enumerated from the radial to the ulnar side, are the scaphoid, semilunar, cuneiform, and pisiform; those of the lower row, enumerated in the same order, are the trapezium, trapezoid, os magnum, and unciform.

Common Characters of the Carpal Bones

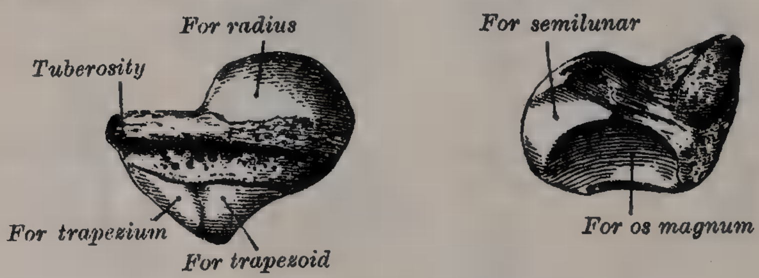
Each bone (excepting the pisiform) presents six surfaces. Of these the *anterior* or *palmar* and the *posterior* or *dorsal* are rough, for ligamentous attachment; the dorsal surface being the broader, except in the scaphoid and semilunar. The *superior* or *proximal* and *inferior* or *distal* are articular, the superior generally convex, the inferior concave; and the *internal* and *external* are also articular when in contact with contiguous bones, otherwise rough and tubercular. The structure in all is similar, consisting of cancellous tissue enclosed in a layer of compact bone. Each bone is also developed from a single centre of ossification.

Bones of the Upper Row

Scaphoid (fig. 297)

The **Scaphoid** is the largest bone of the first row. It has received its name from its fancied resemblance to a boat, being broad at one end, and narrowed, like a prow, at the opposite (σκάφη, *a boat*; εἶδος, *like*). It is situated at the upper and outer part of the carpus, its long axis being from above downwards, outwards, and forwards. The *superior surface* is convex, smooth, of triangular shape, and articulates with the lower end of the radius. The *inferior surface*,

Fig. 297.—The left scaphoid.



directed downwards, outwards, and backwards, is smooth, convex, also triangular, and divided by a slight ridge into two parts, the external of which articulates with the trapezium, the inner with the trapezoid. The *posterior* or *dorsal surface* presents a narrow, rough groove, which runs the entire length of the bone, and serves for the attachment of ligaments. The *anterior* or *palmar surface* is concave above, and elevated at its lower and outer part into a prominent, rounded pro-

jection, called the *tuberosity*, which projects forwards from the front of the carpus and gives attachment to the anterior annular ligament of the wrist and sometimes origin to a few fibres of the Abductor pollicis. The *external surface* is rough and narrow, and gives attachment to the external lateral ligament of the wrist. The *internal surface* presents two articular facets; of these, the superior or smaller is flattened, of semilunar form, and articulates with the semilunar; the inferior or larger is concave, forming, with the semilunar bone, a concavity for the head of the os magnum.

To ascertain to which hand the bone belongs, hold it with the superior or radial, convex, articular surface upwards, and the posterior surface—i.e. the narrow, non-articular, grooved surface—towards you. The tubercle on the outer surface points to the side to which the bone belongs.*

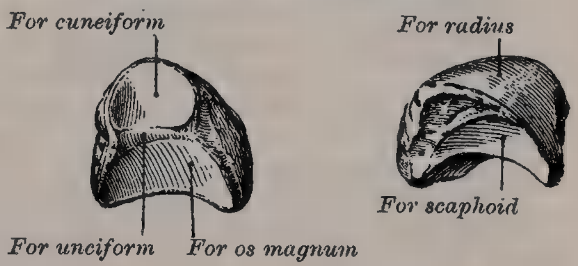
Articulations.—With five bones: the radius above, trapezium and trapezoid below, os magnum and semilunar internally.

Attachment of Muscles.—Occasionally a few fibres of the Abductor pollicis.

Semilunar (fig. 298)

The **Semilunar** bone may be distinguished by its deep concavity and crescentic outline (*semi*, half; *luna*, moon). It is situated in the centre of the upper row of the carpus, between the scaphoid and cuneiform. The *superior surface*, convex, smooth, and bounded by four edges, articulates with the radius. The *inferior surface* is deeply concave, and of greater extent from before backwards than transversely: it articulates with the head of the os magnum, and, by a long, narrow facet (separated by a ridge from the general surface), with the unciform bone. The *anterior* or *palmar* and *posterior* or *dorsal surfaces* are rough, for the attachment of ligaments, the former being the broader, and of a somewhat rounded form. The *external surface* presents a narrow, flattened, semilunar facet for articulation with the scaphoid. The *internal surface* is marked by a smooth, quadrilateral facet, for articulation with the cuneiform.

Fig. 298.—The left semilunar.



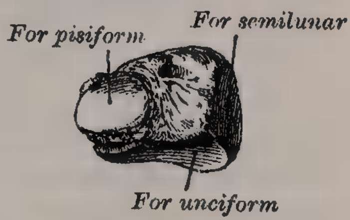
Hold it with the convex articular surface for the radius upwards, and the narrowest non-articular surface towards you. The semilunar facet for the scaphoid will be on the side to which the bone belongs.

Articulations.—With five bones: the radius above, os magnum and unciform below, scaphoid and cuneiform on either side.

Cuneiform (fig. 299)

The **Cuneiform** (cuneus, *a wedge*; forma, *likeness*) may be distinguished by its pyramidal shape (*os triquetrum*), and by its having an oval, isolated facet for articulation with the pisiform bone. It is situated at the upper and inner side of the carpus. The *superior surface* presents an internal, rough, non-articular portion, and an external or articular portion, which is convex, smooth, and articulates with the triangular interarticular fibro-cartilage of the wrist. The *inferior surface*, directed outwards, is concave, sinuously curved, and smooth for articulation with the unciform. The *posterior* or *dorsal surface* is rough for the attachment of ligaments. The *anterior* or *palmar surface* presents, at its inner side, an oval facet, for articulation with the pisiform; and is rough externally,

Fig. 299.
The left cuneiform.



* In these directions each bone is supposed to be placed in its natural position—that is, such a position as it would occupy when the arm is hanging by the side, the forearm in a position of supination, the thumb being directed outwards and the palm of the hand looking forwards.

for ligamentous attachment. The *external surface*, the base of the pyramid, is marked by a flat, quadrilateral, smooth facet, for articulation with the semilunar. The *internal surface*, the summit of the pyramid, is pointed and roughened, for the attachment of the internal lateral ligament of the wrist.

Hold the bone with the surface supporting the pisiform facet away from you, and the concavo-convex surface for the unciform downwards. The base of the wedge (i.e. the broad end of the bone) will be on the side to which it belongs.

Articulations.—With three bones: the semilunar externally, the pisiform in front, the unciform below; and with the triangular, interarticular fibro-cartilage which separates it from the lower end of the ulna.

Pisiform (fig. 300)

The **Pisiform** (pisum, *a pea*; forma, *likeness*) may be known by its small size, and by its presenting a single articular facet. It is situated on a plane anterior to the other bones of the carpus; it is spheroidal in form, with its long diameter directed vertically. Its *posterior* surface presents a smooth, oval facet, for articulation with the cuneiform: this facet approaches the superior, but not the inferior, border of the bone. The *anterior* or *palmar surface* is rounded and rough, and gives attachment to the anterior annular ligament and to the Flexor carpi ulnaris and Abductor minimi digiti muscles. The *outer* and *inner surfaces* are also rough, the former being concave, the latter usually convex.

Fig. 300.
The left pisiform.

Hold the bone with the posterior surface—that which presents the articular facet—towards you, in such a manner that the faceted portion of the surface is uppermost. The outer, concave surface will point to the side to which it belongs.

Articulation.—With one bone, the cuneiform.

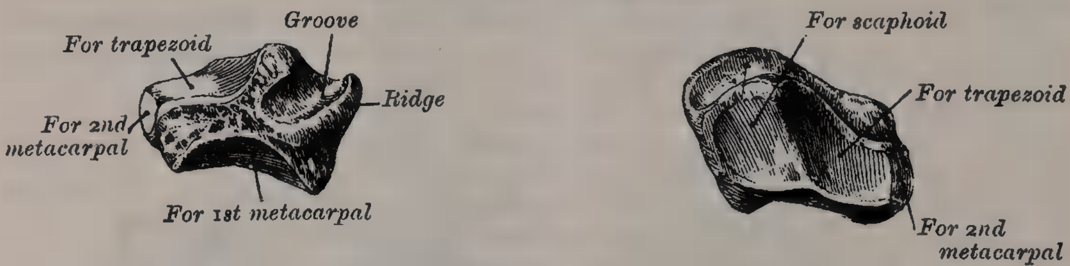
Attachment of Muscles.—To two: the Flexor carpi ulnaris and Abductor minimi digiti; and to the anterior annular ligament.

Bones of the Lower Row

Trapezium (fig. 301)

The **Trapezium** (τράπεζα, *a table*) is of very irregular form. It may be distinguished by a deep groove, for the tendon of the Flexor carpi radialis muscle. It is situated at the external and inferior part of the carpus, between the scaphoid and first metacarpal bone. The *superior surface* is directed upwards and inwards; internally, it is smooth, and articulates with the scaphoid; externally, it is

Fig. 301.—The left trapezium.



rough, and becomes continuous with the external surface. The *inferior surface*, directed downwards and inwards, is oval, concave from side to side, convex from before backwards, so as to form a saddle-shaped surface, for articulation with the base of the first metacarpal bone. The *anterior* or *palmar surface* is narrow and rough. At its upper part is a deep groove, running from above obliquely downwards and inwards: it transmits the tendon of the Flexor carpi radialis, and is bounded externally by a prominent ridge, the *oblique ridge* of the trapezium. This surface gives origin to the Abductor pollicis, Opponens pollicis, and Flexor brevis pollicis muscles, and also affords attachment to the anterior annular

ligament. The *posterior* or *dorsal surface* is rough. The *external surface* is also broad and rough, for the attachment of ligaments. The *internal surface* presents two articular facets: the upper one, large and concave, articulates with the trapezoid; the lower one, small and oval, with the base of the second metacarpal bone.

Hold the bone with the saddle-shaped surface downwards and the grooved surface away from you. The prominent, rough, non-articular surface points to the side to which the bone belongs.

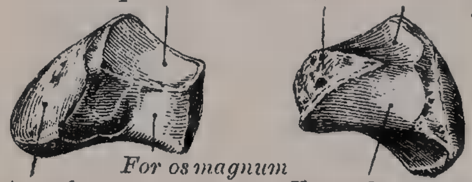
Articulations.—With four bones: the scaphoid above, the trapezoid and second metacarpal bones internally, the first metacarpal below.

Attachment of Muscles.—Abductor pollicis, Opponens pollicis, and part of the Flexor brevis pollicis.

Trapezoid (fig. 302)

The **Trapezoid** is the smallest bone in the second row. It may be known by its wedge-shaped form, the broad end of the wedge forming the dorsal, the narrow end the palmar surface; and by its having four articular surfaces touching each other, and separated by sharp edges. The *superior surface,* quadrilateral in form, smooth, and slightly concave, articulates with the scaphoid. The *inferior surface* articulates with the upper end of the second metacarpal bone; it is convex from side to side, concave from before backwards, and subdivided, by an elevated ridge, into two unequal lateral facets. The *posterior* or *dorsal* and *anterior* or *palmar surfaces* are rough, for the attachment of ligaments, the former being the larger of the two. The *external surface,* convex and smooth, articulates with the trapezium. The *internal surface* is concave and smooth in front, for articulation with the os magnum; rough behind, for the attachment of an interosseous ligament.

Fig. 302.—The left trapezoid.



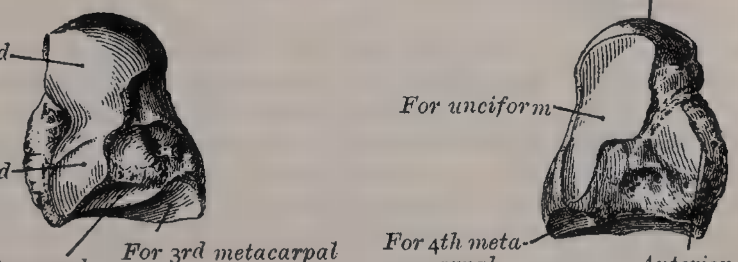
Hold the bone with the larger, non-articular surface towards you, and the smooth, quadrilateral articular surface upwards. The convex, articular surface will point to the side to which the bone belongs.*

Articulations.—With four bones: the scaphoid above, second metacarpal bone below, trapezium externally, os magnum internally.

Os Magnum (fig. 303)

The **Os Magnum** is the largest bone of the carpus, and occupies the centre of the wrist. It presents, above, a rounded portion or head, which is received into

Fig. 303.—The left os magnum.



the concavity formed by the scaphoid and semilunar bones; a constricted portion or neck; and below this, the body. The *superior surface* is round, smooth, and

* Occasionally in a badly marked bone there is some difficulty in ascertaining to which side this bone belongs; the following method will sometimes be found useful. Hold the bone with its broader, non-articular surface upwards, so that its sloping border is directed towards you. The border will slope to the side to which the bone belongs.

articulates with the semilunar. The *inferior surface* is divided by two ridges into three facets, for articulation with the second, third, and fourth metacarpal bones, that for the third (the middle facet) being the largest of the three. The *posterior* or *dorsal surface* is broad and rough; the *anterior* or *palmar*, narrow, rounded, and also rough, for the attachment of ligaments and a part of the Adductor obliquus pollicis. The *external surface* articulates with the trapezoid by a small facet at its anterior inferior angle, behind which is a rough depression for the attachment of an interosseous ligament. Above this is a deep and rough groove, which forms part of the neck, and serves for the attachment of ligaments, bounded superiorly by a smooth, convex surface, for articulation with the scaphoid. The *internal surface* articulates with the unciform by a smooth, concave, oblong facet, which occupies its posterior and superior parts; and is rough in front, for the attachment of an interosseous ligament.

Hold the bone with the broader, non-articular surface towards you, and the head upwards. The small, articular facet at the anterior inferior angle of the external surface will point to the side to which the bone belongs.

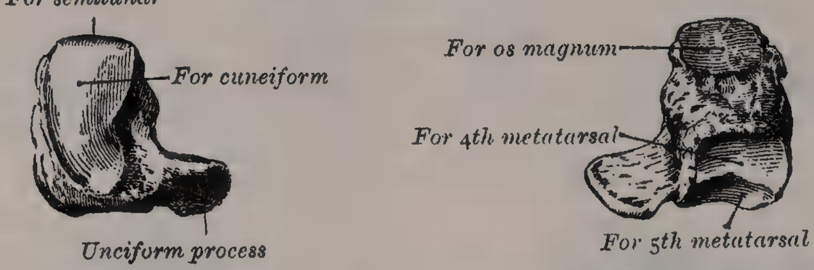
Articulations.—With seven bones: the scaphoid and semilunar above; the second, third, and fourth metacarpal bones below; the trapezoid on the radial side; and the unciform on the ulnar side.

Attachment of Muscles.—Part of the Adductor obliquus pollicis.

Unciform (fig. 304)

The **Unciform** (uncus, *a hook*; forma, *likeness*) may be readily distinguished by its wedge-shaped form, and the hook-like process which projects from its palmar surface. It is situated at the inner and lower angle of the carpus, with its base downwards, resting on the two inner metacarpal bones, and its apex directed upwards and outwards. The *superior surface*, the apex of the wedge, is narrow, convex, smooth, and articulates with the semilunar. The *inferior surface* articulates with the fourth and fifth metacarpal bones, the concave surface for each being separated by a ridge, which runs from before backwards. The *posterior* or *dorsal surface* is triangular and rough, for ligamentous attachment. The *anterior* or *palmar surface* presents, at its lower and inner side, a curved, hook-like process of bone, the *unciform process*, directed from the palmar surface forwards and outwards. It gives attachment, by its apex, to the annular ligament and the Flexor carpi ulnaris; by its inner surface to the Flexor brevis minimi digiti and the Opponens minimi digiti; and is grooved on its outer side, for the passage

Fig. 304.—The left unciform.



of the Flexor tendons into the palm of the hand. This is one of the four eminences on the front of the carpus to which the anterior annular ligament is attached; the others being the pisiform internally, the oblique ridge of the trapezium and the tuberosity of the scaphoid externally. The *internal surface* articulates with the cuneiform by an oblong facet, cut obliquely from above, downwards and inwards. The *external surface* articulates with the os magnum by its upper and posterior part, the remaining portion being rough, for the attachment of ligaments.

Hold the bone with the hooked process away from you, and the articular surface, divided into two parts for the metacarpal bones, downwards. The concavity of the process will be on the side to which the bone belongs.

Articulations.—With five bones: the semilunar above, the fourth and fifth metacarpal below, the cuneiform internally, the os magnum externally.

Attachment of Muscles.—To three: the Flexor brevis minimi digiti, the Opponens minimi digiti, the Flexor carpi ulnaris.

THE METACARPUS

The **Metacarpal Bones** are five in number: they are long cylindrical bones, presenting for examination a shaft and two extremities.

Common Characters of the Metacarpal Bones

The **shaft** is prismoid in form, and curved longitudinally, so as to be convex in the longitudinal direction behind, concave in front. It presents three surfaces: two lateral and one posterior. The *lateral surfaces* are concave, for the attachment of the Interossei muscles, and separated from one another by a prominent anterior ridge. The *posterior* or *dorsal surface* presents in its distal half a smooth, triangular, flattened area which is covered, in the recent state, by the tendons of the Extensor muscles. This triangular surface is bounded by two lines, which commence in small tubercles situated on the dorsal aspect on either side of the digital extremity, and, running backwards, converge to meet some distance behind the centre of the bone and form a ridge which runs along the rest of the dorsal surface to the carpal extremity. This ridge separates two lateral, sloping surfaces for the attachment of the Dorsal interossei muscles.* To the tubercles on the digital extremities are attached the lateral ligaments of the metacarpo-phalangeal joints.

The **carpal extremity,** or **base,** is of a cuboidal form, and broader behind than in front: it articulates above with the carpus, and on each side with the adjoining metacarpal bones; its *dorsal* and *palmar surfaces* are rough, for the attachment of tendons and ligaments.

The **digital extremity,** or **head,** presents an oblong surface markedly convex from before backwards, less so from side to side, and flattened laterally; it articulates with the proximal phalanx; it is broader, and extends farther forwards, on the palmar than on the dorsal aspect. It is longer in the antero-posterior than in the transverse diameter. On either side of the head is a tubercle for the attachment of the lateral ligament of the metacarpo-phalangeal joint. The *posterior surface,* broad and flat, supports the Extensor tendons; the *anterior surface* is grooved in the middle line for the passage of the Flexor tendons and marked on each side by an articular eminence continuous with the terminal articular surface.

Peculiar Characters of the Metacarpal Bones

The **metacarpal bone of the thumb** (fig. 305) is shorter and stouter than the rest, diverges to a greater degree from the carpus, and its *palmar surface* is directed inwards towards the palm. The *shaft* is flattened and broad on its dorsal aspect, and does not present the ridge which is found on the other metacarpal bones; it is concave from above downwards, on its palmar surface. On its outer border is inserted the Opponens pollicis muscle, while its inner border gives origin to the outer head of the First dorsal interosseous muscle. The *carpal extremity,* or *base,* presents a concavo-convex surface, for articulation with the trapezium; it has no lateral facets, but presents externally a tubercle for the insertion of the Extensor ossis metacarpi pollicis. The *digital extremity* is less convex than that of the other metacarpal bones, broader from side to side than from before backwards. It presents on its palmar aspect two distinct articular eminences for the two sesamoid bones in the tendons of the Flexor brevis pollicis; the outer one being the larger of the two.

Fig. 305.—The first metacarpal. (Left.)

The side to which this bone belongs may be known by holding it in the position it occupies in the hand, with the carpal extremity upwards and the

* By these sloping surfaces the metacarpal bones of the hand may be at once distinguished from the metatarsal bones of the foot.

dorsal surface backwards; the tubercle for the Extensor ossis metacarpi pollicis will point to the side to which it belongs.

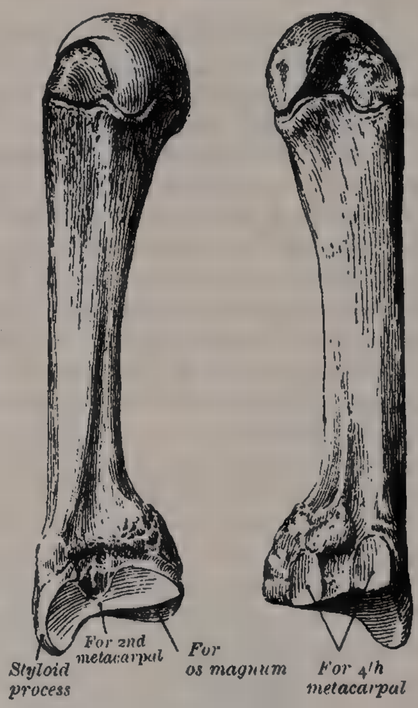
Attachment of Muscles.—To four: the Opponens pollicis, the Extensor ossis metacarpi pollicis, the Flexor brevis pollicis, and the First dorsal interosseous.

The **metacarpal bone of the index finger** (fig. 306) is the longest, and its base the largest, of the four remaining bones. Its *carpal extremity* is prolonged upwards and inwards, forming a prominent ridge. The dorsal and palmar surfaces of this extremity are rough, for the attachment of tendons and ligaments. It presents four articular facets: three on the upper aspect of the base; the middle one of the three is the largest, concave from side to side, convex from before backwards for articulation with the trapezoid; the external one is a small, flat, oval facet, for articulation with the trapezium; the internal one, on the summit of the ridge, is long and narrow, for articulation with the os magnum. The fourth facet is on the inner or ulnar side of the extremity of the bone, and is for articulation with the third metacarpal bone.

The side to which this bone belongs is indicated by the absence of the lateral facet on the outer (radial) side of its base, so that if the bone is placed with its

Fig. 306.—The second metacarpal. (Left.)

Fig. 307.—The third metacarpal. (Left.)



base towards the student, and the palmar surface upwards, the side on which there is no lateral facet will be that to which it belongs.

Attachment of Muscles.—To six: Flexor carpi radialis, Extensor carpi radialis longior, Adductor obliquus pollicis, First and Second dorsal interossei, and First palmar interosseous.

The **metacarpal bone of the middle finger** (fig. 307) is a little smaller than the preceding; it presents a pyramidal eminence, the *styloid process*, on the radial side of its base (dorsal aspect), which extends upwards behind the os magnum; immediately below this, on the dorsal aspect, is a rough surface for the attachment of the Extensor carpi radialis brevior. The carpal articular facet is concave behind, flat in front, and articulates with the os magnum. On the radial side is a smooth, concave facet for articulation with the second metacarpal bone, and on the ulnar side two small, oval facets, for articulation with the fourth metacarpal.

The side to which this bone belongs is easily recognised by the styloid process on the radial side of its base. With the palmar surface uppermost, and the base towards the student, this process points towards the side to which the bone belongs.

Attachment of Muscles.—To six: Extensor carpi radialis brevior, Flexor carpi

radialis, Adductor transversus pollicis, Adductor obliquus pollicis, and Second and Third dorsal interossei.

The **metacarpal bone of the ring-finger** (fig. 308) is shorter and smaller than the preceding, and its base small and quadrilateral; the carpal surface of the base presenting two facets, a large one externally for articulation with the unciform, and a small one internally for the os magnum. On the radial side are two oval facets, for articulation with the third metacarpal bone; and on the ulnar side, a single concave facet, for the fifth metacarpal.

If this bone is placed with the base towards the student, and the palmar surface upwards, the radial side of the base, which has two facets for articulation with the third metacarpal bone, will be on the side to which it belongs. If, as sometimes happens in badly marked bones, one of these facets is indistinguishable, the side may be known by selecting the surface on which the larger articular facet is present. This facet is for the fifth metacarpal bone, and would therefore be situated on the ulnar side—that is, the one to which the bone does *not* belong.

Attachment of Muscles.—To three: the Third and Fourth dorsal and Second palmar interossei.

Fig. 308.—The fourth metacarpal. (Left.)

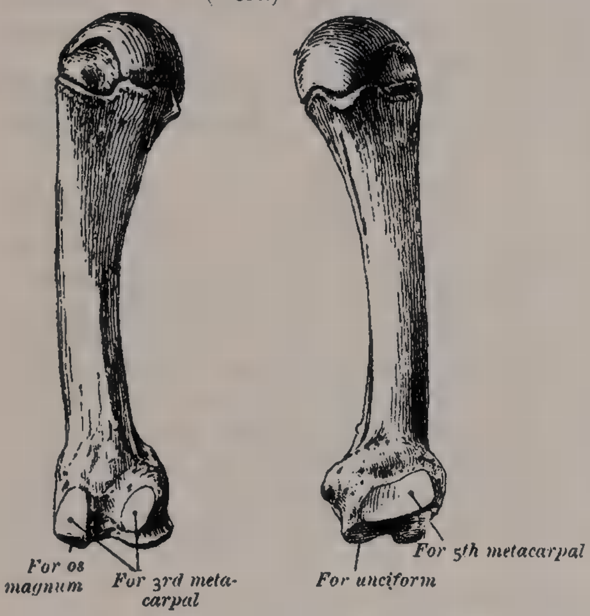


Fig. 309.—The fifth metacarpal. (Left.)

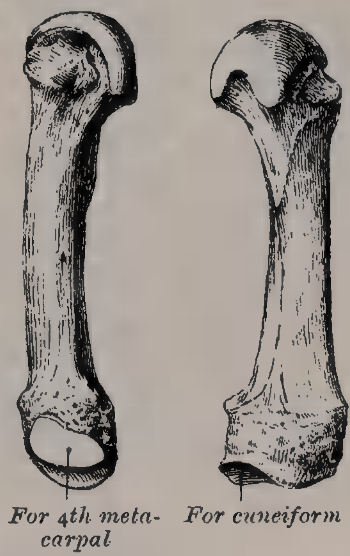


The **metacarpal bone of the little finger** (fig. 309) presents on its base one facet, which is concavo-convex, and articulates with the unciform bone, and one lateral, articular facet on its radial side, which articulates with the fourth metacarpal bone. On its ulnar side is a prominent tubercle, for the insertion of the tendon of the Extensor carpi ulnaris. The dorsal surface of the shaft is marked by an oblique ridge, which extends from near the ulnar side of the upper extremity to the radial side of the lower. The outer division of this surface serves for the attachment of the Fourth dorsal interosseous muscle; the inner division is smooth, triangular, and covered by the Extensor tendons of the little finger.

If this bone is placed with its base towards the student, and its palmar surface upwards, the side of the head which has a lateral facet will be that to which the bone belongs.

Attachment of Muscles.—To five: the Extensor carpi ulnaris, Flexor carpi ulnaris, Opponens minimi digiti, Fourth dorsal, and Third palmar interossei.

Articulations.—Besides the phalangeal articulations, the first metacarpal bone articulates with the trapezium; the second with the trapezium, trapezoid, os magnum, and third metacarpal bone; the third with the os magnum, and second and fourth metacarpal bones; the fourth with the os magnum, unciform, and third and fifth metacarpal bones; and the fifth with the unciform and fourth metacarpal bone.

The *first* has no lateral facets on its carpal extremity; the *second* has no

lateral facet on its radial side, but one on its ulnar side; the third has one on its radial and two on its ulnar side; the fourth has two on its radial and one on its ulnar side; and the fifth has one on its radial side only.

THE PHALANGES

The **Phalanges** (*internodia*) are the bones of the digits; they are fourteen in number, three for each finger, and two for the thumb. They are long bones, and present for examination a shaft and two extremities. The *shaft* tapers from above downwards, is convex posteriorly, concave in front from above downwards, flat from side to side, and marked laterally by rough ridges, which give attachment to the fibrous sheaths of the Flexor tendons. The *metacarpal extremity* or *base*, in the first row presents an oval, concave, articular surface, broader from side to side than from before backwards; and the same extremity in the other two rows, a double concavity, separated by a longitudinal median ridge, extending from before backwards. The *digital extremities* are smaller than the bases, and terminate, in the first and second rows, in two small, lateral condyles, separated by a slight groove; the articular surface being prolonged farther on the palmar than on the dorsal surface, especially in the first row.

The **Ungual Phalanges** are convex on their dorsal, flat on their palmar surfaces; they are recognised by their small size, and by a roughened, elevated surface of a horse-shoe form on the palmar aspect of their ungual extremity, which serves to support the sensitive pulp of the finger.

Articulations.—The first row with the metacarpal bones and the second row of phalanges; the second row with the first and third; the third with the second row.

Attachment of Muscles.—To the base of the first phalanx of the thumb, five muscles: the Extensor brevis pollicis, Flexor brevis pollicis, Abductor pollicis, Adductor transversus and obliquus pollicis. To the second phalanx, two: the Flexor longus pollicis and the Extensor longus pollicis. To the base of the first phalanx of the index finger, the First dorsal and the First palmar interosseous; to that of the middle finger, the Second and Third dorsal interosseous; to that of the ring-finger, the Fourth dorsal and the Second palmar interosseous; and to that of the little finger, the Third palmar interosseous, the Flexor brevis minimi digiti, and Abductor minimi digiti. To the second phalanges, the Flexor sublimis digitorum, Extensor communis digitorum, and, in addition, the Extensor indicis to the index finger, the Extensor minimi digiti to the little finger. To the third phalanges, the Flexor profundus digitorum and Extensor communis digitorum.

Development of the Bones of the Hand

The **Carpal Bones** are each developed by a *single* centre. At birth, they are all cartilaginous. Ossification proceeds in the following order (fig. 310): In the os magnum and unciform an ossific point appears during the first year, the former preceding the latter; in the cuneiform, at the third year; in the semilunar and trapezium, at the fifth year, the former preceding the latter; in the scaphoid, at the sixth year; in the trapezoid, during the eighth year; and in the pisiform, about the twelfth year.

Occasionally an additional bone, the *os centrale*, is found on the back of the carpus, lying between the scaphoid, trapezoid, and os magnum. During the second month of fœtal life it is represented by a small cartilaginous nodule, which usually fuses with the cartilaginous scaphoid. Sometimes the styloid process of the third metacarpal is detached and forms an additional ossicle.

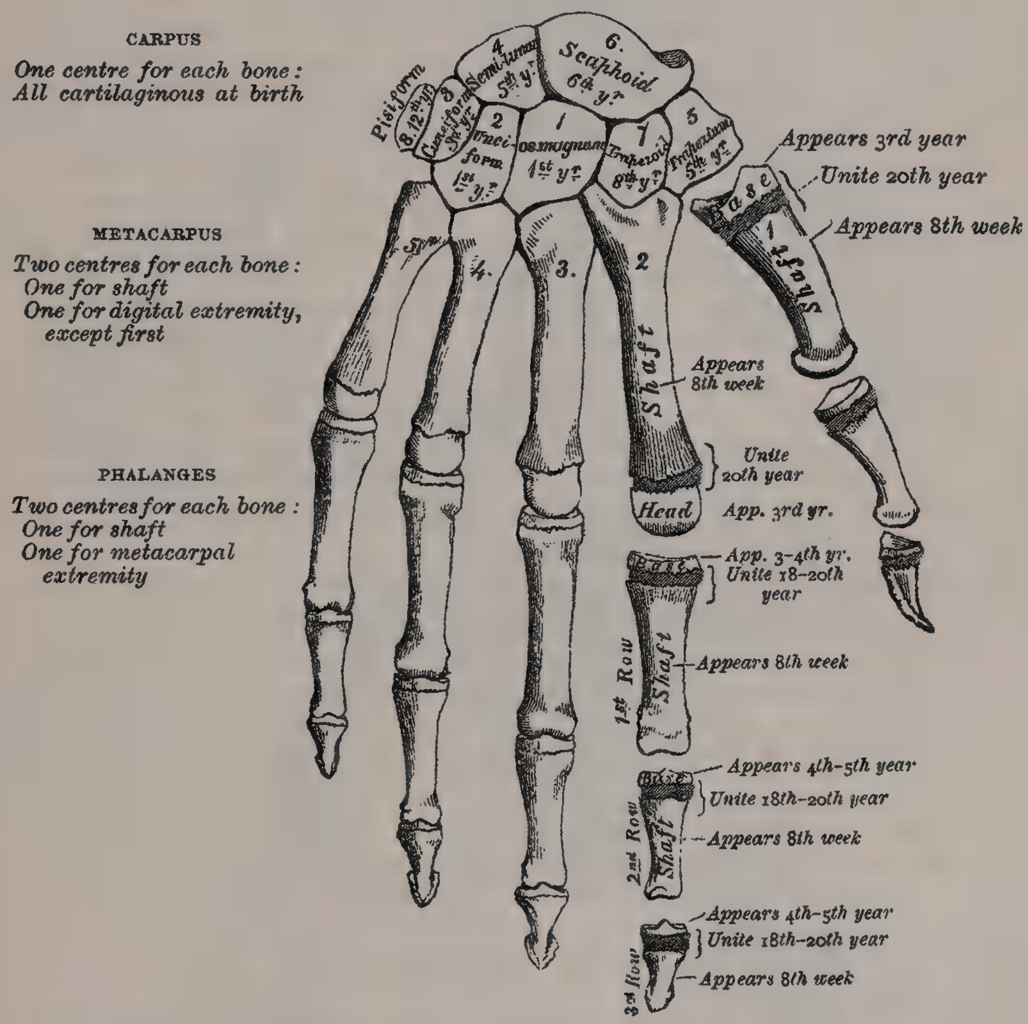
The **Metacarpal Bones** are each developed by *two* centres: one for the shaft and one for the digital extremity of each of the four inner metacarpal bones; one for the shaft and one for the base of the metacarpal bone of the thumb, which in this respect resembles the phalanges.* It will be seen, therefore, that the so-called

* Allen Thomson demonstrated the fact that the first metacarpal bone is often developed from three centres: that is to say, there is a separate nucleus for the distal end, forming a distinct epiphysis visible at the age of seven or eight years. He also states that there are traces of a proximal epiphysis in the second metacarpal bone. *Journal of Anatomy*, 1869.

metacarpal bone of the thumb is ossified in the same manner as the phalanges, and this has led some anatomists to regard this digit as being made up of three phalanges, and not of a metacarpal bone and two phalanges. Ossification commences in the centre of the shaft about the eighth or ninth week, the centre for the first metacarpal bone being the last to appear, and gradually proceeds to either end of the bone; about the third year the digital extremities of the four inner metacarpal bones, and the base of the first metacarpal, begin to ossify, and they unite about the twentieth year.

The **Phalanges** are each developed by *two* centres: one for the shaft, and one for the base. Ossification commences in the shaft, in all three rows, at about the eighth week, and gradually involves the whole of the bone excepting the upper extremity. Ossification of the base commences in the first row

Fig. 310.—Plan of the development of the hand.



between the third and fourth years, and a year later in those of the second and third rows. The two centres become united, in each row, between the eighteenth and twentieth years.

In the ungual phalanges the centre for the shaft appears at the distal extremity of the phalanx, instead of at the middle of the shaft as is the case with the other phalanges. Moreover, of all the bones of the hand they are the first to begin to ossify.

Surface Form.—On the front of the wrist are two subcutaneous eminences, one on the radial side, the larger and flatter, produced by the tuberosity of the scaphoid and the ridge on the trapezium; the other on the ulnar side, caused by the pisiform bone. The tubercle of the scaphoid is to be felt just below and internal to the apex of the styloid process of the radius, between the tendons of the Extensor ossis metacarpi pollicis and the Flexor carpi radialis. It is best perceived by extending the hand on the forearm. Half an inch below this tubercle is to be felt another prominence, better marked than the tubercle; this is

the ridge on the trapezium, which gives attachment to some of the short muscles of the thumb. On the inner side of the front of the wrist the pisiform bone is to be felt, forming a small but prominent projection in this situation. It is some distance below the styloid process of the ulna, and may be said to be just below the level of the styloid process of the radius, and is crossed by the crease which separates the front of the forearm from the palm of the hand. The rest of the front of the carpus is covered by tendons and the annular ligament, and entirely concealed, with the exception of the hooked process of the unciform, which can only be made out with difficulty. The back of the carpus is convex and covered by the Extensor tendons, so that the posterior surface of the cuneiform is the only bone which can be felt. Below the carpus the dorsal surfaces of the metacarpal bones, except the fifth, are covered by tendons, and are only visible in very thin hands. The dorsal surface of the fifth is, however, subcutaneous throughout almost its whole length, and is plainly to be perceived and felt. In addition to this, slightly external to the middle line of the hand, is a prominence, frequently well marked, but occasionally indistinct, formed by the styloid process of the metacarpal bone of the middle finger. This prominence is in the same line as the dorsal radial tubercle, and is an inch and a half vertically above it. The heads of the metacarpal bones are plainly to be felt and seen, rounded in contour and standing out in bold relief under the skin, when the fist is clenched. It should be borne in mind that when the fingers are flexed on the hand, the articular surfaces of the first phalanges glide off the heads of the metacarpal bones on to their anterior surfaces; so that the heads of these bones form the prominence of the knuckles and receive the force of any blow which may be given. The head of the third metacarpal bone is the most prominent, and receives the greater part of the shock of the blow. This bone articulates with the os magnum, so that the concussion is carried through this bone to the scaphoid and semilunar, with which the head of the os magnum articulates, and by these bones is transferred to the radius, along which it may be carried to the capitellum of the humerus. The enlarged extremities of the phalanges are to be plainly felt: they constitute the joints of the fingers. When the digits are bent, the proximal phalanges of the joints form prominences, which in the joint between the first and second phalanges are slightly hollowed, in accordance with the grooved shape of their articular surfaces, while in the last row the prominence is flattened and square-shaped. In the palm of the hand the four inner metacarpal bones are covered by muscles, tendons, and the palmar fascia, and no part of them but their heads is to be distinguished. With regard to the thumb, on the dorsal aspect, the base of the metacarpal bone forms a prominence, below the styloid process of the radius; the shaft is to be felt, covered by tendons, terminating at its head in a flattened prominence, in front of which can be felt the sesamoid bones.

Surgical Anatomy.—The carpal bones are little liable to fracture, except from extreme violence, when the parts are so comminuted as to necessitate amputation. Occasionally they are the seat of tuberculous disease. The metacarpal bones and the phalanges are sometimes broken from direct violence. The first metacarpal bone is the one most commonly fractured, then the second, the fourth and the fifth, the third being the one least frequently broken. There are two diseases of the metacarpal bones and phalanges which require special mention on account of their constant occurrence. One is tuberculous dactylitis, consisting in a deposit of tuberculous material in the medullary canal, expansion of the bone, with subsequent caseation and resulting necrosis. The other is chondroma, which is perhaps more commonly found in connection with the metacarpal bones and phalanges than with any other bones. The tumours are usually multiple, and may spring either from the medullary canal, or from the periosteum.

THE LOWER EXTREMITY

The bones of the lower extremity consist of those of the pelvic girdle, of the thigh, of the leg, and of the foot.

THE PELVIC GIRDLE

The **Pelvic Girdle** consists of a single bone, the *os innominatum*, by which the thigh is connected to the trunk.

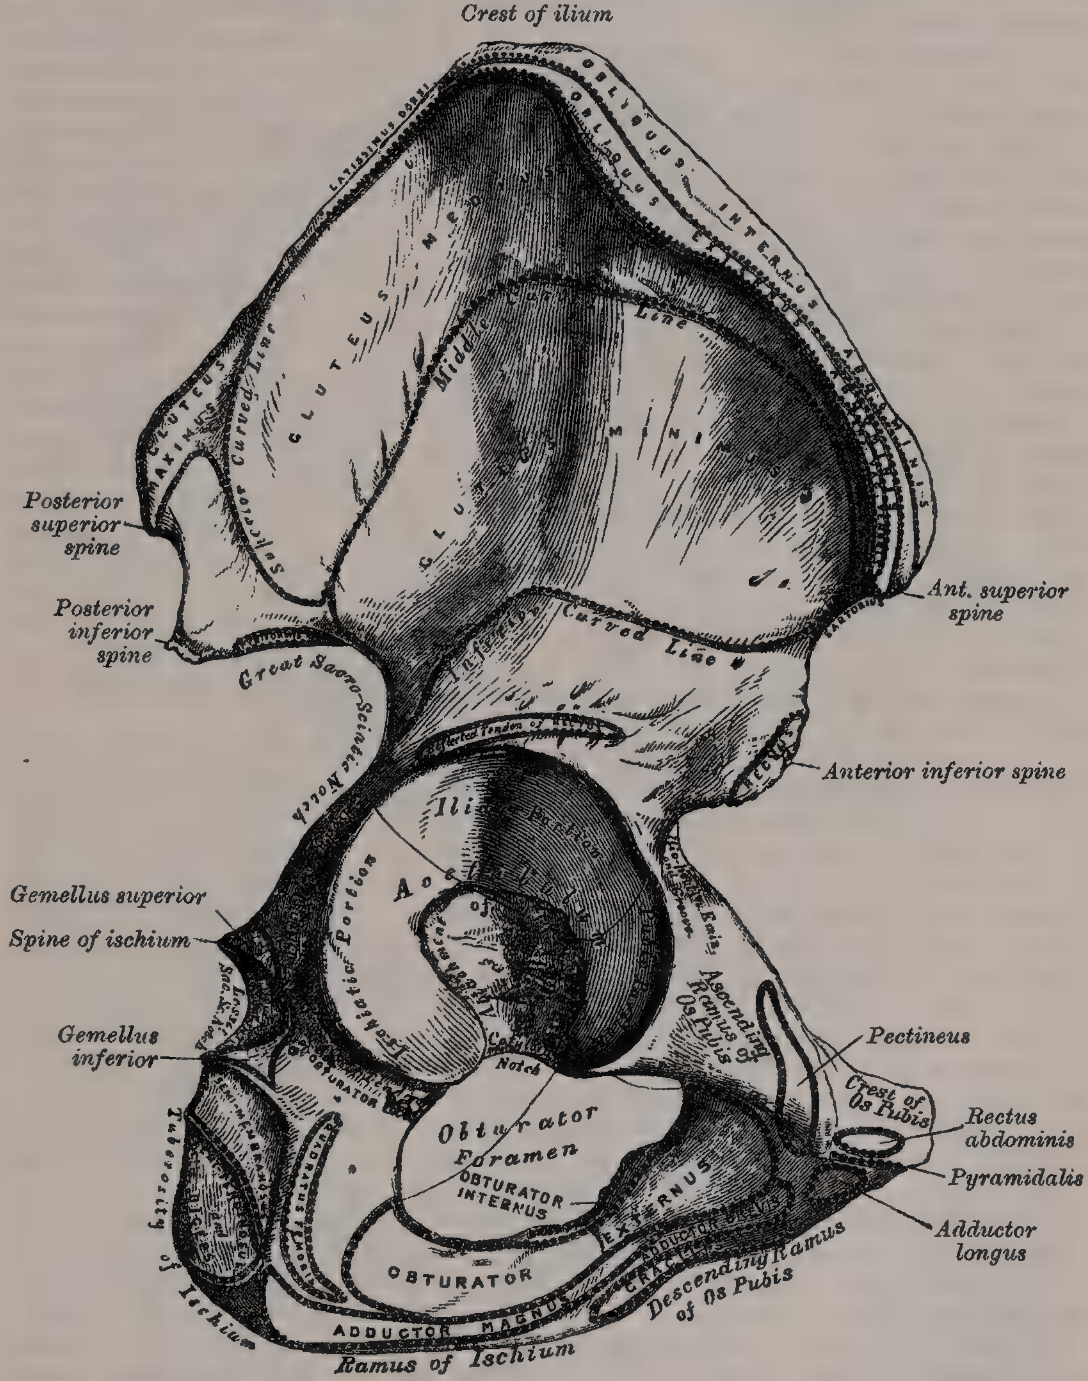
The Os Innominatum

The **Os Innominatum** (in, *not*; nomino, *I name*), or *nameless bone*, so called from bearing no resemblance to any known object, is a large, irregularly shaped, flat bone, constricted in the centre and expanded above and below. With its fellow of the opposite side, it forms the sides and anterior wall of the pelvic cavity. In young subjects it consists of three separate parts, which meet and

form a large, cup-like cavity, the *acetabulum*, situated near the middle of the outer surface of the bone: and, although in the adult these have become united, it is usual to describe the bone as divisible into three portions—the ilium, the ischium, and the os pubis.

The **ilium**, so called from its supporting the flank (*ilia*), is the superior, broad and expanded portion which runs upwards from the acetabulum, and forms the prominence of the hip.

Fig. 311.—Right os innominatum. External surface.



The **ischium** (*ἰσχίον, the hip*) is the inferior and strongest portion of the bone; it proceeds downwards from the acetabulum, expands into a large tuberosity, and then, curving forwards, forms, with the descending ramus of the os pubis, a large aperture, the obturator foramen.

The **os pubis** is that portion which extends inwards and downwards from the acetabulum to articulate in the middle line with the bone of the opposite side: it forms the front of the pelvis, supports the external organs of generation, and has received its name from the skin over it being covered with hair.

The **Ilium** presents for examination two surfaces—an external and an internal—a crest, and two borders—an anterior and a posterior.

The **External Surface** (fig. 311) is divided into two parts: an upper or gluteal, and a lower or acetabular. The *upper portion*, known as the *dorsum of the ilium*, is directed backwards and outwards behind; downwards and outwards in front. It is smooth, convex in front, deeply concave behind; bounded above by the crest, below by the upper border of the acetabulum; in front and behind, by the anterior and posterior borders. This surface is crossed in an arched direction by three semicircular ridges—the superior, middle, and inferior curved lines. The *superior curved line*, the shortest of the three, commences at the crest, about two inches in front of its posterior extremity; it is at first distinctly marked, but as it passes downwards and backwards to the upper part of the great sacro-sciatic notch, where it terminates, it becomes less marked, and is often altogether lost. Behind this line is a narrow semilunar surface, the upper part of which is rough and gives origin to part of the Gluteus maximus; the lower part is smooth and has no muscular fibres attached to it. The *middle curved line*, the longest of the three, commences at the crest, about an inch behind its anterior extremity, and, taking a curved direction downwards and backwards, terminates at the upper part of the great sacro-sciatic notch. The space between the superior and middle curved lines and the crest is concave, and gives origin to the Gluteus medius muscle. Near the central part of this line the orifice of a nutrient foramen may often be observed. The *inferior curved line*, the least distinct of the three, commences in front at the notch on the anterior border, and, taking a curved direction backwards and downwards, terminates at the middle of the great sacro-sciatic notch. The surface of bone included between the middle and inferior curved lines is concave from above downwards, convex from before backwards, and gives origin to the Gluteus minimus muscle. Beneath the inferior curved line, and corresponding to the upper part of the acetabulum, is a roughened surface (sometimes a depression), from which arises the reflected tendon of the Rectus femoris muscle. The *lower* or *acetabular part* of the external surface enters into the formation of the acetabulum, of which it forms rather less than two-fifths. It is separated from the upper gluteal portion of this surface by a prominent rim, which forms part of the margin of the acetabular cavity.

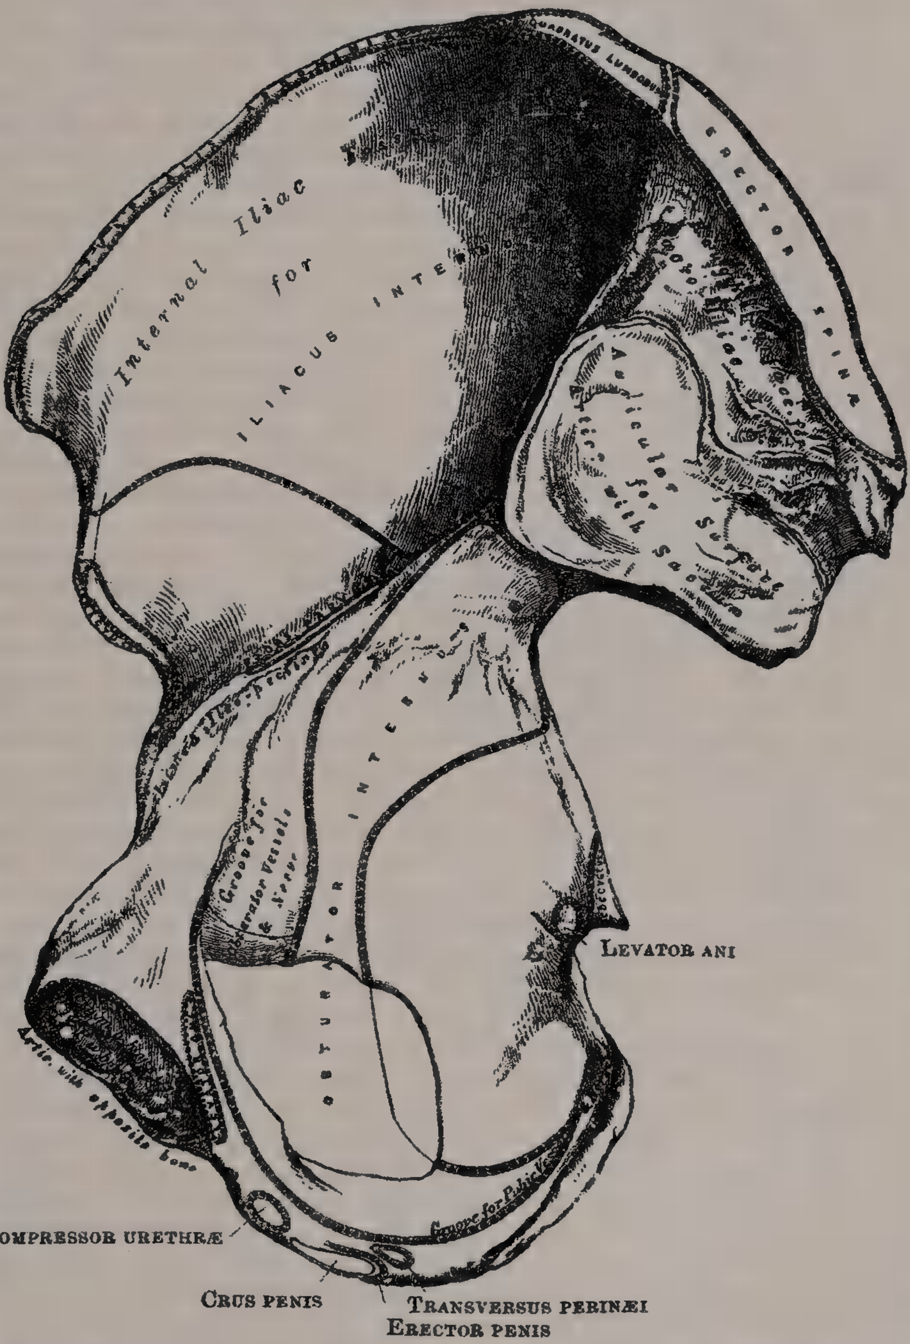
The **Internal Surface** (fig. 312) of the ilium is bounded above by the crest; below, it is continuous with the pelvic surfaces of the os pubis and ischium, a faint line only indicating the place of union; in front and behind, it is bounded by the anterior and posterior borders. It presents a large, smooth, concave surface, called the *iliac fossa*, or *venter ilii*, which gives origin to the Iliacus muscle, and presents at its lower part the orifice of a nutrient canal; and below this a smooth, rounded border, the *linea ilio-pectinea*, which separates the iliac fossa from that portion of the internal surface which enters into the formation of the true pelvis, and which gives origin to part of the Obturator internus muscle. Behind the iliac fossa is a rough surface, divided into two portions, an anterior and a posterior. The anterior or *auricular surface*, so called from its resemblance in shape to the ear, is coated with cartilage in the recent state, and articulates with a surface of similar shape on the side of the sacrum. The posterior portion is rough, for the attachment of the posterior sacro-iliac ligaments and for a part of the origin of the Erector and Multifidus spinæ muscles.

The **crest** of the ilium is convex in its general outline and sinuously curved, being concave inwards in front, concave outwards behind. It is longer in the female than in the male, very thick behind, and thinner at the centre than at the extremities. It terminates at either end in a prominent eminence, the *anterior superior* and *posterior superior iliac spines*. The surface of the crest is broad, and divided into an external lip, an internal lip, and an intermediate space. About two inches behind the anterior superior spinous process there is a prominent tubercle on the outer lip. To the external lip are attached the Tensor fasciæ femoris, Obliquus externus abdominis, and Latissimus dorsi, and along its whole length the fascia lata; to the space between the lips, the Internal oblique; to the internal lip, the Transversalis abdominis, Quadratus lumborum, and Erector spinæ, the Iliacus, and the fascia iliaca.

The **anterior border** of the ilium is concave. It presents two projections, separated by a notch. Of these, the uppermost, situated at the junction of the crest and anterior border, is called the *anterior superior iliac spine*, the

outer border of which gives attachment to the fascia lata, and the origin of the Tensor fasciæ femoris; its inner border, to the Iliacus; while its extremity affords attachment to Poupart's ligament and the origin of the Sartorius muscle. Beneath this eminence is a notch which gives origin to the Sartorius, and across which passes the external cutaneous nerve. Below the notch is the *anterior inferior iliac spine*, which terminates in the upper lip of the acetabulum; it gives attachment to the straight tendon of the Rectus femoris muscle and the ilio-femoral ligament. On the inner side of the anterior inferior spine is a broad,

Fig. 312.—Right os innominatum. Internal surface.



shallow groove, over which passes the Ilio-psoas muscle. This groove is bounded internally by an eminence, the *ilio-pectineal*, which marks the point of union of the ilium and os pubis.

The **posterior border** of the ilium, shorter than the anterior, also presents two projections separated by a notch, the *posterior superior* and the *posterior inferior iliac spines*. The former corresponds with that portion of the inner surface of the ilium which serves for the attachment of the oblique portion of the sacro-iliac ligaments and the Multifidus spinæ; the latter to the auricular portion which

articulates with the sacrum. Below the posterior inferior spine is a deep notch, the *great sacro-sciatic*.

The **Ischium** forms the lower and back part of the os innominatum. It is divisible into a thick and solid portion, the *body*; a large, rough eminence, on which the trunk rests in sitting, the *tuberosity*; and a thin part, which passes forwards and slightly upwards, the *ramus*.

The **body**, somewhat triangular in form, presents three surfaces, external, internal, and posterior; and three borders, external, internal, and posterior. The *external surface* corresponds to that portion of the acetabulum which is formed by the ischium; it is smooth and concave, and constitutes a little more than two-fifths of the acetabular cavity; its outer margin is bounded by a prominent rim or lip, the external border, to which the cotyloid fibro-cartilage is attached. Below the acetabulum, between it and the tuberosity, is a deep groove, along which the tendon of the Obturator externus muscle runs, as it passes outwards to be inserted into the digital fossa of the femur. The *internal surface* is smooth, concave, and enters into the formation of the lateral boundary of the true pelvic cavity. This surface is perforated by two or three large, vascular foramina, and gives origin to part of the Obturator internus muscle. The *posterior surface* is quadrilateral in form, broad and smooth. Below, where it joins the tuberosity, it presents a groove continuous with that on the external surface for the tendon of the Obturator externus muscle. The lower edge of this groove is formed by the tuberosity of the ischium, and gives origin to the Gemellus inferior muscle. This surface is limited, externally, by the margin of the acetabulum; behind by the posterior border; it supports the Pyriformis, the two Gemelli, and the Obturator internus muscles, in their passage outwards to the great trochanter. The *external border* forms the prominent rim of the acetabulum, and separates the posterior from the external surface. To it is attached the cotyloid fibro-cartilage. The *internal border* is thin, and forms the outer circumference of the obturator foramen. The *posterior border* of the body of the ischium presents, a little below the centre, a thin and pointed triangular eminence, the *spine of the ischium*, more or less elongated in different subjects; its external surface gives attachment to the Gemellus superior, its internal surface to the Coccygeus, Levator ani, and white line of the pelvic fascia; while to the pointed extremity is connected the lesser sacro-sciatic ligament. Above the spine is a notch of large size, the *great sacro-sciatic*, converted into a foramen by the lesser sacro-sciatic ligament; it transmits the Pyriformis muscle, the gluteal vessels, the superior and inferior gluteal nerves, the sciatic vessels, the greater and lesser sciatic nerves, the internal pudic vessels and nerve, and the nerves to the Obturator internus and Quadratus femoris. Of these, the gluteal vessels and superior gluteal nerve pass out above the Pyriformis muscle, the other structures below it. Below the spine is a smaller notch, the *lesser sacro-sciatic*; it is smooth, coated in the recent state with cartilage, the surface of which presents two or three ridges corresponding to the subdivisions of the tendon of the Obturator internus, which winds over it. It is converted into a foramen by the sacro-sciatic ligaments, and transmits the tendon of the Obturator internus, the nerve which supplies that muscle, and the internal pudic vessels and nerve.

The **tuberosity** presents for examination three surfaces: external, internal, and posterior. The *external surface* is quadrilateral in shape and rough for the attachment of muscles. It is bounded above by the groove for the tendon of the Obturator externus; in front it is limited by the posterior margin of the obturator foramen, and below it is continuous with the ramus of the bone; behind, it is bounded by a prominent margin which separates it from the posterior surface. In front of this margin the surface gives origin to the Quadratus femoris, and anterior to this to some of the fibres of origin of the Obturator externus. The lower part of the surface gives origin to part of the Adductor magnus. The *internal surface* forms part of the bony wall of the true pelvis. In front, it is limited by the posterior margin of the obturator foramen. Behind, it is bounded by a sharp ridge, for the attachment of a falciform prolongation of the great sacro-sciatic ligament, and, more anteriorly, gives origin to the Transversus perinæi and Erector penis muscles. The *posterior surface* is divided into two portions: a lower, rough, somewhat triangular part, and an upper, smooth, quadrilateral portion. The anterior portion is subdivided by a prominent vertical ridge, passing from base to apex, into two parts; the outer one gives

attachment to the Adductor magnus, the inner to the great sacro-sciatic ligament. The upper portion is subdivided into two facets by an oblique ridge, which runs downwards and outwards; from the upper and outer facet arises the Semimembranosus; from the lower and inner, the long head of the Biceps and the Semitendinosus.

The **ramus** is the thin, flattened part of the ischium, which ascends from the tuberosity upwards and inwards, and joins the descending ramus of the os pubis—their point of junction being indicated in the adult by a raised line. The outer surface of the ramus is uneven, for the origin of the Obturator externus muscle, and also some fibres of the Adductor magnus; its inner surface forms part of the anterior wall of the pelvis. Its inner border is thick, rough, slightly everted, forms part of the outlet of the pelvis, and presents two ridges and an intervening space. The ridges are continuous with similar ones on the descending ramus of the os pubis: to the outer one is attached the deep layer of the superficial perineal fascia (fascia of Colles), and to the inner the superficial layer of the triangular ligament of the urethra. If these two ridges are traced downwards, they will be found to join with each other just behind the point of origin of the Transversus perinæi muscle; here the two layers of fascia are continuous behind the posterior border of the muscle. To the intervening space, just in front of the point of junction of the ridges, is attached the Transversus perinæi muscle, and in front of this a portion of the crus penis vel clitoridis and the Erector penis vel clitoridis muscle. Its outer border is thin and sharp, and forms part of the inner margin of the obturator foramen.

The **Os Pubis** is the anterior part of the os innominatum, and, with the bone of the opposite side, constitutes the front boundary of the true pelvic cavity. It is divisible into a body, an ascending and a descending ramus.

The **body** is somewhat quadrilateral in shape, and presents for examination two surfaces and three borders. The *anterior surface* is rough, directed downwards and outwards, and serves for the origin of various muscles. To the upper and inner angle, immediately below the crest, is attached the Adductor longus; lower down, from without inwards, are attached the Obturator externus, the Adductor brevis, and the upper part of the Gracilis. The *posterior surface*, convex from above downwards, concave from side to side, is smooth, and forms part of the anterior wall of the pelvis. It gives origin to the Levator ani, Obturator internus, a few muscular fibres prolonged from the bladder, and the pubo-prostatic ligaments. The *upper border* presents for examination a prominent tubercle, which projects forwards and is called the *spine*; to it is attached the outer pillar of the external abdominal ring and Poupart's ligament. Passing upwards and outwards from this is a prominent ridge, forming part of the *ilio-pectineal line* which marks the brim of the true pelvis: to it is attached a portion of the conjoined tendon of the Internal oblique and Transversalis muscles, Gimbernat's ligament and the triangular fascia of the abdomen. Internal to the spine of the os pubis is the *crest*, which extends from this process to the inner extremity of the bone. It affords attachment, anteriorly, to the conjoined tendon of the Internal oblique and Transversalis; and posteriorly, to the Rectus and Pyramidalis muscles. The point of junction of the crest with the inner border of the bone is called the *angle*; to it, as well as to the symphysis, is attached the internal pillar of the external abdominal ring. The *internal border* is articular; it is oval, covered by eight or nine transverse ridges, or a series of nipple-like processes arranged in rows, separated by grooves; they serve for the attachment of a thin layer of cartilage, placed between it and the central fibro-cartilage. The *outer border* presents a sharp margin, which forms part of the circumference of the obturator foramen and affords attachment to the obturator membrane.

The **ascending** or **superior ramus** extends from the body to the point of junction of the os pubis with the ilium, and forms the upper part of the circumference of the obturator foramen. It presents for examination a superior, inferior, and posterior surface, and an outer extremity. The *superior surface* presents a continuation of the ilio-pectineal line, already mentioned as commencing at the pubic spine. In front of this ridge, the surface of bone is triangular in form, wider externally than internally, smooth, and is covered by the Pectineus muscle. The surface is bounded externally by a rough eminence, the *ilio-pectineal*, which serves to indicate the point of junction

of the ilium and os pubis. The triangular surface is bounded below by a prominent ridge, the *obturator crest*, which extends from the cotyloid notch to the spine of the os pubis. The *inferior surface* forms the upper boundary of the obturator foramen, and presents, externally, a broad and deep, oblique groove, for the passage of the obturator vessels and nerve; and internally, a sharp margin which is part of the circumference of the obturator foramen, and to which the obturator membrane is attached. The *posterior surface* constitutes part of the anterior boundary of the true pelvis. It is smooth, convex from above downwards, and affords origin to some fibres of the Obturator internus. The *outer extremity*, the thickest part of the ramus, forms one-fifth of the cavity of the acetabulum.

The **descending** or **inferior ramus** of the os pubis is thin and flattened. It passes outwards and downwards, becoming narrower as it descends and joins with the ramus of the ischium. Its *anterior surface* is rough, for the origin of muscles—the Gracilis along its inner border; a portion of the Obturator externus where it enters into the formation of the foramen of that name; and between these two muscles, the Adductores brevis and magnus from within outwards. The *posterior surface* is smooth, and gives origin to the Obturator internus, and, close to the inner margin, to the Compressor urethræ. The *inner border* is thick, rough, and everted, especially in females. It presents two ridges, separated by an intervening space. The ridges extend downwards, and are continuous with similar ridges on the ramus of the ischium; to the external one is attached the fascia of Colles, and to the internal one the superficial layer of the triangular ligament of the urethra. The *outer border* is thin and sharp, forms part of the circumference of the obturator foramen, and gives attachment to the obturator membrane.

The **cotyloid cavity**, or **acetabulum**, is a deep, cup-shaped, hemispherical depression, directed downwards, outwards, and forwards; formed internally by the os pubis, above by the ilium, behind and below by the ischium; a little less than two-fifths being formed by the ilium, a little more than two-fifths by the ischium, and the remaining fifth by the pubic bone. It is bounded by a prominent, uneven rim, which is thick and strong above, and serves for the attachment of the *cotyloid ligament*, which contracts its orifice, and deepens the surface for articulation. It presents below a deep notch, the *cotyloid notch*, which is continuous with a circular depression, the *fossa acetabuli*, at the bottom of the cavity: this depression is perforated by numerous apertures, lodges a mass of fat, and its margins, as well as those of the notch, serve for the attachment of the ligamentum teres. The notch is converted into a foramen by the transverse ligament which passes across it; through this foramen the nutrient vessels and nerves enter the joint.

The **obturator** or **thyroid foramen** is a large aperture, situated between the ischium and os pubis. In the male it is large, of an oval form, its longest diameter being obliquely from before backwards; in the female it is smaller, and more triangular. It is bounded by a thin, uneven margin, to which a strong membrane is attached; and presents, anteriorly, a deep groove, which runs from the pelvis obliquely inwards and downwards. This groove is converted into a foramen by a ligamentous band, a specialised part of the obturator membrane. This band is attached on either side to a tubercle: one on the internal border of the ischium, just in front of the cotyloid notch; the other on the inferior margin of the posterior surface of the ascending ramus of the os pubis. Through the foramen the obturator vessels and nerve pass out of the pelvis.

Structure.—This bone consists of much cancellous tissue, especially where it is thick, enclosed between two layers of dense, compact tissue. In the thinner parts of the bone, as at the bottom of the acetabulum and centre of the iliac fossa, it is usually semi-transparent, and composed entirely of compact tissue.

Development (fig. 313).—By *eight* centres: three primary—one for the ilium, one for the ischium, and one for the os pubis; and *five* secondary—one for the crest of the ilium, one for the anterior inferior spine (said to occur more frequently in the male than in the female), one for the tuberosity of the ischium, one for the symphysis pubis (more frequent in the female than in the male), and one or more for the Y-shaped piece at the bottom of the acetabulum. These various centres appear in the following order: in the lower part of the

ilium, immediately above the sciatic notch, about the eighth or ninth week of fœtal life; in the body of the ischium, about the third month; in the body of the os pubis, between the fourth and fifth months. At birth, the three primary centres are quite separate, the crest, the bottom of the acetabulum, the ischial tuberosity, and the rami of the ischium and pubes being still cartilaginous. About the seventh or eighth year, the rami of the os pubis and ischium are almost completely united by bone. About the thirteenth or fourteenth year, the three divisions of the bone have extended their growth into the bottom of the acetabulum, being separated from each other by a Y-shaped portion of cartilage, which now presents traces of ossification, often by two or more centres. One of these, the *os acetabuli*, appears about the age of twelve, between the ilium and os pubis, and fuses with them about the age of eighteen. It forms the pubic part of the acetabulum. The ilium and ischium then become joined, and lastly the os pubis to the ischium, through the intervention of this Y-shaped portion. At about the age of puberty, ossification takes place in each of the

Fig. 313.—Plan of the development of the os innominatum.

By eight centres { *Three primary (Ilium, Ischium, and Os Pubis)*
Five secondary

The three primary centres unite through Y-shaped piece about puberty. Epiphyses appear about puberty, and unite about 25th year.

remaining portions, and they become joined to the rest of the bone between the twentieth and twenty-fifth years. Separate centres are frequently found for the pubic and ischial spines, and another for the crest and angle of the os pubis.

Articulations.—With its fellow of the opposite side, the sacrum and femur.

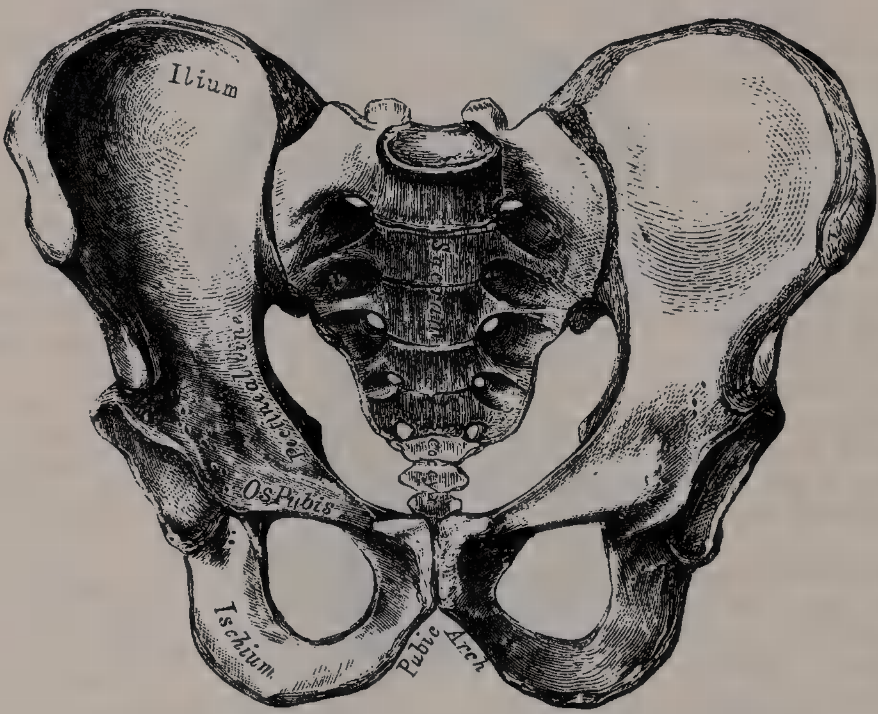
Attachment of Muscles.—To the *ilium*, sixteen. To the outer lip of the crest, the Tensor fasciæ femoris, Obliquus externus abdominis, and Latissimus dorsi; to the internal lip, the Iliacus, Transversalis, Quadratus lumborum, and Erector spinæ; to the interspace between the lips, the Obliquus internus. To the outer surface of the ilium, the Gluteus maximus, Gluteus medius, Gluteus minimus, reflected tendon of the Rectus; to the upper part of the great sacro-sciatic notch, a portion of the Pyriformis; to the internal surface, the Iliacus; to that portion of the internal surface below the linea ilio-pectinea, the Obturator internus; to the internal surface of the posterior superior spine, the Multifidus spinæ; to the anterior border, the Sartorius and straight tendon of the Rectus. To the *ischium*,

thirteen. To the outer surface of the ramus, the Obturator externus and Adductor magnus; to the internal surface, the Obturator internus and Erector penis. To the spine, the Gemellus superior, Levator ani, and Coccygeus. To the tuberosity, the Biceps, Semitendinosus, Semimembranosus, Quadratus femoris, Adductor magnus, Gemellus inferior, Transversus perinæi, Erector penis. To the *os pubis*, sixteen: Obliquus externus, Obliquus internus, Transversalis, Rectus, Pyramidalis, Psoas parvus, Pectineus, Adductor magnus, Adductor longus, Adductor brevis, Gracilis, Obturator externus and internus, Levator ani, Compressor urethræ, and occasionally a few fibres of the Accelerator urinæ.

The Pelvis (figs. 314, 315)

The **Pelvis**, so called from its resemblance to a basin (L. *pelvis*), is stronger and more massively constructed than either the cranial or the thoracic cavity; it is a bony ring, interposed between the movable vertebræ of the spinal column, which it supports, and the lower extremities, upon which it rests. It is composed of four bones: the two ossa innominata, which bound it on either side and in front; and the sacrum and coccyx, which complete it behind.

Fig. 314.—Male pelvis (adult).



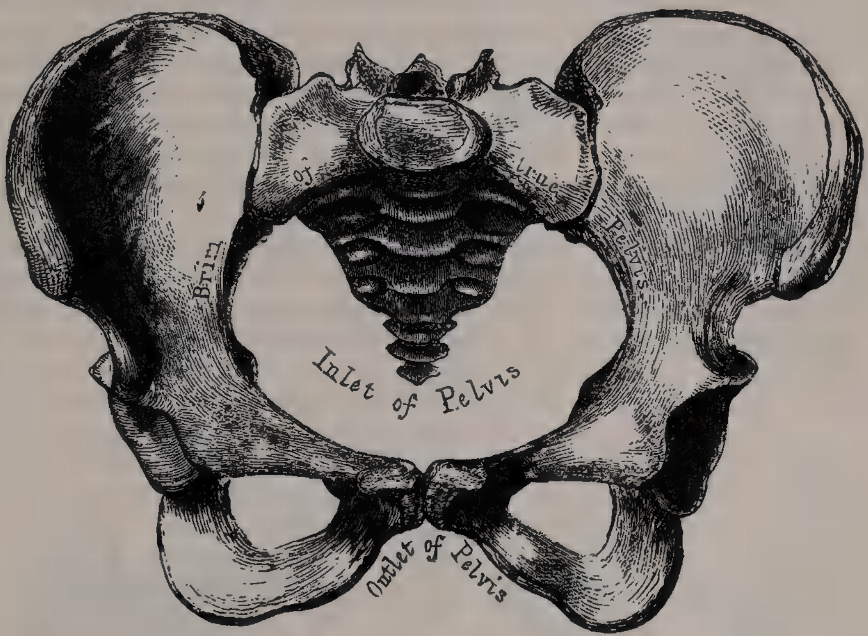
The pelvis is divided by an oblique plane passing through the prominence of the sacrum, the linea ilio-pectinea, and the upper margin of the symphysis pubis, into the false and true pelvis. The circumference of this plane is termed the *pelvic brim.*

The **false pelvis** is the expanded portion of the cavity which is situated above and in front of this plane. It is bounded on each side by the ossa ilii; in front it is incomplete, presenting a wide interval between the spinous processes of the ilia on either side, which is filled up in the recent state by the parietes of the abdomen; behind, in the middle line, is a deep notch. This broad, shallow cavity is fitted to support the intestines, and to transmit part of their weight to the anterior wall of the abdomen, and is, in fact, really a portion of the abdominal cavity. The term false pelvis is incorrect, and this space ought more properly to be regarded as part of the hypogastric and iliac regions of the abdomen.

The **true pelvis** is that part of the pelvic cavity which is situated below and behind the pelvic brim. It is smaller than the false pelvis, but its bony walls are more perfect. For convenience of description, it is divided into a superior circumference or inlet, an inferior circumference or outlet, and a cavity.

The **superior circumference** forms the brim of the pelvis, the included space being called the *inlet* (fig. 316). It is formed by the linea ilio-pectinea, completed in front by the crests of the pubic bones, and behind by the anterior margin of the base of the sacrum and sacro-vertebral angle. The inlet of the pelvis is somewhat heart-shaped, obtusely pointed in front, diverging on either side, and

Fig. 315.—Female pelvis (adult).



encroached upon behind by the projection forwards of the promontory of the sacrum. It has three principal diameters: antero-posterior or conjugate, transverse, and oblique. The antero-posterior extends from the sacro-vertebral angle to the symphysis pubis; its average measurement is four inches in the male, four and three-quarters in the female. The transverse extends across the greatest

Fig. 316.—Diameters of the pelvic inlet.

width of the inlet, from the middle of the brim on one side to the same point on the opposite; its average measurement is four and a half inches in the male, five and a quarter in the female. The oblique extends from the margin of the brim, corresponding to the ilio-pectineal eminence on one side, to the sacro-iliac articulation on the opposite side; its average measurement is four and a quarter inches in the male, and five in the female.

The **cavity** of the true pelvis is bounded in front and below by the symphysis pubis and the bodies of the pubic bones; above and behind, by the concavity of the sacrum and coccyx, which, curving forwards above and below, contracts the inlet and outlet of the canal; and laterally it is bounded by a broad, smooth, quadrangular surface of bone, corresponding to the inner surface of the body of the ischium and that part of the ilium which is below the ilio-pectineal line. The cavity is shallow in front, measuring at the symphysis an inch and a half in depth, three inches and a half in the middle, and four inches and a half posteriorly. From this description, it will be seen that the cavity of the pelvis is a short, curved canal, considerably deeper on its posterior than on its anterior wall. It contains, in the recent subject, the rectum, bladder, and part of the organs of generation. The rectum is placed at the back of the pelvis, and corresponds to the curve of the sacro-coccygeal column; the bladder in front, behind the symphysis pubis. In the female, the uterus and vagina occupy the interval between these viscera.

The **lower circumference** of the pelvis is very irregular, and forms its *outlet* (fig. 317). It is bounded by three prominent eminences: one posterior, formed by the point of the coccyx; and one on each side, the tuberosities of the ischia. These eminences are separated by three notches: one in front, the *pubic arch*, formed by the convergence of the rami of the ischia and pubic bones on each

FIG. 317.—Diameters of the pelvic outlet.

side. The other notches, one on each side, are formed by the sacrum and coccyx behind, the ischium in front, and the ilium above: they are called the *sacro-sciatic notches*; in the natural state they are converted into foramina by the lesser and greater sacro-sciatic ligaments. In the recent state, when the ligaments are *in situ*, the outlet of the pelvis is lozenge-shaped, bounded, in front, by the subpubic ligament and the rami of the ossa pubis and ischia; on each side by the tuberosities of the ischia; and behind, by the great sacro-sciatic ligaments and the tip of the coccyx.

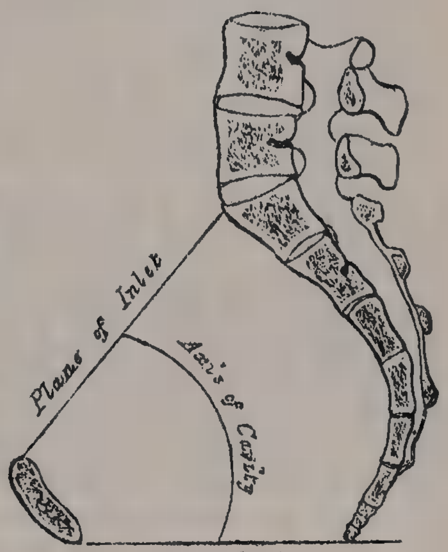
The diameters of the outlet of the pelvis are two, antero-posterior and transverse. The *antero-posterior* (*conjugate*) *diameter* extends from the tip of the coccyx to the lower part of the symphysis pubis; its average measurement is three inches and three-quarters in the male, and five inches in the female. The antero-posterior diameter varies with the length of the coccyx, and is capable of increase or diminution, on account of the mobility of that bone. The *transverse diameter* extends from the posterior part of one ischiatic tuberosity to the same point on the opposite side; the average measurement is three and a half inches in the male, and four and three-quarters in the female.*

* The measurements of the pelvis given above are fairly accurate, but different measurements are given by various authors, no doubt due in a great measure to differences in the physique and stature of the population from whom the measurements have been taken.

Position of the Pelvis.—In the erect posture, the pelvis is placed obliquely with regard to the trunk of the body: the plane of the bony ring, which is the brim of the true pelvis, forms an angle of from 50° to 60° with the horizontal plane. The pelvic surface of the symphysis pubis looks upwards and backwards, the concavity of the sacrum and coccyx downwards and forwards; the base of the sacrum in well-formed female bodies being nearly four inches above the upper border of the symphysis pubis, and the apex of the coccyx a little more than half an inch above its lower border. In consequence of this obliquity of the pelvis, the line of gravity of the head, which passes through the middle of the odontoid process of the axis and through the points of junction of the curves of the vertebral column to the sacro-vertebral angle, descends towards the front of the cavity, so that it bisects a line drawn transversely through the middle of the heads of the thigh-bones (see page 178). And thus the centre of gravity of the head is placed immediately over the heads of the thigh-bones on which the trunk is supported.

Axes of the Pelvis (fig. 318).—A line carried at right angles to the plane of the inlet at its middle, would correspond at one extremity with the umbilicus and at the other with the middle of the coccyx: the axis of the inlet is therefore directed downwards and backwards. The axis of the outlet, produced upwards, would touch the base of the sacrum, and is therefore directed downwards and forwards. The axis of the cavity is curved like the cavity itself: this curve corresponds to the concavity of the sacrum and coccyx, the extremities being indicated by the central points of the inlet and outlet. A knowledge of the direction of these axes serves to explain the course of the fœtus in its passage through the pelvis during parturition. It is also important to the surgeon, as indicating the direction of the force required in the removal of calculi from the bladder, by the perineal operation, and as determining the direction in which instruments should be used in operations upon the pelvic viscera.

Fig. 318.—Vertical section of the pelvis, with lines indicating the axes of the pelvis.



Differences between the Male and Female Pelvis.—The *female* pelvis, looked at as a whole, is distinguished from the *male* by the bones being more delicate and by its depth being smaller. The whole pelvis is less massive, and its bones are lighter and more slender, and its muscular impressions are slightly marked. The ilia are less sloped, and the anterior iliac spines more widely separated; hence the greater prominence of the hips. The *inlet* in the female is larger than in the male; it is more nearly circular, and its obliquity is greater. The *cavity* is shallower and wider; the sacrum is shorter, wider, and its upper part is less curved; the obturator foramina are triangular and smaller in size than in the male. The *outlet* is larger and the coccyx more movable. The sacro-sciatic notches are shallower, and the spines of the ischia project less inwards. The tuberosities of the ischia and the acetabula are wider apart, and the former are more everted. The pubic symphysis is less deep, and the pubic arch is wider and more rounded than in the male, where it is an angle rather than an arch. In consequence of this the width of the fore part of the pelvic outlet is much increased and the passage of the fœtal head facilitated.

The size of the pelvis varies, not only in the two sexes, but also in different members of the same sex. This does not appear to be influenced in any way by the height of the individual. Women of short stature, as a rule, have broad pelves. Occasionally the pelvis is equally contracted in all its dimensions, so much so that all its diameters measure an inch less than the average, and this even in well-formed women of average height. The principal divergences, however, are found at the inlet, and affect the relation of the antero-posterior

to the transverse diameter. Thus the inlet of the pelvis may be elliptical either in a transverse or antero-posterior direction; the transverse diameter in the former, and the antero-posterior in the latter, greatly exceeding the other diameters. Again, the inlet of the pelvis in some instances is seen to be almost circular.

The same differences are found in various races. European women are said to have the most roomy pelves. That of the negress is smaller, circular in shape, and with a narrow pubic arch. The Hottentots and Bushwomen possess the smallest pelves.

In the *fœtus*, and for several years after birth, the pelvis is small in proportion to that of the adult, and the projection of the sacro-vertebral angle less marked. The generally accepted opinion that the female pelvis does not acquire its sexual characters until after puberty has been shown by recent observations * to be erroneous, the characteristic differences between the male and female pelvis being distinctly indicated as early as the fourth month of fœtal life.

Surface Form.—The pelvic bones are so thickly covered with muscles that it is only at certain points that they approach the surface and can be felt through the skin. In front, the anterior superior spine of the ilium is easily to be recognised; a portion of it is subcutaneous, and in thin subjects may be seen to stand out as a prominence at the outer extremity of the fold of the groin. In fat subjects its position is marked by an oblique depression among the surrounding fat, at the bottom of which the bony process may be felt. Proceeding upwards and outwards from this process, the sinuously curved crest of the ilium may be traced throughout its whole length. Its highest point is on a level with the spine of the fourth lumbar vertebra: upon its outer lip, about two and a half inches behind the anterior superior spine, is a prominence, known as the *tubercular point of the ilium*. The crest is represented, in muscular subjects, on the surface, by a groove or furrow, the *iliac furrow*, caused by the projection of the fleshy fibres of the External oblique muscle of the abdomen; the iliac furrow lies slightly below the level of the crest. It terminates behind in the posterior superior spine, the position of which is indicated by a slight depression on a level with the spinous process of the second sacral vertebra. Between the two posterior superior spines, but at a lower level, is to be felt the spinous process of the third sacral vertebra (see page 179). Another part of the bony pelvis which is easily accessible to the touch is the tuberosity of the ischium, situated beneath the gluteal fold, and, when the hip is flexed, easily to be felt, as it is then uncovered by muscle. Finally, the spine of the os pubis can always be readily felt, and constitutes an important surgical guide, especially in connection with the subject of hernia. It is nearly in the same horizontal plane as the upper edge of the great trochanter. In thin subjects it is very apparent, but in the obese it is obscured by the pubic fat. It can, however, be detected by following up the tendon of origin of the Adductor longus muscle. A line drawn from the anterior superior spine of the ilium to the most prominent part of the tuberosity of the ischium passes across the hip at a level with the upper border of the great trochanter. It is known as *Nélaton's line*, and is of service in detecting any displacement of the trochanter in fractures or dislocation in this situation. If a line be drawn from the posterior superior spine of the ilium to the outer part of the tuberosity of the ischium, it will cross the spine of the ischium about four inches below the posterior superior iliac spine. The great sciatic foramen will lie above, and the lesser foramen below this point.

Surgical Anatomy.—There is arrest of development in the bones of the pelvis in cases of extroversion of the bladder; the anterior part of the pelvic girdle being deficient, the bodies of the pubic bones imperfectly developed, and the symphysis absent. 'The pubic bones are separated to the extent of from two to four inches, the superior rami shortened and directed forwards, and the obturator foramen diminished in size, narrowed, and turned outwards. The iliac bones are straightened out more than normal. The sacrum is very peculiar. The lateral curve, instead of being concave, is flattened out or even convex, with the ilio-sacral facets turned more outward than normal, while the vertical curve is straightened.' †

Fractures of the pelvis are divided into fractures of the false pelvis and of the true pelvis. Fractures of the false pelvis vary in extent; a small portion of the crest may be broken, or one of the spinous processes may be torn off, and this may be the result of muscular action; or the bone may be extensively comminuted. This latter accident is the result of some crushing violence, and may be complicated with fracture of the true pelvis. These cases may be accompanied by injury to the intestine as it lies in the hollow of the bone, or to

---

* Fehling, *Zeitschr. für Geburt. u. Gynäk.* Bd. ix. und x.; and Arthur Thomson, *Journal of Anatomy and Physiology*, vol. xxxiii.

† Wood. Heath's *Dictionary of Practical Surgery*, i. 426.

the iliac vessels as they course along the margin of the true pelvis. Fractures of the true pelvis generally occur through the ascending ramus of the os pubis and the ramus of the ischium, as this is the weakest part of the bony ring, and may be caused either by crushing violence applied in an antero-posterior direction, when the fracture occurs from direct force, or by compression laterally, when the acetabula are pressed together and the bone gives way in the same place from indirect violence. It is frequently accompanied by a fracture in the neighbourhood of the sacro-iliac joint, either through the lateral mass of the sacrum, or through the ilium of the same side, parallel and close to the articulation. The cause of this is that, after the pelvic ring has given way in front, the continued violence falls on this part, and the bone yields on one side of the joint, being weaker than the strong unyielding ligaments of the joint itself. Sometimes the fracture may be double, occurring on both sides of the body. It is in these cases that the contained viscera are likely to be injured: the urethra, the bladder, the rectum, the vagina in the female, the small intestines, and even the uterus, have all been lacerated by a displaced fragment. Fractures of the acetabulum are occasionally met with: either a portion of the rim may be broken off, or a fracture may take place through the bottom of the cavity and the head of the femur be driven inwards and project into the pelvic cavity. Separation of the Y-shaped cartilage at the bottom of the acetabulum may also occur in the young subject, separating the bone into its three anatomical portions.

The sacrum is rarely broken by direct violence—i.e. blows, kicks, or falls on the part. The lesion may be complicated with injury to the nerves of the sacral plexus, leading to paralysis and loss of sensation in the lower extremity, or to incontinence of fæces from paralysis of the Sphincter ani.

The coccyx is not infrequently fractured from blows or kicks. The fracture is attended with great pain in walking and on making any expiratory effort, such as coughing, defæcation, &c., because the Coccygeus muscle, which is attached to this bone, forms part of the lower diaphragm of the abdomen. Falls or blows on the coccyx, unaccompanied by fracture, sometimes give rise to a severe neuralgic pain, which is exceedingly intractable and difficult of cure. The condition is known as *coccygodynia*, and for its relief removal of the coccyx has been practised of late years, but the results have not been very satisfactory.

The pelvic bones often undergo important deformity in rickets, the effects of which in the adult woman may interfere seriously with child-bearing. The deformity is due mainly to the weight of the spine and trunk, which presses on the sacro-vertebral angle and greatly increases it, so that the antero-posterior diameter of the pelvis is diminished. But, in addition to this, the weight of the viscera on the venter ilii causes them to expand and the tuberosities of the ischia to be incurved. In osteomalacia also great deformity may occur. The weight of the trunk causes an increase in the sacro-vertebral angle, and a lessening of the antero-posterior diameter of the inlet, and at the same time the pressure of the acetabula on the heads of the thigh-bones causes these cavities, with the adjacent bone, to be pushed upwards and backwards, so that the oblique diameters of the pelvis are also diminished, and the cavity of the pelvis assumes a triradiate shape, with the symphysis pubis pushed forwards.

THE THIGH

The **Thigh** is that portion of the lower extremity which is situated between the pelvis and the knee. Its skeleton consists of a single bone, the femur.

The Femur

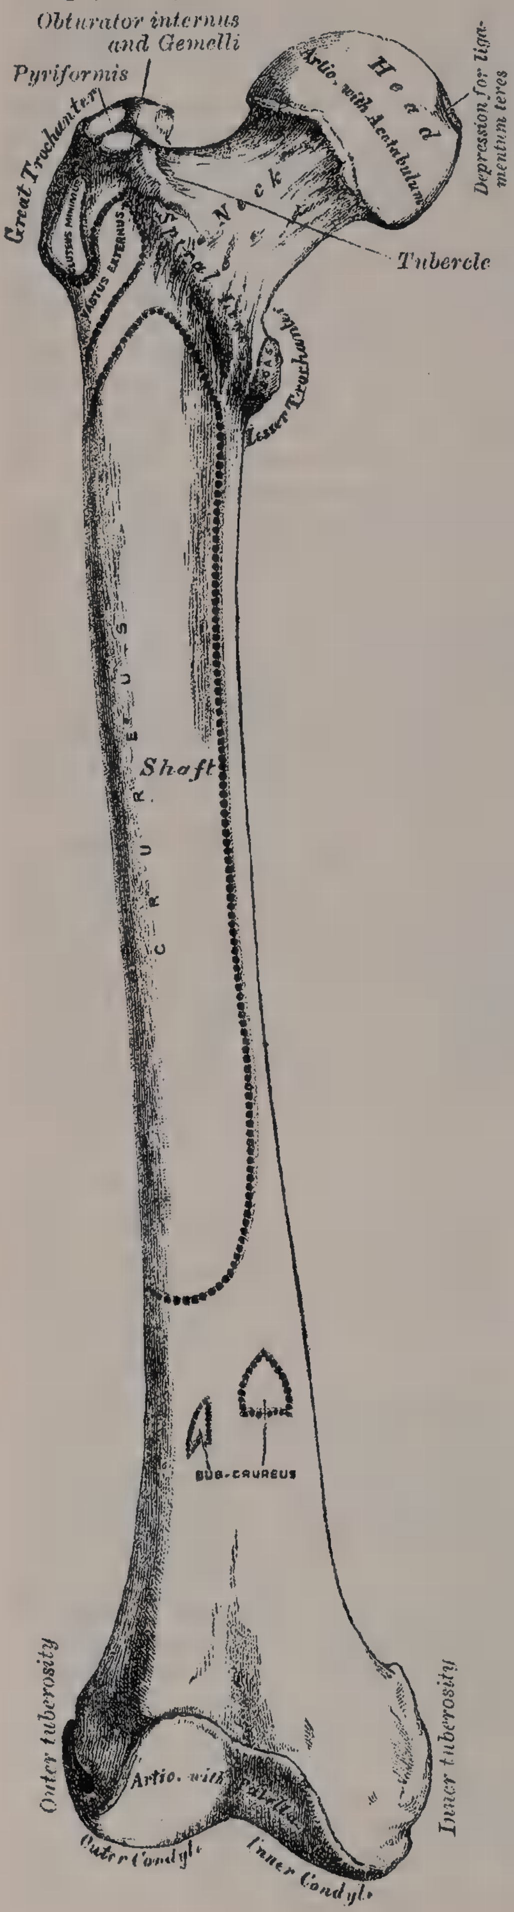
The **Femur** (femur, the *thigh*) is the longest,* largest, and strongest bone in the skeleton, and almost perfectly cylindrical in the greater part of its extent. In the erect posture it is not vertical, being separated from its fellow above by a considerable interval, which corresponds to the breadth of the pelvis, but inclining gradually downwards and inwards, so as to approach its fellow towards its lower part, for the purpose of bringing the knee-joint near the line of gravity of the body. The degree of this inclination varies in different persons, and is greater in the female than in the male, on account of the greater breadth of the pelvis. The femur, like other long bones, is divisible into a shaft and two extremities.

The **Upper Extremity** presents for examination a head, a neck, a great and a small trochanter.

The **head**, which is globular, and forms rather more than a hemisphere, is directed upwards, inwards, and a little forwards, the greater part of its convexity being above and in front. Its surface is smooth, coated with cartilage in the

* In a man six feet high, it measures eighteen inches—one-fourth of the whole body.

FIG. 319.—Right femur. Anterior surface.



recent state, with the exception of an ovoid depression, which is situated a little below and behind its centre, and gives attachment to the ligamentum teres. The **neck** is a flattened pyramidal process of bone, which connects the head with the shaft, and forms with the latter a wide angle. The angle is widest in infancy, and becomes lessened during growth, so that at puberty it forms a gentle curve from the axis of the shaft. In the adult, the neck forms an angle of about 125° with the shaft, but this varies in inverse proportion to the development of the pelvis and the stature. In consequence of the prominence of the hips and widening of the pelvis in the female, the neck of the thigh-bone forms more nearly a right angle with the shaft than it does in man. It has been stated that the angle diminishes in old age and the direction of the neck becomes horizontal, but this statement is founded on insufficient evidence. Humphry stated that the angle decreases during the period of growth, but after full growth has been attained it does not usually undergo any change, even in old age. He further states that the angle varies considerably in different persons of the same age. It is smaller in short than in long bones, and when the pelvis is wide.* The neck is flattened from before backwards, contracted in the middle, and broader at its outer extremity, where it is connected with the shaft, than at its summit, where it is attached to the head. The vertical diameter of the outer half is increased by the thickening of the lower edge, which slopes downwards to join the shaft at the small trochanter, so that the outer half of the neck is flattened from before backwards, and its vertical diameter measures one-third more than the antero-posterior. The inner half is smaller, and of a more circular shape. The *anterior surface* of the neck is perforated by numerous vascular foramina. The *posterior surface* is smooth, and is broader and more concave than the anterior; it gives attachment to the posterior part of the capsular ligament of the hip-joint, about half an inch above the posterior intertrochanteric line. The *superior border* is short and thick, and terminates externally at the great trochanter; its surface is perforated by large foramina. The *inferior border*, long and narrow, curves a little backwards, to terminate at the small trochanter.

* *Journal of Anatomy and Physiology*, vol. xxiii.

The **Trochanters** (τροχάω, *to run* or *roll*) are prominent processes of bone which afford leverage to the muscles which rotate the thigh on its axis. They are two in number, great and small.

The **Great Trochanter** is a large, irregular, quadrilateral eminence, situated at the outer side of the neck, at its junction with the upper part of the shaft. It is directed a little outwards and backwards, and, in the adult, is about three-quarters of an inch lower than the head. It presents for examination two surfaces and four borders. The *external surface*, quadrilateral in form, is broad, rough, convex, and marked by a prominent diagonal impression, which extends from the posterior superior to the anterior inferior angle, and serves for the insertion of the tendon of the Gluteus medius. Above the impression is a triangular surface, sometimes rough for part of the tendon of the same muscle, sometimes smooth for the interposition of a bursa between that tendon and the bone. Below and behind the diagonal line is a smooth, triangular surface, over which the tendon of the Gluteus maximus muscle plays, a bursa being interposed. The *internal surface* is of much less extent than the external, and presents at its base a deep depression, the *digital* or *trochanteric fossa*, for the insertion of the tendon of the Obturator externus muscle, and above and in front of this an impression for the insertion of the Obturator internus and Gemelli. The *superior border* is free; it is thick and irregular, and marked near the centre by an impression for the insertion of the Pyriformis. The *inferior border* corresponds to the line of junction of the base of the trochanter with the outer surface of the shaft; it is marked by a rough, prominent, slightly curved ridge, which gives origin to the upper part of the Vastus externus muscle. The *anterior border* is prominent, somewhat irregular, as well as the surface of bone immediately below it; it affords insertion at its outer part to the Gluteus minimus. The *posterior border* is very prominent, and appears as a free, rounded edge, which forms the back part of the digital fossa.

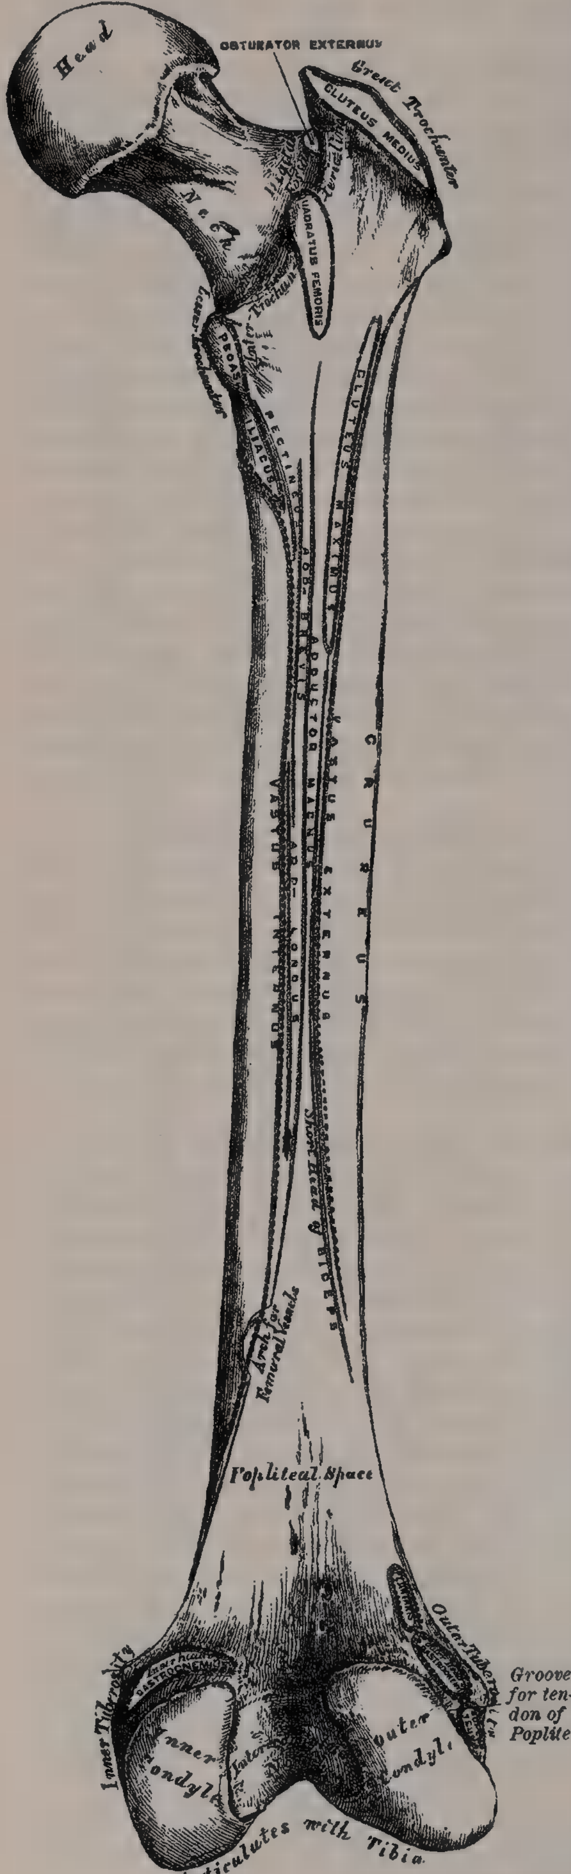
The **Small Trochanter** is a conical eminence, which varies in size in different subjects; it projects from the lower and back part of the base of the neck. Its base is triangular, and connected with the adjacent parts of the bone by three well-marked borders: two of these are above—the *internal* continuous with the lower border of the neck, the *external* with the posterior intertrochanteric line—while the *inferior border* is continuous with the middle division of the linea aspera. Its summit, which is directed inwards and backwards, is rough, and gives insertion to the tendon of the Ilio-psoas. The Iliacus is also inserted into the shaft below the small trochanter, between the Vastus internus in front and the Pectineus behind.

A well-marked prominence, of variable size, which projects at the junction of the upper part of the neck with the great trochanter, is called the *tubercle of the femur*; it is the point of meeting of five muscles: the Gluteus minimus externally, the Vastus externus below, and the tendon of the Obturator internus and Gemelli above. Running obliquely downwards and inwards from the tubercle is the *spiral line* of the femur, or *anterior intertrochanteric line*; it winds round the inner side of the shaft, below the lesser trochanter, and terminates in the linea aspera, about two inches below this eminence. Its upper half is rough, and affords attachment to the ilio-femoral ligament of the hip-joint; its lower half is less prominent, and gives origin to the upper part of the Vastus internus. Running obliquely downwards and inwards from the summit of the great trochanter on the posterior surface of the neck is a very prominent well-marked ridge, the *posterior intertrochanteric line*. Its upper half forms the posterior border of the great trochanter, and its lower half runs downwards and inwards to the upper and back part of the lesser trochanter. A slight ridge sometimes commences about the middle of the posterior intertrochanteric line, and passes vertically downwards for about two inches along the back part of the shaft: it is called the *linea quadrata*, and gives attachment to the Quadratus femoris and a few fibres of the Adductor magnus muscles.*

The **Shaft**, almost cylindrical in form, is a little broader above than in the centre, and somewhat flattened from before backwards below. It is slightly

* Generally there is merely a slight thickening about the middle of the intertrochanteric line, marking the attachment of the upper part of the Quadratus femoris. This is termed by some anatomists the *tubercle of the Quadratus*.

FIG. 320.—Right femur. Posterior surface.



arched, so as to be convex in front and concave behind, where it is strengthened by a prominent longitudinal ridge, the *linea aspera*. It presents for examination three borders, separating three surfaces. Of the three borders, one, the linea aspera, is posterior; the other two are placed laterally.

The **linea aspera** (fig. 320) is a prominent longitudinal ridge or crest, on the middle third of the bone, presenting an external lip, an internal lip, and a rough intermediate space. Above, the linea aspera is prolonged by three ridges. The most external one is very rough, and is continued almost vertically upwards to the base of the great trochanter. It is sometimes termed the *gluteal ridge*, and gives attachment to part of the Gluteus maximus muscle: its upper part is often elongated into a roughened crest, on which is a more or less well-marked, rounded tubercle, a rudimental third trochanter. The middle ridge, the least distinct, is continued to the base of the trochanter minor, and gives attachment to the Pectineus muscle; and the internal one is lost above in the spiral line of the femur. Below, the linea aspera is prolonged by two ridges, which enclose between them a triangular space, the *popliteal surface*, upon which rests the popliteal artery. Of these two ridges, the outer one is the more prominent, and descends to the summit of the outer condyle. The inner one is less marked, especially at its upper part, where it is crossed by the femoral artery. It terminates, below, at the summit of the internal condyle, in a small tubercle, the *Adductor tubercle*, which affords insertion to the tendon of the Adductor magnus.

From the inner lip of the linea aspera and its inner prolongation above and below, the Vastus internus arises; and from the outer lip and its outer prolongation above, the Vastus externus takes origin. The Adductor magnus is inserted into the linea aspera, to its outer prolongation above, and its inner prolongation below. Between the Vastus externus and the Adductor magnus are attached two muscles—viz. the insertion of the Gluteus maximus above and the origin of the short head of the Biceps below. Between the Adductor magnus and the Vastus internus four muscles are inserted: the Iliacus and Pectineus above; the Adductor brevis and Adductor longus below. The linea aspera is perforated a little below its centre by the nutrient canal, which is directed obliquely upwards.

The two *lateral borders* of the femur are only slightly marked, the outer one extending from the anterior inferior angle of the great trochanter to the anterior extremity of the external condyle; the inner one from the spiral line, at a point opposite the trochanter minor, to the anterior extremity of the internal condyle. The internal border marks the limit of attachment of the Crureus muscle internally.

The *anterior surface* includes that portion of the shaft which is situated between the two lateral borders. It is smooth, convex, broader above and below than in the centre, slightly twisted, so that its upper part is directed forwards and a little outwards, its lower part forwards and a little inwards. From the upper three-fourths of this surface the Crureus arises; the lower fourth is separated from the muscle by the intervention of the synovial membrane of the knee-joint and a bursa, and affords attachment to the Subcrureus to a small extent. The *external surface* includes the portion of bone between the external border and the outer lip of the linea aspera; it is continuous above with the outer surface of the great trochanter, below with the outer surface of the external condyle: to its upper three-fourths is attached the outer portion of the Crureus muscle. The *internal surface* includes the portion of bone between the internal border and the inner lip of the linea aspera; it is continuous above with the lower border of the neck, below with the inner side of the internal condyle: it is covered by the Vastus internus muscle.

The **Lower Extremity,** larger than the upper, is of a cuboid form, flattened from before backwards, and divided into two large eminences, the *condyles* (κόνδυλος, *a knuckle*), by an interval which presents a smooth depression in front called the *trochlea,* and a notch of considerable size behind—the *intercondyloid notch.* The *external condyle* is the more prominent anteriorly, and is the broader both in the antero-posterior and transverse diameters. The *internal condyle* is the narrower, longer, and more prominent inferiorly. The difference in the length of the two condyles is only observed when the bone is perpendicular, and depends upon the obliquity of the thigh-bones, in consequence of their separation above at the articulation with the pelvis. If the femur is held obliquely, the surfaces of the two condyles will be seen to be nearly horizontal. The two condyles are directly continuous in front, and form a smooth trochlear surface, which articulates with the patella. This surface presents a median groove, which extends downwards and backwards to the intercondyloid notch; and two lateral convexities, of which the external is the broader, more prominent, and prolonged farther upwards upon the front of the outer condyle. The external border of this articular surface is also more prominent, and ascends higher than the internal one. This trochlear portion of the articular surface is separated from the remainder, which articulates with the tibia and the semilunar cartilages, by two faintly marked grooves, which pass obliquely forwards and outwards and forwards and inwards respectively from the anterior margin of the intercondyloid notch. They receive the anterior edges of the two semilunar fibro-cartilages when the knee is extended. The intercondyloid notch lodges the crucial ligaments; it is bounded laterally by the opposed surfaces of the two condyles, and in front by the lower end of the shaft.

Outer Condyle.—The *outer surface* of the external condyle presents, a little behind its centre, an eminence, the *outer tuberosity*; it is less prominent than the inner tuberosity, and gives attachment to the external lateral ligaments of the knee. Immediately beneath it is a groove which commences at a depression a little behind the centre of the lower border of this surface: the front part of this depression gives origin to the Popliteus muscle, the tendon of which is lodged in the groove during flexion of the knee. The groove is smooth, covered with cartilage in the recent state, and runs upwards and backwards to the posterior extremity of the condyle. The *inner surface* of the outer condyle forms one of the lateral boundaries of the intercondyloid notch, and gives attachment, by its posterior part, to the anterior crucial ligament. The *inferior surface* is convex, smooth, and broader than that of the internal condyle. The posterior extremity is convex and smooth: just above and to the outer side of the articular surface is a depression for the origin of the outer head of the Gastrocnemius, above which is the origin of the Plantaris.

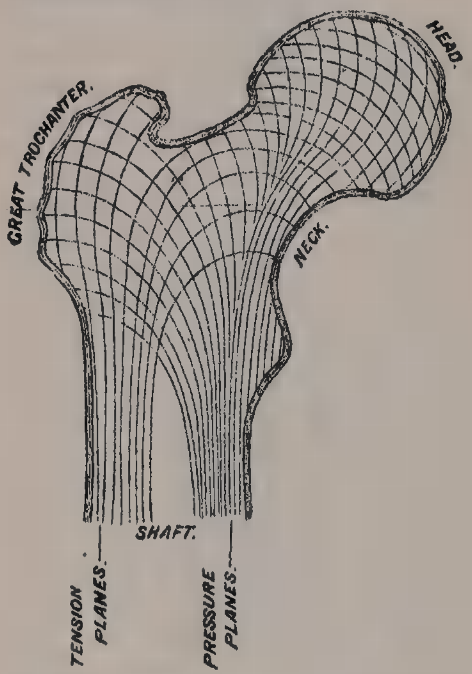
Inner Condyle.—The *inner surface* of the inner condyle presents a convex eminence, the *inner tuberosity*, rough, for the attachment of the internal lateral

ligament. The *outer side* of the inner condyle forms one of the lateral boundaries of the intercondyloid notch, and gives attachment, by its anterior part, to the posterior crucial ligament. Its *inferior* or *articular surface* is convex, and presents a less extensive surface than the external condyle. Just above the articular surface of the condyle, behind, is a depression for the tendon of origin of the inner head of the Gastrocnemius.

Structure.—The shaft of the femur is a cylinder of compact tissue, hollowed by a large medullary canal. The cylinder is of great thickness and density in the middle third of the shaft, where the bone is narrowest and the medullary canal well formed; but above and below this the cylinder gradually becomes thinner, owing to a separation of the layers of the bone into cancelli, which project into the medullary canal and finally obliterate it, so that the upper and lower ends of the shaft, and the articular extremities more especially, consist of cancellated tissue, invested by a thin compact layer.

The arrangement of the cancelli in the ends of the femur is remarkable. In the upper end they are arranged in two sets. One, starting from the top of the head, the upper surface of the neck, and the great trochanter, converge to the inner part of the circumference of the shaft (fig. 321); these are placed in the direction of greatest pressure, and serve to support the vertical weight of the body. The second set are planes of lamellæ intersecting the former nearly at right angles, and are situated in the line of the greatest tension—that is to say, along the lines in which the muscles and ligaments exert their traction. In the head of the bone these planes are arranged in a curved form, in order to strengthen the bone when exposed to pressure in all directions. In the midst of the cancellous tissue of the neck is a vertical plane of compact bone, the *femoral spur* (*calcar femorale*) which commences at the point where the neck joins the shaft midway between the small trochanter and the internal border of the shaft of the bone, and extends in the direction of the digital fossa (fig. 322). This materially strengthens this portion of the bone. Another point in connection with the structure of the neck of the femur requires mention, especially on account of its influence on the production of fracture in this situation. It will be noticed that a considerable portion of the great trochanter lies behind the level of the posterior surface of the neck, and if a section be made through the trochanter at this level, it will be seen that the posterior wall of the neck is prolonged into the trochanter. This prolongation is termed by Bigelow the 'true neck,'* and forms a thin, dense plate of bone, which passes beneath the posterior intertrochanteric ridge towards the outer surface of the bone.

Fig. 321.—Diagram showing the arrangement of the cancelli of the neck of the femur.



In the lower end, the cancelli spring on all sides from the inner surface of the cylinder, and descend in a perpendicular direction to the articular surface, the cancelli being strongest and having a more accurately perpendicular course above the condyles. In addition to this, however, horizontal planes of cancellous tissue are to be seen, so that the spongy tissue in this situation presents an appearance of being mapped out into a series of rectangular areas.

Articulations.—With three bones: the os innominatum, tibia, and patella.

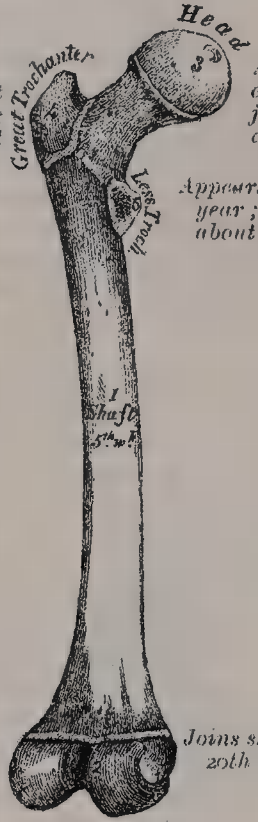
Development (fig. 323).—The femur is developed by *five* centres: one for the shaft, one for each extremity, and one for each trochanter. Of all the long bones, except the clavicle, it is the first to show traces of ossification; this commences in the shaft, at about the seventh week of fœtal life; the centres of ossification

* *Bigelow on the Hip*, p. 121.

in the epiphyses appearing in the following order: In the lower end of the bone, at the ninth month of fœtal life * (from this the condyles and tuberosities are formed); in the head, at the end of the first year after birth; in the great trochanter, during the fourth year; and in the small trochanter, between the thirteenth and fourteenth. The order in which the epiphyses are joined to the shaft is the reverse of that of their appearance: their junction does not commence until after puberty, the small trochanter being first joined, then the great, then the head, and, lastly, the inferior extremity (the first in which ossification commenced), which is not united until the twentieth year.

Fig. 322.—Calcar femorale.

Fig. 323.—Plan of the development of the femur. By five centres.



Attachment of Muscles.—To twenty-three. To the great trochanter: the Gluteus medius, Gluteus minimus, Pyriformis, Obturator internus, Obturator externus, Gemellus superior, Gemellus inferior, and Quadratus femoris. To the lesser trochanter: the Psoas magnus and the Iliacus below it. To the shaft: the Vastus externus, Gluteus maximus, short head of the Biceps, Adductor magnus, Pectineus, Adductor brevis, Adductor longus, Vastus internus, Crureus, and Subcrureus. To the condyles: the Gastrocnemius, Plantaris, and Popliteus.

Surface Form.—The femur is covered with muscles, so that in fairly muscular subjects the shaft is not to be detected through its fleshy covering, and the only parts always accessible to the touch are the outer surface of the great trochanter and the lower expanded end of the bone. In very thin subjects, the head of the bone may be felt through the overlying muscles, immediately below and external to the mid-point of Poupart's ligament. The external surface of the great trochanter is to be felt, especially in certain positions of the limb. Its situation is generally indicated by a depression, owing to the thickness of the Gluteus medius and minimus, which project above it. When, however, the thigh is flexed, and especially if crossed over the opposite one, the trochanter produces a blunt eminence on the surface. The upper border is about on a level with the centre of the hip-joint, and its exact level is indicated by a line drawn from the anterior superior spinous

* This is said to be the only epiphysis in which ossification begins before birth; though according to some observers the centre for the upper epiphysis of the tibia also appears before birth.

process of the ilium, over the outer side of the hip, to the most prominent point of the tuberosity of the ischium. This is known as Nélaton's line. The outer and inner condyles of the lower extremity are accessible to the touch. The outer one is more subcutaneous than the inner one, and readily felt. The tuberosity on it is comparatively little developed, but can be more or less easily recognised. The inner condyle is more thickly covered, and this gives a general convex outline to this part, especially when the knee is flexed. The tuberosity on it is easily felt, and at the upper part of the condyle the sharp tubercle for the insertion of the tendon of the Adductor magnus can be recognised without difficulty. When the knee is flexed, and the patella situated in the interval between the condyles and the upper end of the tibia, a part of the trochlear surface of the femur can be made out above the patella.

Surgical Anatomy.—There are one or two points about the ossification of the femur bearing on practice to which allusion must be made. It has been stated that the lower end of the femur is the only epiphysis in which ossification has commenced at the time of birth. The presence of this ossific centre is, therefore, a proof, in newly born children found dead, that the child has arrived at the full period of utero-gestation, and is always relied upon in medico-legal investigations. The position of the epiphysial line should be carefully noted. It is on a level with the Adductor tubercle, and the epiphysis does not, therefore, form the whole of the cartilage-clad portion of the lower end of the bone. It is essential to bear this point in mind in performing excision of the knee, since growth in length of the femur takes place chiefly from the lower epiphysis, and any interference with the epiphysial cartilage in a young child would involve such ultimate shortening of the limb, from want of growth, as to render the limb almost useless. Separation of the lower epiphysis may take place up to the age of twenty, at which time it becomes completely joined to the shaft of the bone; but, as a matter of fact, few cases occur after the age of sixteen or seventeen. The epiphysis of the head of the femur is of interest principally on account of its being the seat of origin in a large number of cases of tuberculous disease of the hip-joint. The disease commences in the majority of cases in the highly vascular and growing tissue at the end of the shaft in the neighbourhood of the epiphysial cartilage, and from here extends into the joint.

Fractures of the femur are divided, like those of the other long bones, into fractures of the upper end; of the shaft; and of the lower end. The fractures of the upper end may be classified into (1) fracture of the neck; (2) fracture at the junction of the neck with the great trochanter; (3) fracture of the great trochanter; and (4) separation of the epiphysis, either of the head or of the great trochanter. The first of these, fracture of the neck, is usually termed intracapsular fracture, but this is scarcely a correct designation, as, owing to the attachment of the capsular ligament, the fracture is partly within and partly without the capsule when the fracture occurs at the lower part of the neck. It generally takes place in old people, principally women, and usually from a very slight degree of indirect violence. Probably the main cause of the fracture occurring in old people is in consequence of the degenerative changes which the bone has undergone. Merkel believes that it is mainly due to the absorption of the calcar femorale. These fractures are occasionally impacted. As a rule they unite by fibrous tissue, but frequently no union takes place, and the surfaces of the fracture become smooth and eburnated.

Fractures at the junction of the neck with the great trochanter are usually termed extra-capsular, but this designation is also incorrect, as the fracture is partly within the capsule, owing to its attachment in front to the anterior intertrochanteric line, which is situated below the line of fracture. These fractures are produced by direct violence to the great trochanter, as from a blow or fall laterally on the hip. From the manner in which the accident is caused, the neck of the bone is driven into the trochanter, where it may remain impacted, or the trochanter may be split up into two or more fragments, and thus no fixation takes place.

Fractures of the great trochanter may be either 'oblique fracture through the trochanter major, without implicating the neck of the bone' (Astley Cooper), or separation of the great trochanter. Most of the recorded cases of this latter injury occurred in young persons, and were probably cases of separation of the epiphysis of the great trochanter. Separation of the epiphysis of the head of the femur has been said to occur, but has never been verified by post-mortem examination.

Fractures of the shaft may occur at any part, but the most usual situation is at or near the centre of the bone. They may be caused by direct or indirect violence or by muscular action. Fractures of the upper third of the shaft are almost always the result of indirect violence, while those of the lower third are the result, for the most part, of direct violence. In the middle third fractures occur from both forms of injury in about equal proportions. Fractures of the shaft are generally oblique, but they may be transverse, longitudinal, or spiral. The transverse fracture occurs most frequently in children. The fractures of the lower end of the femur include transverse fracture above the condyles, the most common; and this may be complicated by a vertical fracture between the condyles, constituting the T-shaped fracture. In these cases the popliteal artery is in danger of being wounded. Oblique fracture separating either the internal or external condyle, and a longitudinal incomplete fracture between the condyles, may also take place.

The femur as well as the other bones of the leg are frequently the seat of acute necrosis in young children. This is no doubt due to their greater exposure to injury, which is often the exciting cause of this disease. Tumours are not infrequently found growing from the femur: the most common forms being sarcoma, which may grow either from the periosteum or from the medullary tissue within the interior of the bone; and exostosis, which is commonly found originating in the neighbourhood of the epiphysial cartilage of the lower end.

THE LEG

The skeleton of the Leg consists of three bones: the Patella, a large, sesamoid bone, placed in front of the knee; the Tibia; and the Fibula.

The Patella (figs. 324, 325)

The **Patella** (patella, *a small pan*) is a flat, triangular bone, situated at the anterior part of the knee-joint. It is usually regarded as a sesamoid bone, developed in the tendon of the Quadriceps extensor. It resembles these bones (1) in its being developed in a tendon; (2) in its centre of ossification presenting a knotty or tubercular outline; (3) in its structure being composed mainly of dense cancellous tissue, as in the other sesamoid bones. It serves to protect the front of the joint, and increases the leverage of the Quadriceps extensor by making it act at a greater angle. It presents an anterior and posterior surface, three borders, and an apex.

The **anterior surface** is convex, perforated by small apertures, for the passage of nutrient vessels, and marked by numerous rough, longitudinal striæ. This surface is covered, in the recent state, by an expansion from the tendon of the Quadriceps extensor, which is continuous below with the superficial fibres of the ligamentum patellæ. It is separated from the integument by a bursa. The **posterior surface** presents a smooth, oval-shaped, articular surface, covered with cartilage in the recent state, and divided into two facets by a vertical ridge, which descends from the superior border towards the inferior angle of the bone. The ridge corresponds to the groove on the trochlear surface of the femur, and the two facets to the inner and outer parts of the same surface; the outer facet being the broader and deeper. This character serves to indicate the side to which the bone belongs. Below the articular surface is a rough, convex, non-articular depression, the lower half of which gives attachment to the ligamentum patellæ; the upper half being separated from the head of the tibia by adipose tissue.

Fig. 324.—Right patella. Anterior surface.

Fig. 325.—Right patella. Posterior surface.

The **superior border** is thick, and sloped from behind, downwards and forwards: it gives attachment to that portion of the Quadriceps extensor which is derived from the Rectus and Crureus muscles. The **lateral borders** are thinner, converging below: they give attachment to that portion of the Quadriceps extensor derived from the external and internal Vasti muscles.

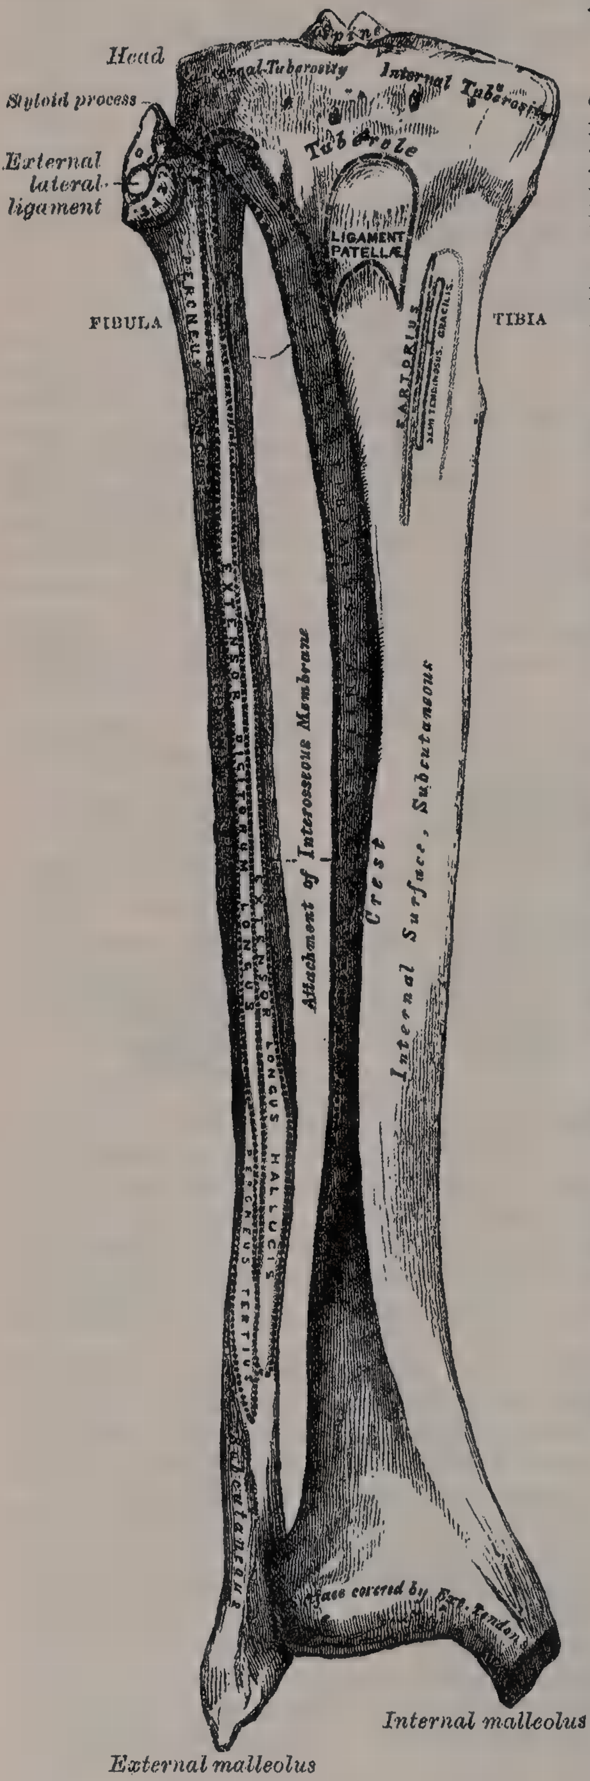
The **apex** is pointed, and gives attachment to the ligamentum patellæ.

Structure.—The patella consists of a nearly uniform dense cancellous tissue, covered by a thin compact lamina. The cancelli immediately beneath the anterior surface are arranged parallel with it. In the rest of the bone they radiate from the posterior articular surface towards the other parts of the bone.

Development.—By a single centre, which makes its appearance in the second or third year, but which may be delayed until the sixth year. More rarely, the bone is developed by two centres, placed side by side. Ossification is completed about the age of puberty.

Articulations.—With the two condyles of the femur.

Fig. 326.—Bones of the right leg. Anterior surface.



Attachment of Muscles.—To four: the Rectus, Crureus, Vastus internus, and Vastus externus. These muscles, joined at their insertion, constitute the Quadriceps extensor cruris.

Surface Form.—The external surface of the patella can be seen and felt in front of the knee. In the extended position of the limb the internal border is a little more prominent than the outer, and if the Quadriceps extensor is relaxed, the bone can be moved from side to side and appears to be loosely fixed. If the joint is flexed, the patella recedes into the hollow between the condyles of the femur and the upper end of the tibia, and becomes firmly fixed against the femur.

Surgical Anatomy.—The main surgical interest about the patella is in connection with fractures, which are of common occurrence. They may be produced by muscular action—that is to say, by violent contraction of the Quadriceps extensor, while the limb is in a position of semiflexion, so that the bone is snapped across the condyles; or by direct violence, such as falls on the knee. In the former class of cases the fracture is transverse; in the latter it may be oblique, longitudinal, stellate, or the bone variously comminuted. The principal interest in these cases attaches to their treatment. Owing to the displacement of the fragments, and the difficulty there is in maintaining them in apposition, union takes place by fibrous tissue, and this may subsequently stretch, producing wide separation of the fragments and permanent lameness. Various plans, including opening the joint and suturing the fragments, have been advocated for overcoming this difficulty.

In the larger number of cases of fracture of the patella, the knee-joint is involved, the cartilage which covers its posterior surface being also torn. In some cases of fracture from direct violence, however, this need not necessarily happen, the lesion involving only the superficial part of the bone; and, as Morris has pointed out, it is an anatomical possibility, in complete fracture, if the lesion involve only the lower and non-articular part of the bone, for it to take place without injury to the synovial membrane.

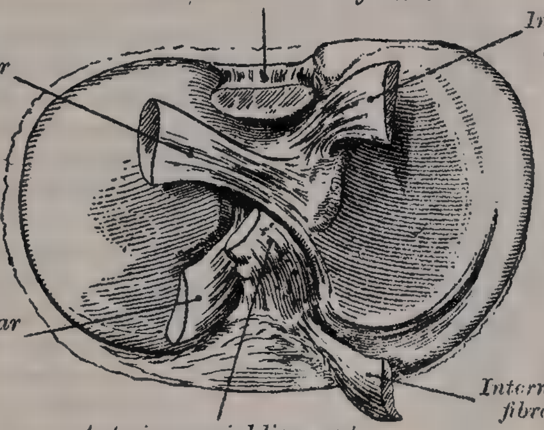
The Tibia (figs. 326, 328)

The **Tibia** (tibia, *a flute* or *pipe*) is situated at the front and inner side of the leg, and, excepting the femur, is the longest and largest bone in the skeleton. It is prismoid in form, expanded above, where it enters into the knee-joint, more slightly enlarged below. In the

male, its direction is vertical, and parallel with the bone of the opposite side; but in the female it has a slightly oblique direction downwards and outwards, to compensate for the oblique direction of the femur inwards. It presents for examination a shaft and two extremities.

The **Upper Extremity,** or **Head,** is large, and expanded on each side into two lateral eminences, the *tuberosities. Superiorly,* the tuberosities present two smooth articular surfaces, one on either side of the middle line. The inner of these is oval in shape, and slightly concave from side to side and from before backwards. The outer, nearly circular, is concave from side to side, but slightly convex from before backwards, especially at its posterior part, where it is prolonged on to the posterior surface for a short distance. The central portions of these facets articulate with the condyles of the femur, while their peripheral portions support the semilunar cartilages of the knee, which here intervene between the two bones. In the middle line, but nearer the posterior than the anterior aspect of the bone, is an eminence, the *spinous process* of the tibia, surmounted on each side by a prominent tubercle, on to the lateral aspect of which the facets, just described, are prolonged; in front and behind the spinous process is a rough depression for the attachment of the anterior and posterior crucial ligaments and the semilunar fibro-cartilages (fig. 327). The *anterior surfaces* of the tuberosities are continuous with one another, forming a single large surface, which is somewhat flattened: it is triangular, broad above, and perforated by large vascular foramina: narrow below where it terminates in a prominent oblong elevation

Fig. 327.—Upper surface of tibia, showing attachment of crucial ligament and fibro-cartilages.



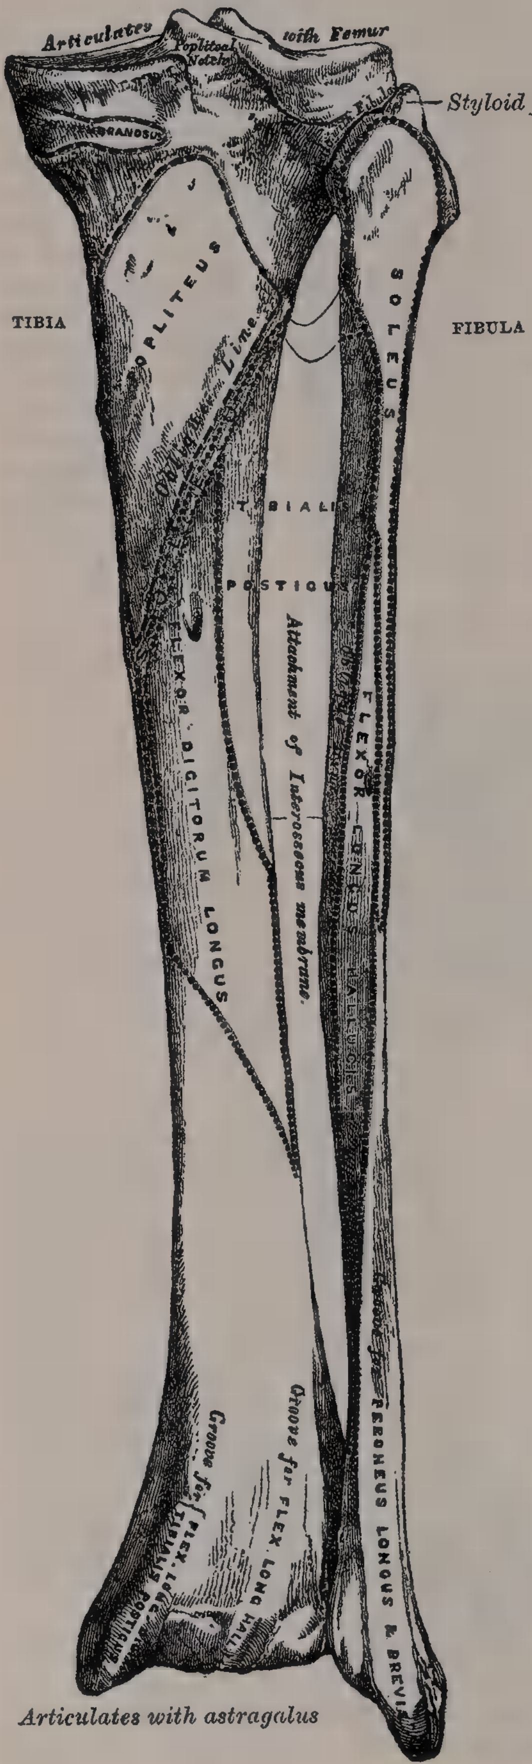
of large size, the *tubercle* of the tibia, which gives attachment to the ligamentum patellæ; a bursa intervenes between the deep surface of the ligament and the part of the bone immediately above the tubercle. *Posteriorly,* the tuberosities are separated from each other by a shallow depression, the *popliteal notch,* which gives attachment to part of the posterior crucial ligament, and part of the posterior ligament of the knee-joint. The *inner tuberosity* presents posteriorly a deep transverse groove, for the insertion of the tendon of the Semimembranosus. Its *lateral surface* is convex, rough and prominent: it gives attachment to the internal lateral ligament. The *outer tuberosity* presents posteriorly a flat articular facet, nearly circular in form, directed downwards, backwards, and outwards, for articulation with the head of the fibula. Its *lateral surface* is convex and rough, more prominent in front than the internal: it presents an eminence, situated on a level with the upper border of the tubercle of the tibia at the junction of its anterior and outer surfaces, for the attachment of the ilio-tibial band. Just below this the Extensor longus digitorum and a slip from the Biceps are attached.

The **Shaft** of the tibia is of a triangular prismoid form, broad above, gradually decreasing in size to its most slender part, at the commencement of its lower fourth, where fracture most frequently occurs. It then enlarges again towards its lower extremity. It presents for examination three borders and three surfaces.

The **anterior border,** the most prominent of the three, is called the *crest of the*

tibia, or, in popular language, the *shin*; it commences above at the tubercle, and terminates below at the anterior margin of the inner malleolus. This border is sinuous, prominent in the upper two-thirds of its extent, smooth and rounded below; it gives attachment to the deep fascia of the leg.

Fig. 328.—Bones of the right leg. Posterior surface.



The **internal border** is smooth and rounded above and below, but more prominent in the centre; it commences at the back part of the inner tuberosity, and terminates at the posterior border of the internal malleolus; its upper part gives attachment to the internal lateral ligament of the knee to the extent of about two inches, and insertion to some fibres of the Popliteus muscle; from its middle third some fibres of the Soleus and Flexor longus digitorum muscles take origin.

The **external border**, or **interosseous ridge**, is thin and prominent, especially its central part, and gives attachment to the interosseous membrane; it commences above in front of the fibular articular facet, and bifurcates below, to form the boundaries of a triangular rough surface, for the attachment of the interosseous ligament connecting the tibia and fibula.

The **internal surface** is smooth, convex, and broader above than below; its upper third, directed forwards and inwards, is covered by the aponeurosis derived from the tendon of the Sartorius, and by the tendons of the Gracilis and Semitendinosus, all of which are inserted nearly as far forwards as the anterior border; in the rest of its extent it is subcutaneous.

The **external surface** is narrower than the internal; its upper two-thirds presents a shallow groove for the origin of the Tibialis anticus muscle; its lower third is smooth, convex, curves gradually forwards to the anterior aspect of the bone, and is covered from within outwards by the tendons of the following muscles: Tibialis anticus, Extensor proprius hallucis, Extensor longus digitorum.

The **posterior surface** (fig. 328) presents, at its upper part, a prominent ridge, the *oblique line* of the tibia, which extends from the back part of the articular facet

for the fibula obliquely downwards, to the internal border, at the junction of its upper and middle thirds. It marks the lower limit of the insertion of the Popliteus muscle and serves for the attachment of the popliteal fascia ; it gives origin to part of the Soleus, Flexor longus digitorum, and Tibialis posticus muscles ; the triangular area, above and to the inner side of this line, gives insertion to the Popliteus muscle. The middle third of the posterior surface is divided by a vertical ridge into lateral halves : the ridge is well marked at its commencement at the oblique line, but becomes gradually indistinct below ; the inner and broader half gives origin to the Flexor longus digitorum, the outer and narrower to part of the Tibialis posticus. The remaining part of the bone presents a smooth surface covered by the Tibialis posticus, Flexor longus digitorum, and Flexor longus hallucis muscles. Immediately below the oblique line is the medullary foramen, which is large and directed obliquely downwards.

The **Lower Extremity**, much smaller than the upper, presents five surfaces ; it is prolonged downwards, on its inner side into a strong process, the *internal malleolus.* The *inferior surface* of the bone is quadrilateral, and smooth for articulation with the astragalus. It is concave from before backwards, broader in front than behind, and traversed from before backwards by a slight elevation, separating two lateral depressions. It is narrow internally, where the articular surface becomes continuous with that on the inner malleolus. The *anterior surface* of the lower extremity is smooth and rounded above, and covered by the tendons of the Extensor muscles of the toes ; its lower margin presents a rough transverse depression, for the attachment of the anterior ligament of the ankle-joint ; the *posterior surface* presents a superficial groove directed obliquely downwards and inwards, continuous with a similar groove on the posterior surface of the astragalus, and serving for the passage of the tendon of the Flexor longus hallûcis ; the *external surface* presents a triangular rough depression for the attachment of the inferior interosseous ligament connecting it with the fibula ; the lower part of this depression is smooth, covered with cartilage in the recent state, and articulates with the fibula. The surface is bounded by two prominent borders, continuous above with the interosseous ridge ; they afford attachment to the anterior and posterior inferior tibio-fibular ligaments. The *internal surface* of the lower extremity is prolonged downwards to form a strong pyramidal process, flattened from without inwards—the *internal malleolus.* The *inner surface* of this process is convex and subcutaneous ; its *outer surface* is smooth and slightly concave, and articulates with the astragalus ; its *anterior border* is rough, for the attachment of the anterior fibres of the internal lateral or Deltoid ligament ; its *posterior border* presents a broad and deep groove, directed obliquely downwards and inwards, which is occasionally double ; this groove transmits the tendons of the Tibialis posticus and Flexor longus digitorum muscles. The *summit* of the internal malleolus is marked by a rough depression behind, for the attachment of the internal lateral ligament of the ankle-joint.

Fig. 329.—Plan of the development of the tibia. By three centres.

Structure.—Like that of the other long bones. At the junction of the middle and lower thirds, where the bone is smallest, the wall of the shaft is thicker than in other parts, in order to compensate for the smallness of the calibre of the bone.

Development.—By *three* centres (fig. 329) : one for the shaft, and one for

each extremity. Ossification commences in the centre of the shaft about the seventh week, and gradually extends towards either extremity. The centre for the upper epiphysis appears before or shortly after birth; it is flattened in form, and has a thin tongue-shaped process in front, which forms the tubercle. That for the lower epiphysis appears in the second year. The lower epiphysis joins the shaft at about the eighteenth, and the upper one about the twentieth year. Two additional centres occasionally exist, one for the tongue-shaped process of the upper epiphysis, which forms the tubercle, and one for the inner malleolus.

Articulations.—With three bones: the femur, fibula, and astragalus.

Attachment of Muscles.—To twelve: to the inner tuberosity, the Semimembranosus; to the outer tuberosity, the Tibialis anticus and Extensor longus digitorum and Biceps; to the internal surface of the shaft, the Sartorius, Gracilis, and Semitendinosus; to its external surface, the Tibialis anticus; to its posterior surface, the Popliteus, Soleus, Flexor longus digitorum, and Tibialis posticus; to the tubercle, the ligamentum patellæ, by which the Quadriceps extensor muscle is inserted into the tibia. In addition to these muscles, the Tensor fasciæ femoris is inserted indirectly into the tibia, through the ilio-tibial band, and the Peroneus longus occasionally derives a few fibres of origin from the outer tuberosity.

Surface Form.—A considerable portion of the tibia is subcutaneous and easily to be felt. At the upper extremity the tuberosities are to be recognised just below the knee. The internal one is broad and smooth, and merges into the subcutaneous surface of the shaft below. The external one is narrower and more prominent, and on it, about midway between the apex of the patella and the head of the fibula, may be felt a prominent tubercle for the insertion of the ilio-tibial band. In front of the upper end of the bone, between the tuberosities, is the tubercle of the tibia, forming an oval eminence, which is continuous below with the anterior border or crest of the bone. This border can be felt, forming the prominence of the shin, in the upper two-thirds of its extent as a sharp and flexuous ridge. In the lower third of the leg the border disappears and the bone is concealed by the tendons of the muscles on the front of the leg. Internal to the anterior border is to be felt the broad internal surface of the tibia, slightly encroached upon by the muscles in front and behind. It commences above at the wide expanded inner tuberosity and terminates below at the internal malleolus. The internal malleolus is a broad prominence situated on a higher level and somewhat farther forwards than the external malleolus. It overhangs the inner border of the arch of the foot. Its anterior border is nearly straight, its posterior border presents a sharp edge, which forms the inner margin of the groove for the tendon of the Tibialis posticus muscle.

The Fibula (figs. 326, 328)

The **Fibula** (fibula, *a clasp*) is situated at the outer side of the leg. It is the smaller of the two bones, and, in proportion to its length, the most slender of all the long bones; it is placed on the outer side of the tibia, with which it is connected above and below. Its upper extremity is small, placed towards the back of the head of the tibia, below the level of the knee-joint, and excluded from its formation; the lower extremity inclines a little forwards, so as to be on a plane anterior to that of the upper end; it projects below the tibia, and forms the outer ankle. The bone presents for examination a shaft and two extremities.

The **Upper Extremity,** or **Head,** is of an irregular quadrate form, presenting above a flattened articular facet, directed upwards, forwards and inwards, for articulation with a corresponding facet on the external tuberosity of the tibia. On the outer side is a thick and rough prominence, continued behind into a pointed eminence, the *styloid process,* which projects upwards from the posterior part of the head. The prominence, at its upper and outer part, gives attachment to the tendon of the Biceps muscle, and to the long external lateral ligament of the knee, the ligament dividing the tendon into two parts. The summit of the styloid process gives attachment to the short external lateral ligament. The remaining part of the circumference of the head is rough, for the attachment of muscles and ligaments. It presents in front a tubercle for the origin of the upper and anterior part of the Peroneus longus, and the adjacent surface gives attachment to the anterior superior tibio-fibular ligament; and behind,

another tubercle for the attachment of the posterior superior tibio-fibular ligament, and the origin of the upper fibres of the Soleus muscle.

The **Shaft** presents four borders—the antero-external, the antero-internal, the postero-external, and the postero-internal; and four surfaces—anterior, posterior, internal, and external.

The **antero-external border** commences above in front of the head, runs vertically downwards to a little below the middle of the bone, and then curving somewhat outwards, bifurcates so as to embrace a triangular subcutaneous surface immediately above the outer surface of the external malleolus. This border gives attachment to an intermuscular septum, which separates the Extensor muscles on the anterior surface of the leg from the Peroneus longus and brevis muscles on the outer surface.

The **antero-internal border,** or **interosseous ridge,** is situated close to the inner side of the preceding, and runs nearly parallel with it in the upper third of its extent, but diverges from it so as to include a broader space in the lower two-thirds. It commences above just beneath the head of the bone (sometimes it is quite indistinct for about an inch below the head), and terminates at the apex of a rough triangular surface immediately above the articular facet of the external malleolus. It serves for the attachment of the interosseous membrane, which separates the Extensor muscles in front from the Flexor muscles behind.

The **postero-external border** is prominent; it commences above at the base of the styloid process, and terminates below in the posterior border of the outer malleolus. It is directed outwards above, backwards in the middle of its course, backwards and a little inwards below, and gives attachment to an aponeurosis which separates the Peronei muscles on the outer surface of the shaft from the Flexor muscles on its posterior surface.

The **postero-internal border,** sometimes called the *oblique line*, commences above at the inner side of the head, and terminates by becoming continuous with the antero-internal border or interosseous ridge at the lower fourth of the bone. It is well marked and prominent at the upper and middle parts of the bone. It gives attachment to an aponeurosis which separates the Tibialis posticus from the Soleus above and the Flexor longus hallucis below.

The **anterior surface** is the interval between the antero-external and antero-internal borders. It is extremely narrow and flat in the upper third of its extent; broader and grooved longitudinally in its lower third; it serves for the origin of three muscles, the Extensor longus digitorum, Extensor proprius hallucis, and Peroneus tertius.

The **posterior surface** is the space included between the postero-external and the postero-internal borders; it is continuous below with the triangular surface above the articular facet of the outer malleolus; it is directed backwards above, backwards and inwards at its middle, directly inwards below. Its upper third is rough, for the origin of the Soleus muscle; its lower part presents a triangular surface, connected to the tibia by a strong interosseous ligament, and between these two points the entire surface is covered by the fibres of origin of the Flexor longus hallucis muscle. At about the middle of this surface is the nutrient foramen, which is directed downwards.

The **internal surface** is the interval included between the antero-internal and the postero-internal borders. It is directed inwards, and is grooved for the origin of the Tibialis posticus muscle.

The **external surface** is the space between the antero-external and postero-external borders. It is much broader than the preceding, and often deeply grooved, is directed outwards in the upper two-thirds of its course, backwards in the lower third, where it is continuous with the posterior border of the external malleolus. This surface is completely occupied by the Peroneus longus and brevis muscles.

The **Lower Extremity,** or **external malleolus,** is of a pyramidal form, somewhat flattened from without inwards, and is longer, and descends lower, than the internal malleolus. Its *external surface* is convex, subcutaneous, and continuous with the triangular, subcutaneous surface on the outer side of the shaft. The *internal surface* presents in front a smooth triangular facet, broader above than below, and convex from above downwards, which articulates with a corresponding surface on the outer side of the astragalus. Behind and beneath the

articular surface is a rough depression, which gives attachment to the posterior fasciculus of the external lateral ligament of the ankle. The *anterior border* is thick and rough, and marked below by a depression for the attachment of the anterior fasciculus of the external lateral ligament. The *posterior border* is broad and marked by a shallow groove, for the passage of the tendons of the Peroneus longus and brevis muscles. The *summit* is rounded, and gives attachment to the middle fasciculus of the external lateral ligament.

In order to distinguish the side to which the bone belongs, hold it with the lower extremity downwards, and the broad groove for the Peronei tendons backwards, i.e. towards the holder: the triangular subcutaneous surface will then be directed to the side to which the bone belongs.

Fig. 330.—Plan of the development of the fibula. By three centres.

Articulations.—With two bones: the tibia and astragalus.

Development.—By *three* centres (fig. 330): one for the shaft, and one for each extremity. Ossification commences in the shaft about the eighth week of fœtal life, a little later than in the tibia, and extends gradually towards the extremities. At birth both ends are cartilaginous. Ossification commences in the lower end in the second year, and in the upper one about the fourth year. The lower epiphysis, the first in which ossification commences, becomes united to the shaft about the twentieth year; the upper epiphysis joins about the twenty-fifth year. Ossification appearing first in the lower epiphysis is contrary to the rule which prevails with regard to the commencement of ossification in epiphyses, viz. that the epiphysis towards which the nutrient artery is directed commences to ossify last; but it follows the rule which prevails with regard to the union of epiphyses, by uniting first.

Attachment of Muscles.—To nine: to the head, the Biceps, Soleus, and Peroneus longus; to the anterior surface of the shaft, the Extensor longus digitorum, Peroneus tertius, and Extensor proprius hallucis; to the internal surface, the Tibialis posticus; to the posterior surface, the Soleus and Flexor longus hallucis; to the external surface, the Peroneus longus and brevis.

Surface Form.—The only parts of the fibula which are to be felt are the head, the lower part of the external surface of the shaft, and the external malleolus. The head is to be seen and felt behind and to the outer side of the outer tuberosity of the tibia. It presents a small, prominent, triangular eminence slightly above the level of the tubercle of the tibia. The external malleolus presents a narrow elongated prominence, situated on a plane posterior to the internal malleolus and reaching to a lower level. From it may be traced the lower third or half of the external surface of the shaft of the bone in the interval between the Peroneus tertius in front and the other two Peronei tendons behind.

Surgical Anatomy.—In fractures of the bones of the leg, both bones are generally fractured, but each bone may be broken separately, the fibula more frequently than the tibia. Fracture of both bones may be caused either by direct or indirect violence. When it occurs from indirect force, the fracture in the tibia is at the junction of the middle and lower third of the bone. Many causes conduce to render this the weakest part of the bone. The fracture of the fibula is usually at rather a higher level. These fractures present great variety, both as regards their direction and condition. They may be oblique, transverse, longitudinal, or spiral. When oblique, they are for the most part the result of indirect violence, and the direction of the fracture is from behind, downwards, forwards, and inwards in many cases, but may be downwards and outwards, or downwards and backwards. When transverse, the fracture is often at the upper part of the bone, and is the result of direct violence. The spiral fracture of the tibia generally commences as a vertical fissure, involving the ankle-joint, and is associated with fracture of the fibula higher up. It is the result of torsion, from twisting of the body while the foot is fixed.

FIG. 331.—Bones of the right foot. Dorsal surface.

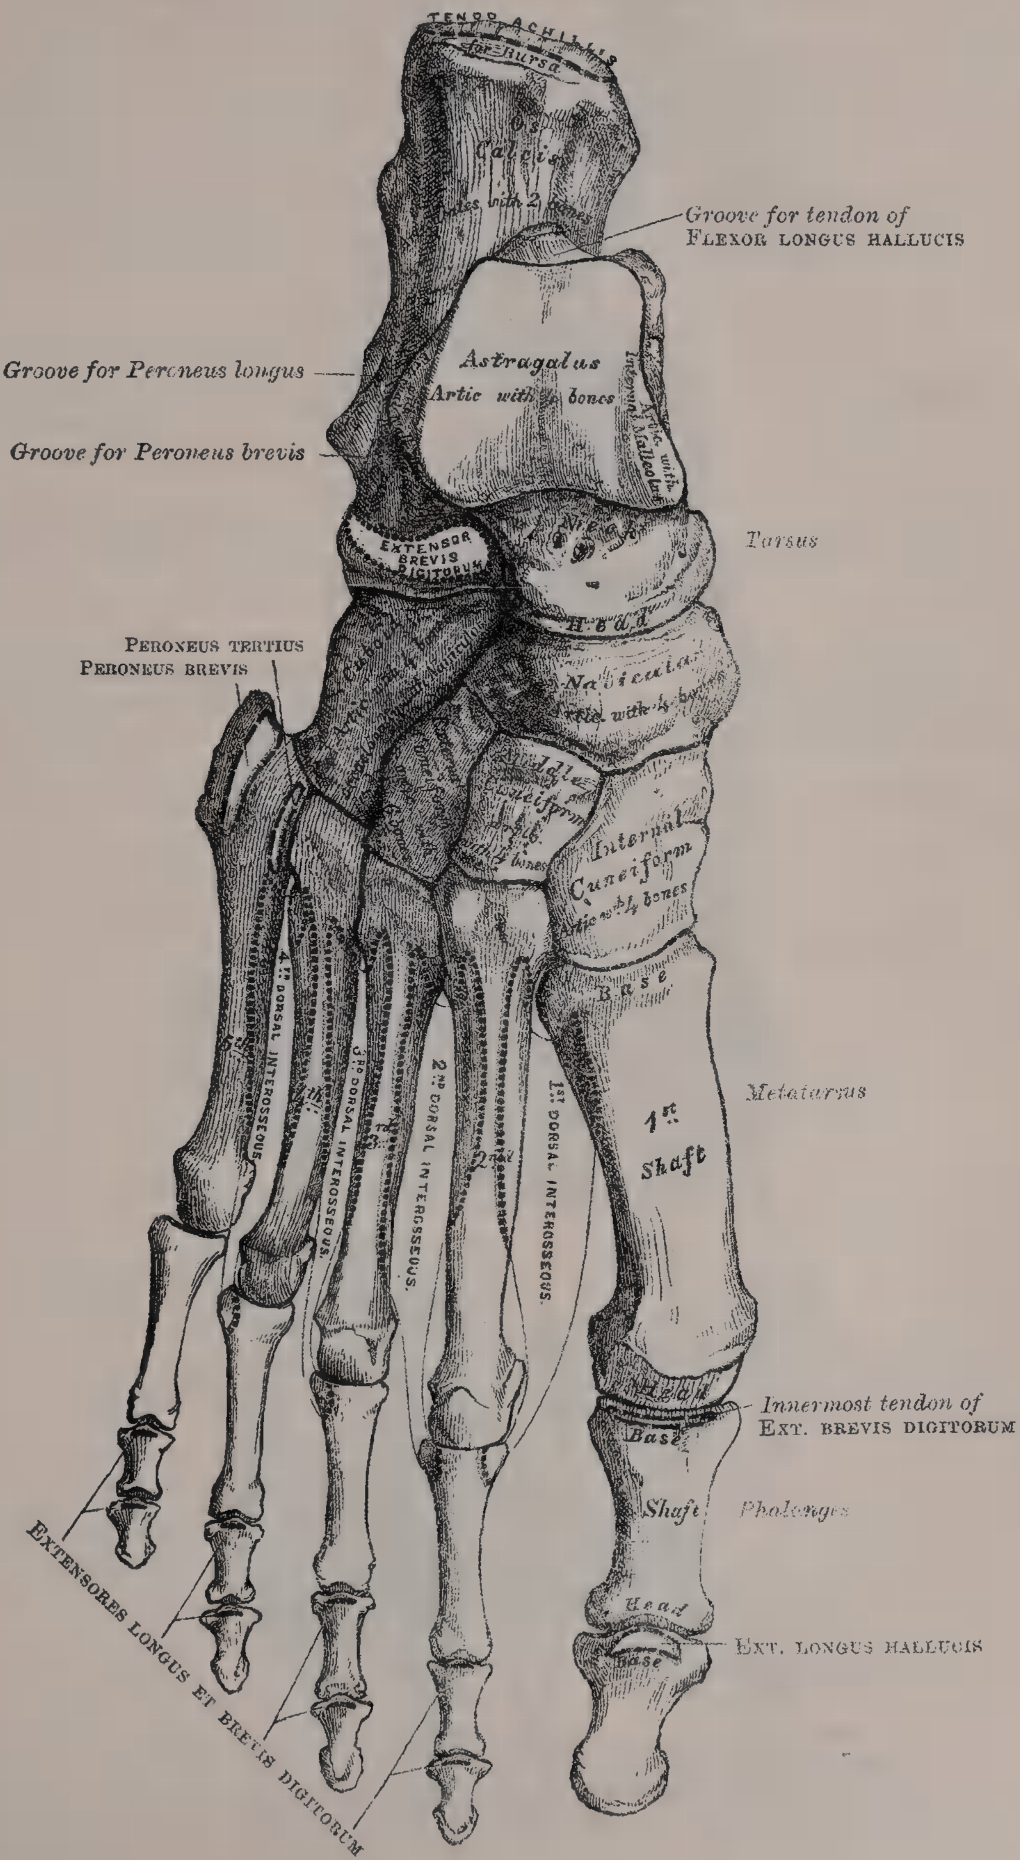


FIG. 332.—Bones of the right foot. Plantar surface.

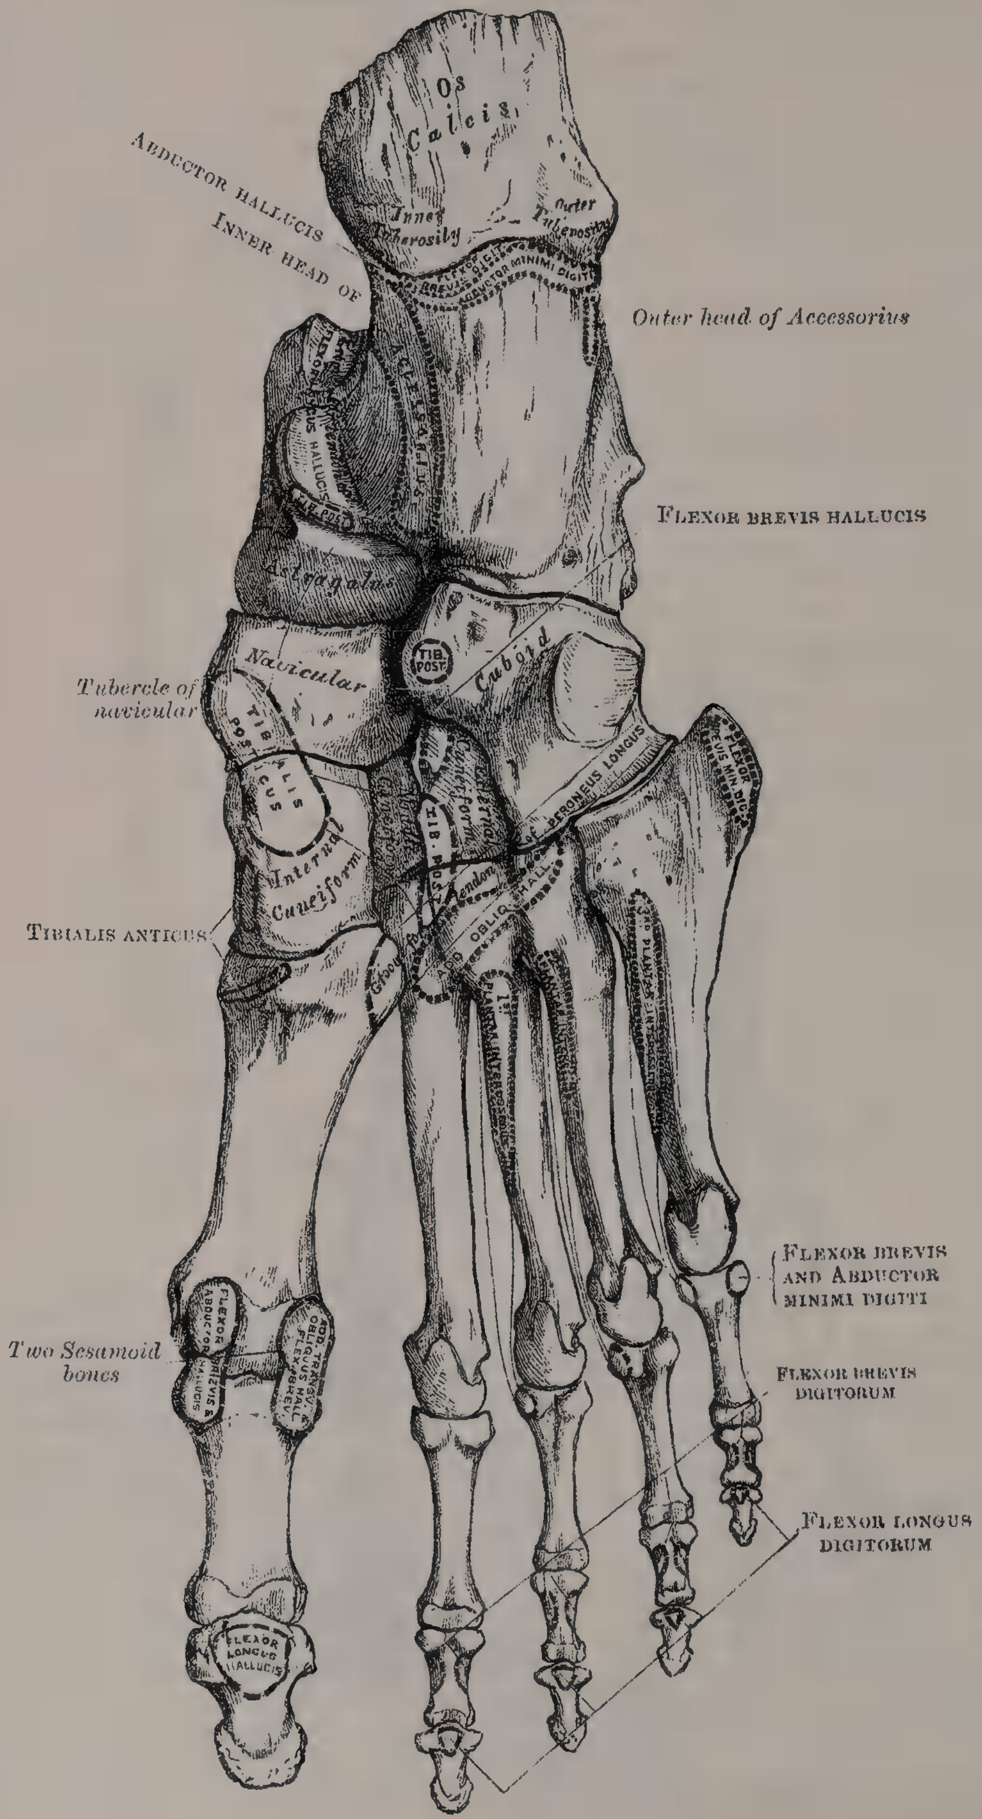


Fractures of the tibia alone are almost always the result of direct violence, except where the malleolus is broken off by twists of the foot. Fractures of the fibula alone may arise from indirect or direct force, those of the lower end being usually the result of the former, and those higher up being caused by a direct blow on the part.

The tibia and fibula, like the femur, are often the seat of acute necrosis. Chronic abscess is more frequently met with in the cancellous tissue of the head and lower end of the tibia than in any other bone of the body. The abscess is of small size, very chronic, and probably the result of tuberculous osteitis in the highly vascular growing tissue at the end of the shaft near the epiphysial cartilage in the young subject.

The tibia is the bone which is most commonly and most extensively distorted in rickets. It gives way at the junction of the middle and lower third, its weakest part, and presents a curve forwards with generally some lateral displacement.

THE FOOT (figs. 331, 332)

The skeleton of the Foot consists of three divisions: the Tarsus, Metatarsus, and Phalanges.

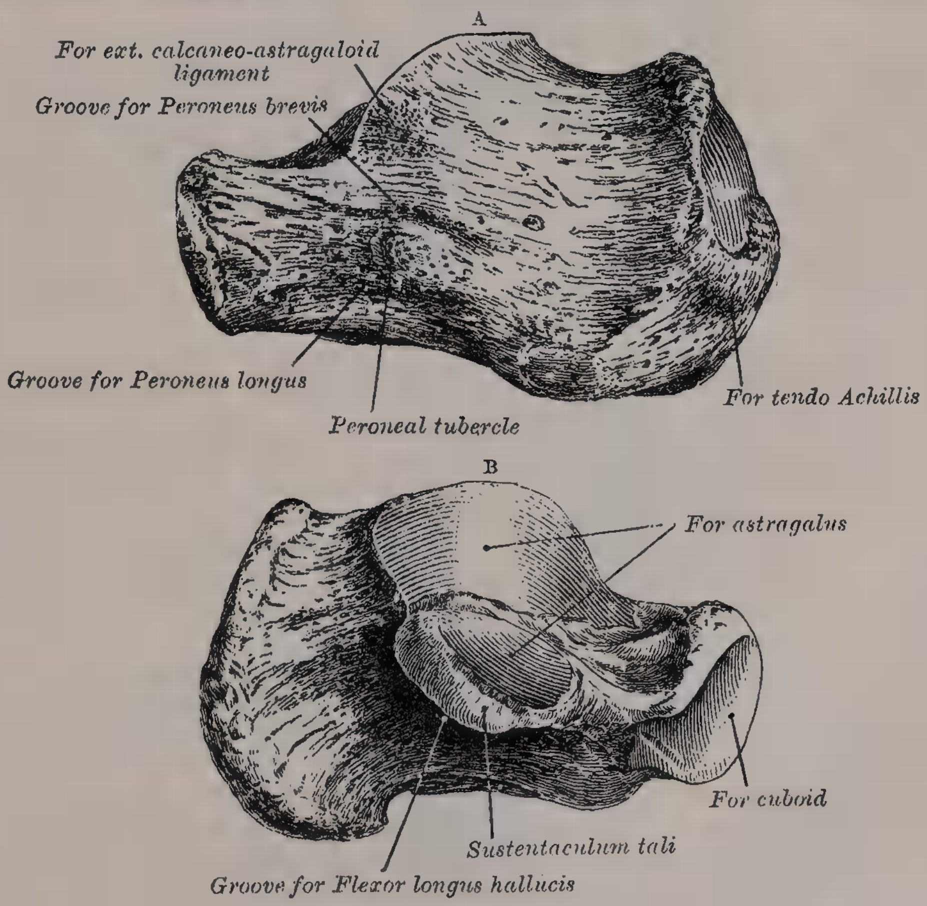
THE TARSUS

The bones of the **Tarsus** are seven in number: viz. the calcaneum or os calcis, astragalus, cuboid, navicular, internal, middle, and external cuneiform bones.

The Calcaneum (fig. 333)

The **Calcaneum**, or **Os Calcis** (calx, *the heel*), is the largest and strongest of the tarsal bones. It is situated at the lower and back part of the foot, serving to transmit the weight of the body to the ground, and forming a strong lever for the

Fig. 333.—The left os calcis. A. Postero-external view. B. Antero-internal view.



muscles of the calf. It is irregularly cuboidal in form, having its long axis directed forwards and outwards; it presents for examination six surfaces.

The *superior surface* is formed behind by the upper aspect of that part of the bone which projects backwards to form the heel. This varies in length in

different individuals; is convex from side to side, concave from before backwards, and upon it rests a mass of fat placed in front of the tendo Achillis. In front of this area is a large, usually somewhat oval-shaped facet, which looks upwards and forwards; it is convex from behind forwards, and articulates with the posterior calcanean facet on the under aspect of the astragalus. It is bounded anteriorly by a deep depression which is continued backwards and inwards in the form of a groove. In the articulated foot this groove lies below a similar one on the under aspect of the astragalus, and the two form a canal (*sinus tarsi*) for the lodgment of the interosseous calcaneo-astragaloid ligament. In front and to the inner side of this groove is an elongated facet, concave from behind forwards, and with its long axis directed forwards and outwards. This facet is frequently divided into two by a notch: of the two, the posterior, and larger, is supported on a projecting process of bone, termed the *sustentaculum tali*, and articulates with the middle calcanean facet on the under aspect of the astragalus; the anterior, and smaller, is placed on the anterior part of the body of the bone, and articulates with the anterior calcanean facet on the astragalus. The outer portion of the upper surface of the anterior part of the bone is rough, for the attachment of ligaments and for the origin of the Extensor brevis digitorum muscle.

The *inferior surface* is uneven, wider behind than in front, and convex from side to side; it is bounded posteriorly by two tubercles, separated by a depression; the *external*, small, prominent, and rounded, gives origin to part of the Abductor minimi digiti; the *internal*, broader and larger, for the support of the heel, gives attachment, by its prominent inner margin, to the Abductor hallucis, and in front to the Flexor brevis digitorum muscles and plantar fascia; the depression between the tubercles gives origin to the Abductor minimi digiti. The rough surface in front of the tubercles gives attachment to the long plantar ligament, and to the outer head of the Flexor accessorius muscle; while to a prominent tubercle nearer the anterior part of this surface, as well as to a transverse groove in front of it, is attached the short plantar ligament.

The *external surface* is broad behind and narrow in front, flat, and almost subcutaneous; it presents near its centre a tubercle, for the attachment of the middle fasciculus of the external lateral ligament. At its upper and anterior part, this surface gives attachment to the external calcaneo-astragaloid ligament; and in front of the tubercle it presents a narrow surface marked by two oblique grooves, separated by an elevated ridge, or tubercle, which varies much in size in different bones; it is named the *peroneal tubercle*, and gives attachment to a fibrous process from the external annular ligament. The *superior groove* transmits the tendon of the Peroneus brevis; the *inferior*, the tendon of the Peroneus longus.

The *internal surface* is deeply concave; it is directed obliquely downwards and forwards, and serves for the transmission of the plantar vessels and nerves into the sole of the foot; it affords attachment to part of the Flexor accessorius muscle. At its upper and fore part it presents an eminence of bone, the *lesser process* or *sustentaculum tali*, which projects horizontally inwards, and to it a slip of the tendon of the Tibialis posticus is attached. This process is concave above, and supports the middle articular surface of the astragalus; below, it is grooved for the tendon of the Flexor longus hallucis. Its anterior margin gives attachment to the inferior calcaneo-navicular ligament, and its inner margin to a part of the internal lateral ligament of the ankle-joint.

The *anterior surface*, of a somewhat triangular form, articulates with the cuboid. It is concave from above, downwards and outwards, and convex in the opposite direction. Its inner border gives attachment to the inferior calcaneo-navicular ligament.

The *posterior surface* is prominent, convex, wider below than above, and divisible into three areas. The lowest of these is rough, and covered by the fatty and fibrous tissue of the heel; the middle, also rough, gives insertion to the tendo Achillis and Plantaris; while the highest is smooth, and is covered by a bursa which intervenes between it and the tendo Achillis.

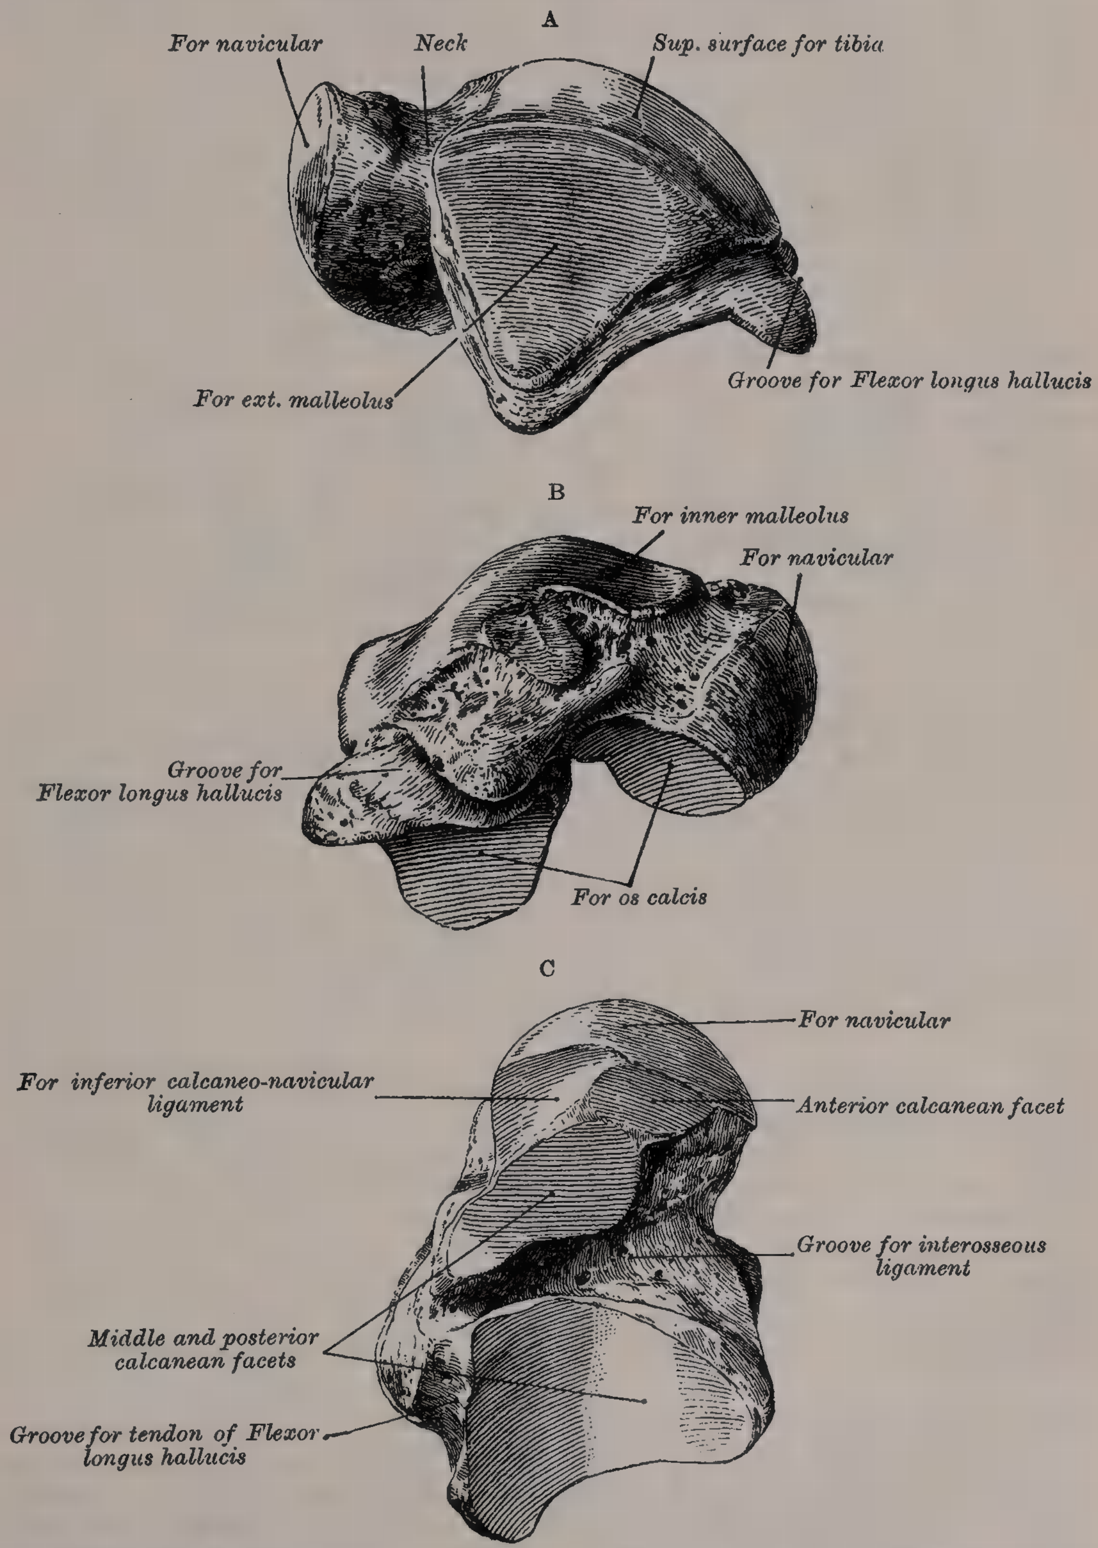
Articulations.—With two bones: the astragalus and cuboid.

Attachment of Muscles.—To eight; part of the Tibialis posticus, the tendo Achillis, Plantaris, Abductor hallucis, Abductor minimi digiti, Flexor brevis digitorum, Flexor accessorius, and Extensor brevis digitorum.

The Astragalus (fig. 334)

The **Astragalus** (ἀστράγαλος, *a die*) is the largest of the tarsal bones, next to the os calcis. It occupies the middle and upper part of the tarsus, supporting the tibia above, articulating with the malleoli on either side, resting below upon

Fig. 334.—The left astragalus. A. Superior and external view. B. Inferior and internal view. C. Viewed from below.



the os calcis, and articulating in front with the navicular. This bone may easily be recognised by its large oval head, by the broad articular facet on its upper convex surface, or by the two articular facets separated by a deep groove on its under concave surface. It consists of a *head*, *neck*, and *body*.

The *superior surface* of the **body** presents, behind, a broad smooth trochlear surface, for articulation with the tibia. The trochlea is broader in front than behind, convex from before backwards, slightly concave from side to side: in front of it is the upper surface of the neck of the bone. The *inferior surface* presents two articular facets separated by a deep groove. The groove runs obliquely forwards and outwards, becoming gradually broader and deeper in front: it corresponds with a similar groove upon the upper surface of the os calcis, and forms, when articulated with that bone, a canal (*sinus tarsi*) filled up in the recent state by the interosseous calcaneo-astragaloid ligament. Of the two articular facets, the posterior (*posterior calcanean facet*) is the larger, of an oblong form, and deeply concave from without inwards and forwards: it articulates with the corresponding facet on the upper surface of the os calcis; the anterior (*middle calcanean facet*) is shorter and narrower, of an elongated oval form, convex longitudinally, and articulates with the upper surface of the sustentaculum tali of the os calcis. The *internal surface* presents at its upper part a pear-shaped articular facet for the inner malleolus, continuous above with the trochlear surface; below the articular surface is a rough depression, for the attachment of the deep portion of the internal lateral ligament of the ankle-joint. The *external surface* presents a large triangular facet, concave from above downwards, for articulation with the external malleolus; its anterior half is continuous above with the trochlear surface; and in front of it is a rough depression for the attachment of the anterior fasciculus of the external lateral ligament of the ankle-joint. Professor E. Fawcett * has directed attention to a triangular facet which comes into contact with the inferior tibio-fibular ligament during flexion of the ankle. It is situated between the posterior half of the outer border of the trochlea and the corresponding part of the base of the triangular facet for the external malleolus of the fibula. It is triangular in shape, the apex being directed forwards and the base backwards. Its length from base to apex is from three-quarters of an inch to an inch; its breadth at the base, about a quarter of an inch. The *posterior surface* is narrow, and traversed by a groove, which runs obliquely downwards and inwards, and transmits the tendon of the Flexor longus hallucis, external to which is a prominent tubercle, to which the posterior fasciculus of the external lateral ligament is attached. This tubercle is sometimes separated from the rest of the astragalus, and is then known as the *os trigonum*. To the inner side of the groove is a second, but less marked tubercle.

The **neck** is directed forwards and inwards, and comprises the constricted portion of the bone between the body and the oval head. Its upper and inner surfaces are rough, for the attachment of ligaments; its external surface is concave, directed downwards and outwards, and is continuous below with the deep groove for the interosseous calcaneo-astragaloid ligament.

The **head** looks forwards and inwards, and its anterior surface presents a large, oval, convex facet, for articulation with the navicular. Its inferior surface has two facets, which are best seen in the recent condition. The inner of these, situated immediately in front of the middle calcaneal facet, is convex, triangular or semi-oval in shape, and rests on the inferior calcaneo-navicular ligament; the outer (*anterior calcanean facet*) is somewhat flattened, and articulates with the upper surface of the anterior part of the os calcis.

To ascertain to which foot the bone belongs, hold it with the broad articular surface upwards, and the rounded head forwards; the lateral triangular articular surface for the external malleolus will then point to the side to which the bone belongs.

Articulations.—With four bones: tibia, fibula, os calcis, and navicular.

The Cuboid (fig. 335)

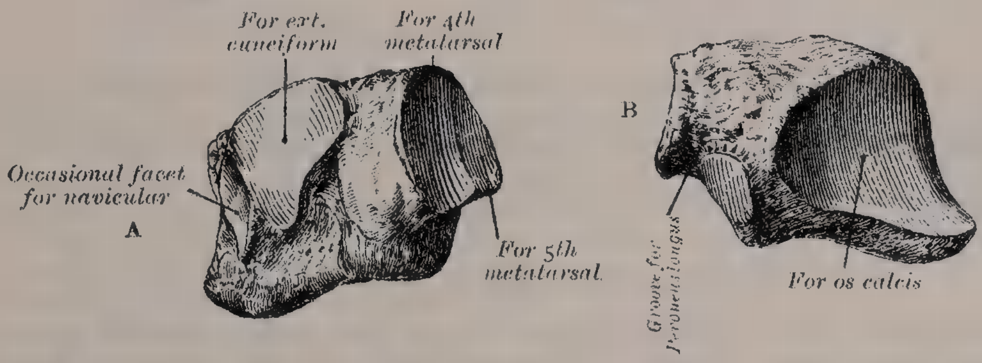
The **Cuboid** (κύβος, *a cube*; εἶδος, *like*) bone is placed on the outer side of the foot, in front of the os calcis, and behind the fourth and fifth metatarsal bones. It is of a pyramidal shape, its base being directed inwards, its apex outwards. It may be distinguished from the other tarsal bones by the existence of a deep groove on its under surface, for the tendon of the Peroneus longus muscle. It presents for examination six surfaces: three articular, and three non-articular.

* *Edinburgh Medical Journal*, 1895.

The **non-articular surfaces** are the superior, inferior, and external. The *superior* or *dorsal surface*, directed upwards and outwards, is rough, for the attachment of numerous ligaments. The *inferior* or *plantar surface* presents in front a deep groove, which runs obliquely from without, forwards and inwards; it lodges the tendon of the Peroneus longus, and is bounded behind by a prominent ridge, to which is attached the long calcaneo-cuboid ligament. The ridge terminates externally in an eminence, the *tuberosity of the cuboid*, the surface of which presents a convex facet, over which the sesamoid bone or cartilage, frequently found in the tendon of the Peroneus longus, glides. The surface of bone behind the groove is rough, for the attachment of the short plantar ligament, a few fibres of the Flexor brevis hallucis and a fasciculus from the tendon of the Tibialis posticus. The *external surface*, the smallest and narrowest of the three, presents a deep notch formed by the commencement of the peroneal groove.

The **articular surfaces** are the posterior, anterior, and internal. The *posterior surface* is smooth, triangular, and concavo-convex, for articulation with the anterior surface of the os calcis. The *anterior surface*, of smaller size, but also irregularly

Fig. 335.—The left cuboid. A. Antero-internal view. B. Postero-external view.



triangular, is divided by a vertical ridge into two facets: the inner, quadrilateral in form, articulates with the fourth metatarsal bone; the outer, larger and more triangular, articulates with the fifth metatarsal. The *internal surface* is broad, rough, irregularly quadrilateral, presenting at its middle and upper part a smooth oval facet, for articulation with the external cuneiform bone; and behind this (occasionally) a smaller facet, for articulation with the navicular; it is rough in the rest of its extent, for the attachment of strong interosseous ligaments.

To ascertain to which foot the bone belongs, hold it so that its under surface, marked by the peroneal groove, looks downwards, and the large concavo-convex articular surface backwards, towards the holder: the narrow non-articular surface, marked by the commencement of the peroneal groove, will point to the side to which the bone belongs.

Articulations.—With four bones: the os calcis, external cuneiform, and the fourth and fifth metatarsal bones; occasionally with the navicular.

Attachment of Muscles.—Part of the Flexor brevis hallucis and a slip from the tendon of the Tibialis posticus.

The Navicular (fig. 336)

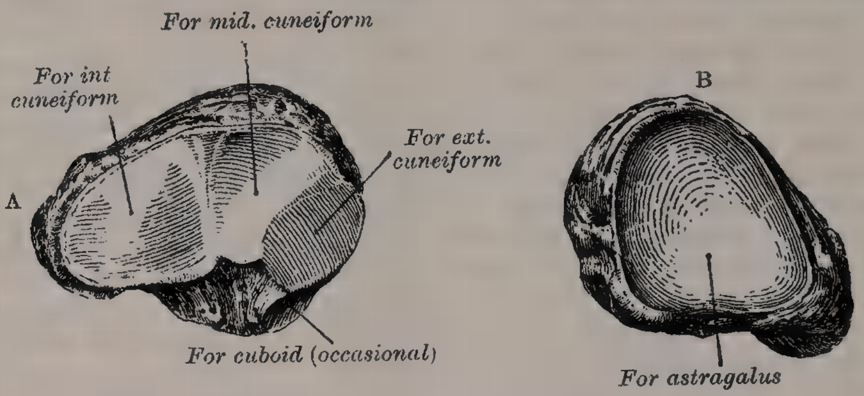
The **Navicular** or **Scaphoid bone** is situated at the inner side of the tarsus, between the astragalus behind and the three cuneiform bones in front. It may be distinguished by its form, being concave behind, convex and subdivided into three facets in front.

The *anterior surface* is convex from side to side, and subdivided by two ridges into three facets, for articulation with the three cuneiform bones. The *posterior surface* is oval, concave, broader externally than internally, and articulates with the rounded head of the astragalus. The *superior surface* is convex from side to side, and rough for the attachment of ligaments. The *inferior surface* is irregular, and also rough for the attachment of ligaments. The *internal surface* presents a rounded tubercular eminence, the *tuberosity* of the navicular, the lower part of which projects, and gives attachment to part of the tendon of the Tibialis posticus. The *external surface* is rough, and irregular, for the attachment of

ligamentous fibres, and occasionally presents a small facet for articulation with the cuboid bone.

To ascertain to which foot the bone belongs, hold it with the concave articular surface backwards, and the convex dorsal surface upwards; the external surface,

Fig. 336.—The left navicular. A. Antero-external view. B. Postero-internal view.



i.e. the surface opposite the tubercle, will point to the side to which the bone belongs.

Articulations.—With four bones: astragalus and three cuneiform; occasionally also with the cuboid.

Attachment of Muscles.—Part of the Tibialis posticus.

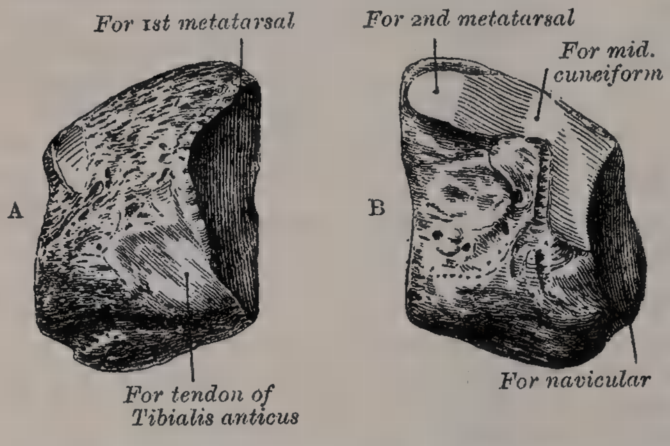
The Cuneiform Bones

The **Cuneiform Bones** have received their name from their wedge-like shape (cuneus, *a wedge*; forma, *likeness*). They are three in number, and form, with the cuboid, the anterior row of the tarsus, being placed between the navicular behind, the three innermost metatarsal bones in front, and the cuboid externally. They are named, from their position, *internal*, *middle*, and *external*.

The Internal Cuneiform (fig. 337)

The **Internal Cuneiform** is the largest of the three. It is situated at the inner side of the foot, between the navicular behind and the base of the first metatarsal in front. It may be distinguished from the other two by its large size, and by its not presenting such a distinct wedge-like form. Without the others, it may be known by the large kidney-shaped anterior articulating surface, and by the prominence on the inferior or plantar surface for the attachment of the Tibialis posticus. It presents for examination six surfaces.

Fig. 337.—The left internal cuneiform. A. Antero-internal view. B. Postero-external view.



The *internal surface* is subcutaneous, and forms part of the inner border of the foot; it is broad, quadrilateral, and presents at its anterior inferior angle a smooth oval impression, into which the tendon of the Tibialis anticus is partially inserted; in the rest of its extent it is rough, for the attachment of ligaments. The *external surface* is concave, presenting, along its superior and posterior borders, a narrow reversed L-shaped surface for articulation with the middle cuneiform behind, and second metatarsal bone in front: in the rest of its extent it is rough for the attachment of ligaments and

part of the tendon of the Peroneus longus. The *anterior surface*, kidney-shaped, much larger than the posterior, articulates with the metatarsal bone of the great toe. The *posterior surface* is triangular, concave, and articulates with the innermost and largest of the three facets on the anterior surface of the navicular. The *inferior* or *plantar surface* is rough, and forms the base of the wedge; it presents a prominent tuberosity at its back part for the insertion of part of the tendon of the Tibialis posticus. It also gives insertion in front to part of the tendon of the Tibialis anticus. The *superior surface* is the narrow pointed end of the wedge, which is directed upwards and outwards; it is rough for the attachment of ligaments.

To ascertain to which side the bone belongs, hold it so that its superior narrow edge looks upwards, and the long, kidney-shaped, articular surface forwards; the external surface, marked by its vertical and horizontal articular facets, will point to the side to which it belongs.

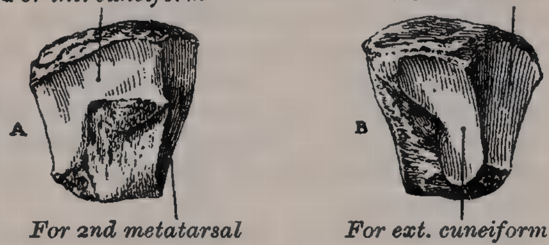
Articulations.—With four bones: navicular, middle cuneiform, first and second metatarsal bones.

Attachment of Muscles.—To three: the Tibialis anticus and posticus, and Peroneus longus.

The Middle Cuneiform (fig. 338)

The **Middle Cuneiform**, the smallest of the three, is of very regular wedge-like form, the broad extremity being placed upwards, the narrow end downwards. It is situated between the other two bones of the same name, and articulates with the navicular behind, and the second metatarsal in front. It is smaller than the external cuneiform bone, from which it may be further distinguished by the L-shaped articular facet, which runs round the upper and back part of its inner surface.

Fig. 338.—The left middle cuneiform.
A. Antero-internal view.
B. Postero-external view.



The *anterior surface*, triangular in form, and narrower than the posterior, articulates with the base of the second metatarsal bone. The *posterior surface*, also triangular, articulates with the middle facet on the anterior surface of the navicular. The *internal surface* presents a reversed L-shaped articular facet, running along the superior and posterior borders, for articulation with the internal cuneiform, and is rough in the rest of its extent for the attachment of ligaments. The *external surface* presents posteriorly a smooth facet for articulation with the external cuneiform bone. The *superior surface* forms the base of the wedge; it is quadrilateral, broader behind than in front, and rough for the attachment of ligaments. The *inferior surface*, sharp and tubercular, is also rough for ligamentous attachment, and for the insertion of a slip from the tendon of the Tibialis posticus.

To ascertain to which foot the bone belongs, hold its superior or dorsal surface upwards, the larger, triangular surface being towards the holder: the smooth facet (limited to the posterior border) will then point to the side to which it belongs.

Articulations.—With four bones: navicular, internal and external cuneiform, and second metatarsal bone.

Attachment of Muscle.—A slip from the tendon of the Tibialis posticus is attached to this bone.

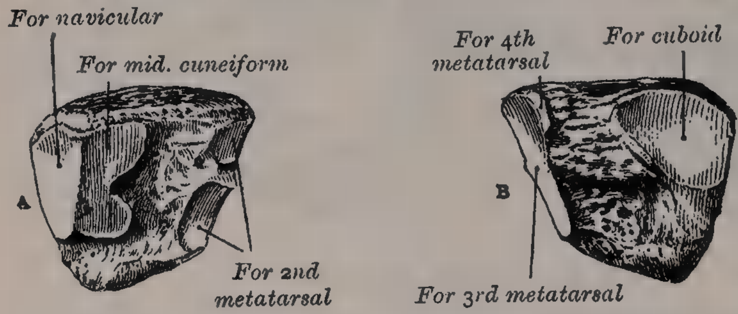
The External Cuneiform (fig. 339)

The **External Cuneiform**, intermediate in size between the two preceding, is of a very regular wedge-like form, the broad extremity being placed upwards, the narrow end downwards. It occupies the centre of the front row of the tarsus between the middle cuneiform internally, the cuboid externally, the navicular behind, and the third metatarsal in front. It is distinguished from

the internal cuneiform bone by its more regular wedge-like shape, and by the absence of the kidney-shaped articular surface: from the middle cuneiform, by the absence of the reversed L-shaped facet, and by the two articular facets which are present on both its inner and outer surfaces. It presents six surfaces for examination.

The *anterior surface*, triangular in form, articulates with the third metatarsal bone. The *posterior surface* articulates with the most external facet of the navicular, and is rough below for the attachment of ligamentous fibres. The *internal surface* presents two articular facets, separated by a rough depression: the anterior one, sometimes divided into two, articulates with the outer side of the base of the second metatarsal bone; the posterior one skirts the posterior border, and articulates with the middle cuneiform; the rough depression between the two gives attachment to an interosseous ligament. The *external surface* also presents two articular facets, separated by a rough non-articular surface; the anterior facet, situated at the superior angle of the bone, is small and semi-oval in shape, and articulates with the inner side of the base of the fourth metatarsal bone; the posterior and larger one is triangular or oval, and articulates with the cuboid; the rough, non-articular surface serves for the attachment of an interosseous ligament. The three facets for articulation with the three metatarsal bones are continuous with one another; those for articulation with the middle cuneiform and navicular are also continuous, but that for articulation with the cuboid is usually separate. The *superior* or *dorsal surface* is of an oblong form; its postero-external angle being prolonged backwards. The *inferior* or *plantar surface* is a rounded margin, and serves for the attachment of part of the tendon of the Tibialis posticus, part of the Flexor brevis hallucis, and ligaments.

Fig. 339.—The left external cuneiform.
A. Postero-internal view. B. Antero-external view.



To ascertain to which side the bone belongs, hold it with the broad dorsal surface upwards, the prolonged edge backwards; the separate articular facet for the cuboid will point to the side to which it belongs.

Articulations.—With six bones: the navicular, middle cuneiform, cuboid, and second, third, and fourth metatarsal bones.

Attachment of Muscles.—To two: part of the Tibialis posticus, and Flexor brevis hallucis.

The number of tarsal bones may be reduced owing to congenital ankylosis, which may occur between the os calcis and cuboid, the os calcis and navicular, the os calcis and astragalus, or the astragalus and navicular.

The Metatarsal Bones

The **Metatarsal Bones** are five in all, and are numbered one to five, in accordance with their position from within outwards; they are long bones, and present for examination a shaft and two extremities.

Common Characters of the Metatarsal Bones

The *Shaft* is prismoid in form, tapers gradually from the tarsal to the phalangeal extremity, and is curved longitudinally, so as to be concave below, slightly convex above. The *posterior extremity*, or *base*, is wedge-shaped, articulating by its terminal surface with the tarsal bones, and by its lateral surfaces with the contiguous metatarsal bones: its dorsal and plantar surfaces are rough for the attachment of ligaments. The *anterior extremity*, or *head*, presents a terminal convex articular surface, oblong from above downwards,

and extending farther backwards below than above. Its sides are flattened, and each presents a depression, surmounted by a tubercle, for ligamentous attachment. Its under surface is grooved in the middle line for the passage of the Flexor tendon, and marked on each side by an articular eminence continuous with the terminal articular surface.

Peculiar Characters of the Metatarsal Bones

The **First** (fig. 340) is remarkable for its great thickness, and is the shortest of all the metatarsal bones. The *shaft* is strong, and of well-marked prismoid form. The *posterior extremity* presents, as a rule, no lateral articular facets, but occasionally on the outer side there is an oval facet, by which it articulates with the second metatarsal bone. Its terminal articular surface is of large size and kidney-shaped; its circumference is grooved, for the tarso-metatarsal ligaments, and internally gives insertion to part of the tendon of the Tibialis anticus; its inferior angle presents a rough oval prominence for the insertion of the tendon of the Peroneus longus. The *head* is of large size; on its plantar surface are two grooved facets, over which glide sesamoid bones; the facets are separated by a smooth elevated ridge.

This bone is known by the single kidney-shaped articular surface on its base; the deeply grooved appearance of the plantar surface of its head; and its

Fig. 340.—The first metatarsal. (Left.)

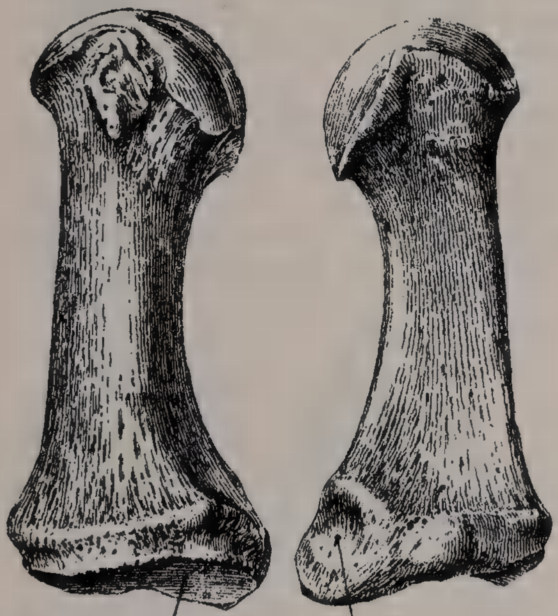


Fig. 341.—The second metatarsal. (Left.)

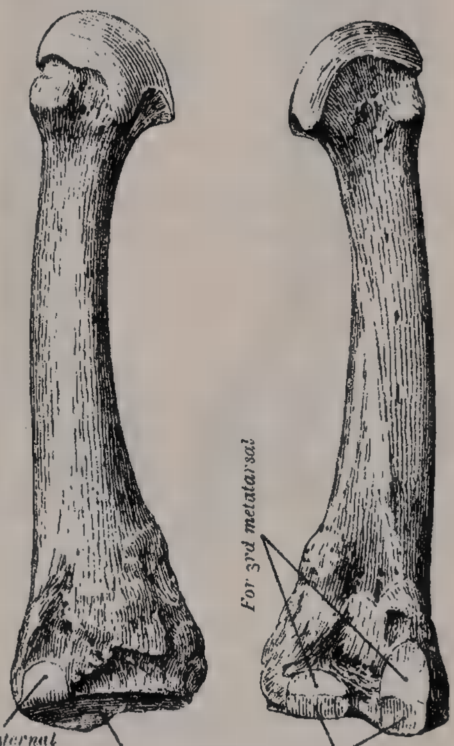


great thickness, relatively to its length. When it is placed in its natural position, the concave border of the kidney-shaped articular surface on its base points to the foot to which the bone belongs.

Attachment of Muscles.—To three: part of the Tibialis anticus, the Peroneus longus, and the First dorsal interosseous.

The **Second** (fig. 341) is the longest and largest of the remaining metatarsal bones, being prolonged backwards into the recess formed between the three cuneiform bones. Its *tarsal extremity* is broad above, narrow and rough below. It presents four articular surfaces: one behind, of a triangular form, for articulation with the middle cuneiform; one at the upper part of its internal lateral surface, for articulation with the internal cuneiform; and two on its external lateral surface, an upper and lower, separated by a rough non-articular interval. Each of these articular surfaces is divided by a vertical ridge into two, thus making four facets; the two anterior of these articulate with the third metatarsal; the two posterior (sometimes continuous) with the external cuneiform.

In addition to these articular surfaces, there is occasionally a fifth when this bone articulates with the first metatarsal bone. It is oval in shape, and is situated on the inner side of the shaft near the base.

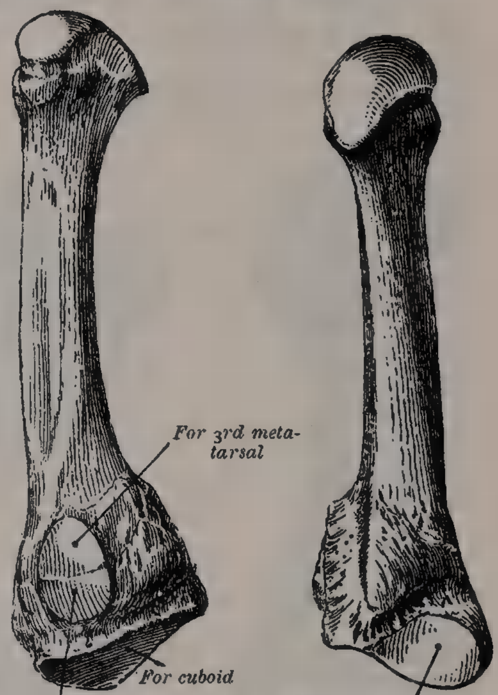
The facets on the tarsal extremity of the second metatarsal bone serve at once to distinguish it from the rest, and to indicate the foot to which it belongs; there being one facet at the upper angle of the internal surface, and two facets, each subdivided into two parts, on the external surface, pointing to the foot to which the bone belongs. The fact that the two posterior subdivisions of these external facets sometimes run into one should not be forgotten.

Attachment of Muscles.—To four: the Adductor obliquus hallucis, First and Second dorsal interossei, a slip from the tendon of the Tibialis posticus, and occasionally a slip from the Peroneus longus.

The **Third** (fig. 342) articulates behind, by means of a triangular smooth surface, with the external cuneiform; on its inner side, by two facets, with the second metatarsal; and on its outer side, by a single facet, with the fourth metatarsal bone. The latter facet is situated at the upper angle of the base.

Fig. 342.—The third metatarsal. (Left.)

Fig. 343.—The fourth metatarsal. (Left.)



The third metatarsal bone is known by its having at its tarsal end two undivided facets on the inner side, and a single facet on the outer. This distinguishes it from the second metatarsal, in which the two facets, found on one side of its tarsal end, are each subdivided into two. The single facet (when the bone is put in its natural position) is on the side to which the bone belongs.

Attachment of Muscles.—To five: Adductor obliquus hallucis, Second and Third dorsal and First plantar interossei, and a slip from the tendon of the Tibialis posticus.

The **Fourth** (fig. 343) is smaller in size than the preceding; its *tarsal extremity* presents an oblique quadrilateral surface for articulation with the cuboid; a smooth facet on the inner side, divided by a ridge into an anterior portion for articulation with the third metatarsal, and a posterior portion for articulation with the external cuneiform; on the outer side a single facet, for articulation with the fifth metatarsal.

The fourth metatarsal is known by its having a single facet on either side of the tarsal extremity, that on the inner side being divided into two parts. If this subdivision be not recognisable, the fact that its tarsal end is bent somewhat outwards will indicate the side to which it belongs.

Attachment of Muscles.—To five: Adductor obliquus hallucis, Third and Fourth dorsal and Second plantar interossei, and a slip from the tendon of the Tibialis posticus.

The **Fifth** (fig. 344) is recognised by the tubercular eminence, the *tuberosity*, on the outer side of its base. It articulates behind, by a triangular surface cut obliquely from without inwards, with the cuboid; and internally, with the fourth metatarsal. On the inner part of the dorsal aspect of the base is inserted the tendon of the Peroneus tertius, and on the dorsal aspect of the tuberosity that of the Peroneus brevis. A strong band of the plantar fascia connects the projecting part of the tuberosity with the outer tuberosity on the under surface of the os calcis. The plantar aspect of the base is grooved for the tendon of the Abductor minimi digiti, and gives origin to the Flexor brevis minimi digiti.

Fig. 344.—The fifth metatarsal. (Left.)

The projection on the outer surface of this bone at its tarsal end at once distinguishes it from the others, and points to the side to which it belongs.

Attachment of Muscles.—To six: the Peroneus brevis, Peroneus tertius, Flexor brevis minimi digiti, Adductor transversus hallucis, Fourth dorsal and Third plantar interossei.

Articulations.—Each bone articulates with one or more of the tarsal bones by its proximal extremity, and by the other with one of the first row of phalanges. The number of tarsal bones with which each metatarsal articulates is one for the first, three for the second, one for the third, two for the fourth, and one for the fifth.

Phalanges

The **Phalanges** of the foot, both in number and general arrangement, resemble those of the hand; there being two in the great toe, and three in each of the other toes. They differ from them, however, in their size, the shafts being much reduced in length and, especially in the first row, laterally compressed.

The phalanges of the *first row* closely resemble those of the hand. The *shaft* is compressed from side to side, convex above, concave below. The *posterior extremity* is concave; and the *anterior extremity* presents a trochlear surface, for articulation with the second phalanges.

The phalanges of the *second row* are remarkably small and short, but rather broader than those of the first row.

The *ungual* phalanges, in form, resemble those of the fingers; but they are smaller, flattened from above downwards, presenting a broad base for articulation with the second row, and an expanded extremity for the support of the nail and end of the toe.

Articulations.—The first row, with the metatarsal bones behind and second phalanges in front; the second row, of the four outer toes, with the first and third phalanges; of the great toe, with the first phalanx; the third row, of the four outer toes, with the second phalanges.

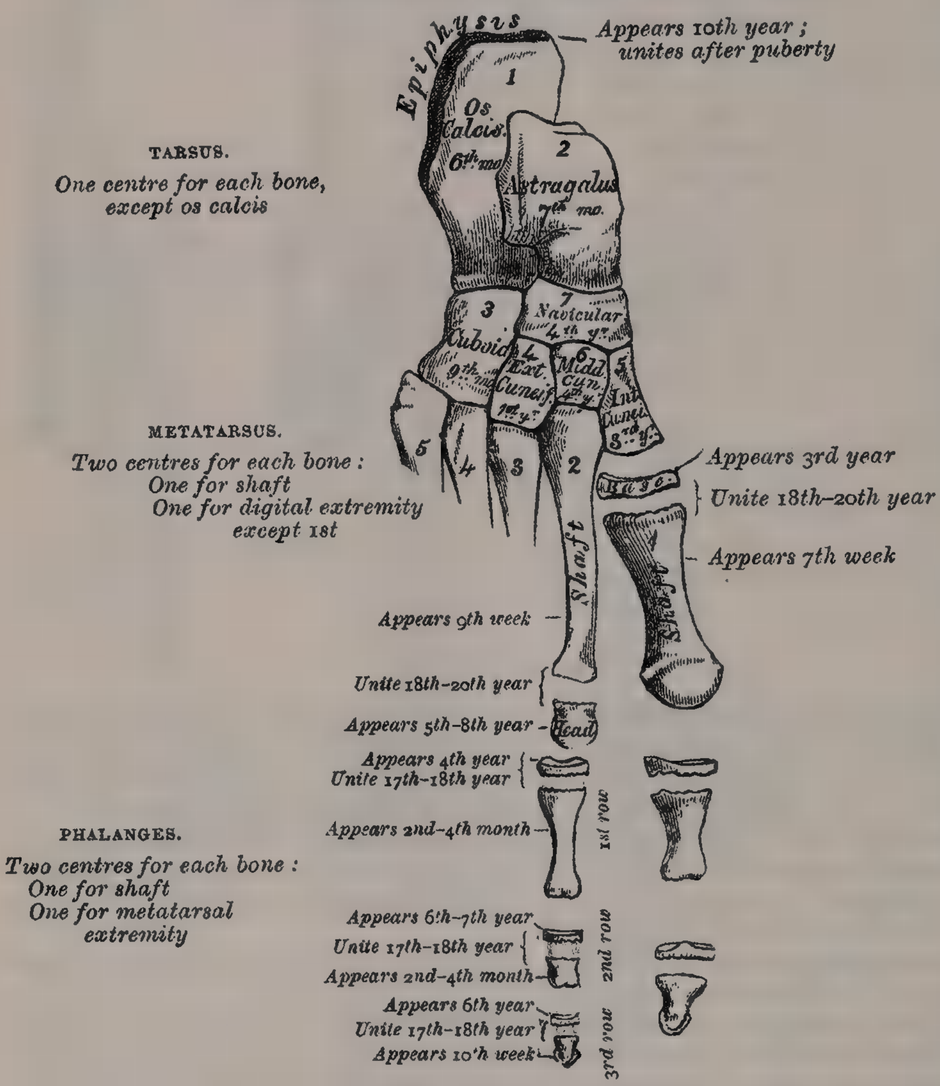
Attachment of Muscles.—To the first phalanges. Great toe, five muscles: innermost tendon of Extensor brevis digitorum, Abductor hallucis, Adductor obliquus hallucis, Flexor brevis hallucis, Adductor transversus hallucis. Second toe, three muscles: First and Second dorsal interossei, and First lumbrical. Third toe, three muscles: Third dorsal and First plantar interossei, and Second lumbrical. Fourth toe, three muscles: Fourth dorsal and Second plantar interossei, and Third lumbrical. Fifth toe, four muscles: Flexor brevis minimi digiti, Abductor minimi digiti, Third plantar interosseous, and Fourth lumbrical.—Second phalanges. Great toe: Extensor longus hallucis, Flexor longus

hallucis. Other toes: Flexor brevis digitorum, and one slip of the common tendon of the Extensor longus and Extensor brevis digitorum.*—Third phalanges: Flexor longus digitorum, and two slips of the common tendon of the Extensor longus and Extensor brevis digitorum.

Development of the Bones of the Foot (fig. 345)

The **Tarsal bones** are each developed by a single centre, excepting the os calcis, which has an epiphysis for its posterior extremity. The centres make their appearance in the following order: os calcis, at the sixth month of fœtal life; astragalus, about the seventh month; cuboid, at the ninth month; external

Fig. 345.—Plan of the development of the foot.



cuneiform, during the first year; internal cuneiform, in the third year; middle cuneiform and navicular, in the fourth year. The epiphysis for the posterior extremity of the os calcis appears at the tenth year, and unites with the rest of the bone soon after puberty. The tubercle on the posterior surface of the astragalus is sometimes ossified from a separate centre, and may remain distinct from the main mass of the bone, when it is named the *os trigonum*.

The **Metatarsal bones** are each developed by *two* centres: one for the shaft, and one for the digital extremity, in the four outer metatarsals; one for the shaft, and one for the proximal extremity, in the metatarsal bone of the great toe.† Ossification commences in the centre of the shaft about the ninth week, and

* Except the second phalanx of the fifth toe, which receives no slip from the Extensor brevis digitorum.

† As was noted in the first metacarpal bone, so in the first metatarsal, there is often a second epiphysis for its distal extremity (see footnote, page 298).

extends towards either extremity. The centre in the proximal end of the first metatarsal bone appears about the third year; the centres in the distal ends of the other bones between the fifth and eighth years; they become joined between the eighteenth and twentieth years.

The **Phalanges** are developed by *two* centres for each bone: one for the shaft, and one for the metatarsal extremity. The centre for the shaft appears about the tenth week, that for the epiphysis between the fourth and tenth years; they join the shaft about the eighteenth year.

Skeleton of the Foot as a Whole

The skeleton of the foot is constructed on the same principles as the hand, but modified to form a firm basis of support for the rest of the body when in the erect position. It is more solidly built up, and its component parts are less movable on each other than in the hand. This is especially the case with the great toe, which has to assist in supporting the body, and is therefore constructed with greater solidity; it lies parallel with the other toes, and has a very limited degree of mobility, whereas the thumb, which is occupied in numerous and varied movements, is constructed in such a manner as to permit of great mobility; its metacarpal bone is directed away from the others, so as to form an acute angle with the second, and it enjoys a considerable range of motion at its articulation with the carpus. The foot is placed at right angles to the leg—a position which is almost peculiar to man, and has relation to the erect position which he maintains. In order to allow of its supporting the weight of the whole body in this position with the least expenditure of material, it is constructed in the form of an arch. This arch is not, however, made up of two equal limbs. The hinder one, which is made up of the os calcis and the posterior part of the astragalus, is about half the length of the anterior limb, and measures about three inches. The anterior limb consists of the rest of the tarsal and the metatarsal bones, and measures about seven inches. It may be said to consist of two parts, an inner segment made up of the head of the astragalus, the navicular, the three cuneiforms, and the three inner metatarsal bones; and an outer segment composed of the os calcis, the cuboid and the two outer metatarsal bones. The summit of the arch is at the superior articular surface of the astragalus; and its two extremities—that is to say the two piers on which the arch rests in standing—are the tubercles on the under surface of the os calcis posteriorly, and the heads of the metatarsal bones anteriorly. The weakest part of the arch is the joint between the astragalus and scaphoid, and here it is more liable to yield in those who are overweighted, and in those in whom the ligaments which complete and preserve the arch are relaxed. This weak point in the arch is braced on its concave surface by the inferior calcaneo-navicular ligament, which is more elastic than most other ligaments, and thus allows the arch to yield from jars or shocks applied to the anterior portion of the foot, and quickly restores it to its pristine condition. This ligament is supported internally by blending with the Deltoid or internal lateral ligament of the ankle, and inferiorly by the tendon of the Tibialis posticus muscle, which is spread out into a fan-shaped insertion, and prevents undue tension of the ligament or such an amount of stretching as would permanently elongate it.

In addition to this longitudinal arch the foot presents a transverse arch, at the anterior part of the tarsus and hinder part of the metatarsus. This, however, can scarcely be described as a true arch, but presents more the character of a half-dome. The inner border of the central portion of the longitudinal arch is elevated from the ground, and from this point the bones arch over to the outer border, which is in contact with the ground, and, assisted by the longitudinal arch, produce a sort of rounded niche on the inner side of the foot, which gives the appearance of a transverse as well as a longitudinal arch.

The line of the foot, from the point of the heel to the toes, is not quite straight, but is directed slightly outwards, so that the inner border is a little convex and the outer border concave. This disposition of the bones becomes more marked when the longitudinal arch of the foot is lost, as in the disease known under the name of 'flat-foot.'

Surface Form.—On the dorsum of the foot the individual bones are not to be distinguished, with the exception of the head of the astragalus, which forms a rounded

projection in front of the ankle-joint when the foot is forcibly extended. The whole surface forms a smooth convex outline, the summit of which is the ridge formed by the head of the astragalus, the navicular, the middle cuneiform, and the second metatarsal bones; from this it gradually inclines outwards and more rapidly inwards. On the inner side of the foot, the internal tuberosity of the os calcis and the ridge separating the inner from the posterior surface of the bone may be felt most posteriorly. In front of this, and below the internal malleolus, may be felt the projection of the sustentaculum tali. Passing forwards is the well-marked tuberosity of the navicular bone, situated about an inch or an inch and a quarter in front of the internal malleolus. Farther towards the front, the ridge formed by the base of the first metatarsal bone can be obscurely felt, and from this the shaft of the bone can be traced to the expanded head articulating with the base of the first phalanx of the great toe. Immediately beneath the base of this phalanx, the internal sesamoid bone is to be felt. Lastly, the expanded ends of the bones forming the last joint of the great toe are to be felt. On the outer side of the foot the most posterior bony point is the outer tuberosity of the os calcis, with the ridge separating the posterior from the outer surface of the bone. In front of this the greater part of the external surface of the os calcis is subcutaneous; on it, below and in front of the external malleolus, may be felt the peroneal ridge, when this process is present. Farther forwards, the base of the fifth metatarsal bone forms a prominent and well-defined landmark, and in front of this the shaft of the bone, with its expanded head, and the base of the first phalanx, may be made out. The sole of the foot is almost entirely covered by soft parts, so that but few bony parts are to be made out, and these somewhat obscurely. The hinder part of the under surface of the os calcis and the heads of the metatarsal bones, with the exception of the first, which is concealed by the sesamoid bones, may be recognised.

Surgical Anatomy.—Considering the injuries to which the foot is subjected, it is surprising how seldom the tarsal bones are fractured. This is no doubt due to the fact that the tarsus is composed of a number of bones, articulated by a considerable extent of surface and joined together by very strong ligaments, which serve to break the force of violence applied to this part of the body. When fracture does occur, these bones being composed for the most part of a soft cancellous structure, covered only by a thin shell of compact tissue, are often extensively comminuted, especially as most of the fractures are produced by direct violence; and, having only a very scanty amount of soft parts over them, the fractures are very often compound, and amputation is often necessary.

When fracture occurs in the anterior group of tarsal bones, it is almost invariably the result of direct violence; but fractures of the posterior group—that is, of the calcaneum and astragalus—are usually produced by falls from a height on to the feet; though fracture of the os calcis may be caused by direct violence or by muscular action. The posterior part of the bone—that is, the part behind the articular surfaces—is the most common seat of the fracture, though some few cases of fracture of the sustentaculum tali and of vertical fracture between the two articulating facets have been recorded. The neck of the astragalus, being the weakest part of the bone, is most frequently fractured, though fractures may occur in any part and almost in any direction, either associated or not with fracture of other bones.

In cases of club-foot, especially in congenital cases, the bones of the tarsus become altered in shape and size, and displaced from their proper positions. This is principally the case in congenital equino-varus, in which the astragalus, particularly about the head, becomes twisted and atrophied, and a similar condition may be present in the other bones, more especially the navicular. The tarsal bones are peculiarly liable to become the seat of tuberculous caries from comparatively trivial injuries. There are several reasons to account for this. They are composed of a delicate cancellated structure, surrounded by intricate synovial membranes. They are situated at the farthest point from the central organ of the circulation and exposed to vicissitudes of temperature; and, moreover, on their dorsal surface are thinly clad with soft parts which have but a scanty blood-supply. And finally, after slight injuries, they are not maintained in a condition of rest to the same extent as some other parts of the body after similar injuries. Caries of the calcaneum or astragalus may remain limited to the one bone for a long period, but when one of the other bones is affected, the remainder frequently become involved, in consequence of the disease spreading through the large and complicated synovial membrane which is more or less common to these bones.

Amputation of the whole or a part of the foot is often required either for injury or disease. The principal amputations are as follows: (1) Syme's: amputation at the ankle-joint by a heel-flap, with removal of the malleoli and sometimes a thin slice from the lower end of the tibia. (2) Roux's: amputation at the ankle-joint by a large internal flap. (3) Pirogoff's amputation: removal of the whole of the tarsal bones, except the posterior part of the os calcis, and a thin slice from the tibia and fibula including the two malleoli. The sawn surface of the os calcis is then turned up and united to the similar surface of the tibia. (4) Subastragaloid amputation: removal of the foot below the astragalus through the joint between it and the os calcis. This operation has been modified by Hancock, who leaves the posterior third of the os calcis and turns it up against the denuded surface of the astragalus. This latter operation is of doubtful utility, and is rarely performed.

(5) Chopart's or medio-tarsal: removal of the anterior part of the foot with all the tarsal bones except the os calcis and astragalus; disarticulation being effected through the astragalo-scaphoid and calcaneo-cuboid joints. (6) Lisfranc's: amputation of the anterior part of the foot through the tarso-metatarsal joints. This has been modified by Hey, who disarticulated through the joints of the four outer metatarsal bones with the tarsus, and sawed off the projecting internal cuneiform; and by Skey, who sawed off the base of the second metatarsal bone and disarticulated the others.

The bones of the tarsus occasionally require removal individually. This is especially the case with the astragalus and os calcis for disease limited to the one bone, or again the astragalus may require excision in cases of subastragaloid dislocation, or, as recommended by Lund, in cases of inveterate talipes. The cuboid has been removed for the same reason by Solly. But both these two latter operations have fallen very much into disuse, and have been superseded by resection of a wedge-shaped piece of bone from the outer side of the tarsus. Finally, Mickulicz and Watson have devised operations for the removal of more extensive portions of the tarsus. Mickulicz's operation consists in the removal of the os calcis and astragalus, along with the articular surfaces of the tibia and fibula, and also of the scaphoid and cuboid. The remaining portion of the tarsus is then brought into contact with the sawn surfaces of the tibia and fibula, and fixed there. The result is a position of the shortened foot resembling talipes equinus. Watson's operation is adapted to those cases where the disease is confined to the anterior tarsal bones. By two lateral incisions he saws through the bases of the metatarsal bones in front and opens up the joints between the scaphoid and astragalus, and the cuboid and os calcis, and removes the intervening bones.

The metatarsal bones and phalanges are nearly always broken by direct violence, and in the majority of cases the injury is the result of severe crushing accidents, necessitating amputation. The metatarsal bones, and especially that of the great toe, are frequently diseased, either in tuberculous subjects or in perforating ulcer of the foot.

SESAMOID BONES

The sesamoid bones are small, more or less rounded masses, cartilaginous in early life, which are developed in those tendons which exert a great amount of pressure upon the parts over which they glide. It is said that they are more commonly found in the male than in the female, and in persons of an active muscular habit than in those who are weak and debilitated. They are invested throughout their whole surface by the fibrous tissue of the tendon in which they are found, excepting upon that side which lies in contact with the part over which they play, where they present a free articular facet. They may be divided into two kinds: those which glide over the articular surfaces of joints, and those which play over the cartilaginous facets found on the surfaces of certain bones.

The sesamoid bones of the joints in the upper extremity are two on the palmar surface of the metacarpo-phalangeal joint in the thumb, developed in the tendons of the Flexor brevis pollicis; of these the internal is the larger; sometimes one or two opposite the metacarpo-phalangeal articulations of the index and little fingers; and, still more rarely, one opposite the same joints of the third and fourth fingers, at the interphalangeal joint of the thumb and at the articulation between the second and third phalanges of the index finger. In the lower extremity they consist of the patella, which is developed in the tendon of the Quadriceps extensor muscle; two small sesamoid bones, of which the inner is the larger, found in the tendons of the Flexor brevis hallucis, opposite the metatarso-phalangeal joint of the great toe; occasionally one at the metatarso-phalangeal joints of the second and fifth toes, and, still more rarely, at the corresponding joints of the third and fourth toes, or at the interphalangeal joint of the great toe.

Those found in the tendons which glide over certain bones occupy the following situations: one sometimes found in the tendon of the Biceps cubiti, opposite the tuberosity of the radius; one in the tendon of the Peroneus longus, where it glides through the groove in the cuboid bone; one, appearing late in life, in the tendon of the Tibialis anticus, opposite the smooth facet of the internal cuneiform bone; one is found in the tendon of the Tibialis posticus, opposite the inner side of the head of the astragalus; one in the outer head of the Gastrocnemius, behind the outer condyle of the femur; and one in the conjoined tendon of the Psoas and Iliacus, where it glides over the os pubis. Sesamoid bones are found occasionally in the tendon of the Gluteus maximus, as it passes over the great trochanter; and in the tendons which wind round the inner and outer malleoli.

THE ARTICULATIONS

THE various bones of the Skeleton are connected together at different parts of their surfaces, and such a connection is designated by the name of *Joint* or *Articulation*. If the joint is *immovable*, as between the cranial and most of the facial bones, the adjacent margins of the bones are applied in almost close contact, a thin layer of fibrous membrane, the *sutural ligament*, and, at the base of the skull, in certain situations, a thin layer of cartilage being interposed. Where slight movement is required, combined with great strength, the osseous surfaces are united by tough and elastic fibro-cartilages, as in the joints between the vertebral bodies and in the interpubic articulation; but in the *movable* joints, the bones forming the articulation are generally expanded for greater convenience of mutual connection, covered by *cartilage*, held together by strong bands or capsules of fibrous tissue, called *ligaments*, and partially lined by a membrane, the *synovial membrane*, which secretes a fluid to lubricate the various parts of which the joint is formed: so that the structures which enter into the formation of a movable joint are bone, cartilage, fibro-cartilage, ligament, and synovial membrane.

Bone constitutes the fundamental element of all the joints. In the long bones, the extremities are the parts which form the articulations; they are generally somewhat enlarged, and consist of spongy cancellous tissue with a thin coating of compact substance. In the flat bones, the articulations usually take place at the edges; and in the short bones at various parts of their surface. The layer of compact bone which forms the joint surface, and to which the articular cartilage is attached, is called the *articular lamella*. It is white, extremely dense, and varies in thickness. Its structure differs from ordinary bone-tissue in this respect, that it contains no Haversian canals, and its lacunæ are larger than in ordinary bone, and have no canaliculi. The vessels of the cancellous tissue, as they approach the articular lamella, turn back in loops, and do not perforate it; this layer is consequently denser and firmer than ordinary bone, and is evidently designed to form an unyielding support for the articular cartilage.

The **articular cartilage**, which covers the articular surfaces of bone, is of the hyaline variety, and has been described in the section on General Anatomy.

Ligaments, properly so called, are peculiar to the movable joints, and serve to connect together the articular surfaces of bones. They are composed mainly of bundles of *white fibrous tissue* placed parallel with, or closely interlaced with one another, and presenting a white, shining, silvery aspect. In the freely movable joints, or diarthrodia, they form envelopes or capsules connecting together the articular extremities of bones. These capsules in particular places undergo thickening and form strong ligamentous bands, which, though strictly speaking constituent parts of the capsule, are usually described as distinct ligaments. A ligament is pliant and flexible, so as to allow of the most perfect freedom of movement, but strong, tough, and inextensile, so as not to yield readily under the most severely applied force; it is consequently well adapted to serve as the connecting medium between the bones. Some ligaments consist entirely of *yellow elastic tissue*, as the ligamenta subflava, which connect together the laminæ of adjacent vertebræ, and the ligamentum nuchæ in the lower animals.

In these cases it will be observed that the elasticity of the ligament is intended to act as a substitute for muscular power.

Synovial membrane is composed of a thin, delicate connective tissue, with branched connective-tissue corpuscles. Its secretion is thick, viscid, and glairy, like the white of egg; and is hence termed *synovia*. The synovial membranes in the body admit of subdivision into three kinds—articular, bursal, and vaginal.

The *articular synovial membranes* are found in all the freely movable joints. The membrane invests the inner surface of the capsule enclosing the joint, and is reflected over the surface of any tendons passing through its cavity, as the tendon of the Popliteus in the knee, and the tendon of the Biceps in the shoulder. Hence the articular synovial membrane may be regarded as a short wide tube, attached by its open ends to the margins of the articular cartilages and covering the inner surface of the various ligaments which connect the articular surfaces, so that along with the cartilages it completely encloses the joint cavity. In the fœtus this membrane is said, by Toynbee, to be continued over the surface of the cartilages; but in the adult it is wanting, excepting at their circumference, upon which it encroaches for a short distance and to which it is firmly attached. In some of the joints the synovial membrane is thrown into folds, which pass across the cavity. They are called *synovial ligaments*, and are especially distinct in the knee. In other joints there are flattened folds, subdivided at their margins into fringe-like processes, the vessels of which have a convoluted arrangement. These latter generally project from the synovial membrane near the margin of the cartilage, and lie flat upon its surface. They consist of connective tissue, covered with endothelium, and contain fat-cells in variable quantities, and, more rarely, isolated cartilage-cells. The larger folds often contain considerable quantities of fat. They were described, by Clopton Havers, as *mucilaginous glands*, and as the source of the synovial secretion. Under certain diseased conditions, similar processes are found covering the entire surface of the synovial membrane, forming a mass of pedunculated fibro-fatty growths, which projects into the joint. Similar structures are also found in some of the bursal and vaginal synovial membranes.

The *bursal synovial membranes* are found interposed between surfaces which move upon each other, as in the gliding of a tendon, or of the integument over projecting bony surfaces. They admit of subdivision into two kinds, the *bursæ mucosæ* and the *bursæ synoviæ*. The *bursæ mucosæ* are large, simple, or irregular cavities in the subcutaneous areolar tissue, enclosing a clear viscid fluid. They are found in various situations, as between the integument and the front of the patella, over the olecranon, the malleoli, and other prominent parts. The *bursæ synoviæ* are found interposed between muscles or tendons as they play over projecting bony surfaces, as between the Glutei muscles and the surface of the great trochanter. They consist of a thin wall of connective tissue, partially covered by patches of cells, and contain a viscid fluid. Where one of these exists in the neighbourhood of a joint, it may communicate with its cavity, as in the case of the bursa between the tendon of the Psoas and Iliacus and the capsular ligament of the hip, or that interposed between the deep surface of the Subscapularis and the capsular ligament of the shoulder-joint.

The *vaginal synovial membranes* (*synovial sheaths*) serve to facilitate the gliding of tendons in the osseo-fibrous canals through which they pass. The membrane is here arranged in the form of a sheath, one layer of which adheres to the wall of the canal, and the other is reflected upon the surface of the enclosed tendon; the space between the two free surfaces of the membrane containing synovia. These sheaths are chiefly found surrounding the tendons of the flexor and extensor muscles of the fingers and toes, as they pass through the osseo-fibrous canals in the hand or foot.

Synovia is a transparent, yellowish-white, or slightly reddish fluid, viscid like the white of egg, having an alkaline reaction and slightly saline taste. It consists, according to Frerichs, in the ox, of 94·85 water, 0·56 mucus and epithelium, 0·07 fat, 3·51 albumen and extractive matter, and 0·99 salts.

CLASSIFICATION OF JOINTS

The articulations are divided into three classes: *synarthrosis*, or immovable; *amphiarthrosis*, or mixed; and *diarthrosis*, or movable joints.

1. Synarthrosis. Immovable Articulations

Synarthrosis includes all those articulations in which the surfaces of the bones are in almost direct contact, fastened together by an intervening mass of connective tissue or hyaline cartilage, and in which there is no appreciable motion, as the joints between the bones of the cranium and face, excepting those of the lower jaw. The varieties of synarthrosis are four in number: Sutura, Schindylesis, Gomphosis, and Synchrondrosis.

Sutura (*a seam*) is that form of articulation where the contiguous margins of flat bones are united by a thin layer of fibrous tissue. It is met with only in the skull. When the articulating surfaces are connected by a series of processes and indentations interlocked together, it is termed a *true suture* (*sutura vera*); of which there are three varieties: sutura dentata, serrata, and limbosa. The surfaces of the bones are not in direct contact, being separated by a layer of membrane, continuous externally with the pericranium, internally with the dura mater. The *sutura dentata* (dens, *a tooth*) is so called from the tooth-like form of the projecting articular processes, as in the suture between the parietal bones. In the *sutura serrata* (serra, *a saw*) the edges of the two bones forming the articulation are serrated like the teeth of a fine saw, as between the two portions of the frontal bone. In the *sutura limbosa* (limbus, *a selvage*), besides the dentated processes, there is a certain degree of bevelling of the articular surfaces, so that the bones overlap one another, as in the suture between the parietal and frontal bones. When the articulation is formed by roughened surfaces placed in apposition with one another, it is termed a *false suture* (*sutura notha*), of which there are two kinds, the *sutura squamosa* (squama, *a scale*), formed by the overlapping of two contiguous bones by broad bevelled margins, as in the squamo-parietal (squamous) suture; and the *sutura harmonia* (*ἁρμονία, a joining together*), where there is simple apposition of two contiguous rough bony surfaces, as in the articulation between the two superior maxillary bones, or of the horizontal plates of the palate bones.

Schindylesis (σχινδύλησις, *a fissure*) is that form of articulation in which a thin plate of bone is received into a cleft or fissure formed by the separation of two laminæ in another bone, as in the articulation of the rostrum of the sphenoid and perpendicular plate of the ethmoid with the vomer, or in the reception of the latter in the fissure between the superior maxillary and palate bones.

Gomphosis (γόμφος, *a nail*) is an articulation formed by the insertion of a conical process into a socket, as a nail is driven into a board; this is not illustrated by any articulation between bones, properly so called, but is seen in the articulation of the teeth with the alveoli of the maxillary bones.

Synchondrosis.—Where the connecting medium is cartilage the joint is termed a synchondrosis. This is a temporary form of joint, for the cartilage becomes converted into bone before adult life. Such a joint is found between the epiphyses and shafts of long bones, and in the junction between the occipital bone and the sphenoid and between the petrous portion of the temporal bone and the jugular process of the occipital bone.

2. Amphiarthrosis. Mixed Articulations

In this form of articulation only a slight amount of movement is possible, the contiguous osseous surfaces being either connected together by broad flattened discs of fibro-cartilage, of a more or less complex structure, which adhere to each bone, as in the articulation between the bodies of the vertebræ, and in the pubic symphysis. This is termed **Symphysis.** Or, secondly, the bony surfaces are united by an interosseous ligament, as in the inferior tibio-fibular articulation. To this the term **Syndesmosis** is applied.

3. Diarthrosis. Movable Articulations

This form of articulation includes the greater number of the joints in the body, mobility being their distinguishing character. They are formed by the approximation of two contiguous bony surfaces, covered with cartilage, connected by ligaments, and lined by synovial membrane. The varieties of joints in this class have been determined by the kind of motion permitted in each. There are two varieties in which the movement is uniaxial; that is to say, all movements take place around one axis. In one form, the Ginglymus, this axis is practically speaking transverse; in the other, the Trochoid or pivot-joint, it is longitudinal. There are two varieties where the movement is biaxial, or around two horizontal axes at right angles to each other, or at any intervening axis between the two. These are the Condyloid and saddle-joint. There is one form of joint where the movement is polyaxial, the Enarthrosis or ball-and-socket joint. And finally there are the Arthrodia or gliding joints.

Ginglymus or **Hinge-joint** (*γίγγλυμος, a hinge*).—In this form of joint the articular surfaces are moulded to each other in such a manner as to permit motion only in one plane, forwards and backwards; the extent of motion at the same time being considerable. The direction which the distal bone takes in this motion is never in the same plane as that of the axis of the proximal bone, but there is always a certain amount of alteration from the straight line during flexion. The articular surfaces are connected together by strong lateral ligaments, which form their chief bond of union. The most perfect forms of ginglymus are the interphalangeal joints and the joint between the humerus and ulna; the knee and ankle are less perfect, as they allow a slight degree of rotation or lateral movement in certain positions of the limb.

Trochoid (*pivot-joint*).—Where the movement is limited to rotation, the joint is formed by a pivot-like process turning within a ring, or the ring on the pivot, the ring being formed partially of bone, partly of ligament. In the superior radio-ulnar articulation, the ring is formed partly by the lesser sigmoid cavity of the ulna; in the rest of its extent, by the orbicular ligament; here, the head of the radius rotates within the ring. In the articulation of the odontoid process of the axis with the atlas, the ring is formed in front by the anterior arch of the atlas; behind, by the transverse ligament; here, the ring rotates round the odontoid process.

Condyloid Articulation.—In this form of joint, an ovoid articular head, or condyle, is received into an elliptical cavity in such a manner as to permit of flexion and extension, adduction and abduction and circumduction, but no axial rotation. The articular surfaces are connected together by anterior, posterior, and lateral ligaments. An example of this form of joint is found in the wrist.

Articulation by Reciprocal Reception (*saddle-joint*).—In this variety the articular surfaces are concavo-convex; that is to say, they are inversely convex in one direction and concave in the other. The movements are the same as in the preceding form; that is to say, there is flexion, extension, adduction, abduction, and circumduction, but no axial rotation. The articular surfaces are connected by a capsular ligament. The best example of this form of joint is the carpo-metacarpal joint of the thumb.

Enarthrosis is that form of joint in which the distal bone is capable of motion around an indefinite number of axes, which have one common centre. It is formed by the reception of a globular head into a deep cup-like cavity (hence the name 'ball-and-socket'), the parts being kept in apposition by a capsular ligament strengthened by accessory ligamentous bands. Examples of this form of articulation are found in the hip and shoulder.

Arthrodia is that form of joint which admits of a gliding movement; it is formed by the approximation of plane surfaces, or one slightly concave, the other slightly convex; the amount of motion between them being limited by the ligaments, or osseous processes, surrounding the articulation; as in the articular processes of the vertebræ, the carpal joints, except that of the os magnum with the scaphoid and semilunar bones, and the tarsal joints with the exception of the joint between the astragalus and the navicular.

On the next page, in a tabular form, are the names, distinctive characters, and examples of the different kinds of articulations.

- *Synarthrosis*, or Immovable Joint. Surfaces separated by fibrous membrane or cartilage, without any intervening synovial cavity, and immovably connected with each other. As in joints of cranium and face (except the lower jaw).
  - *Sutura*. Articulation by processes and indentations interlocked together.
    - *Sutura vera* (true) articulate by indented borders.
      - *Dentata*, having tooth-like processes. As in interparietal suture.
      - *Serrata*, having serrated edges like the teeth of a saw. As in interfrontal suture.
      - *Limbosa*, having bevelled margins, and dentated processes. As in fronto-parietal suture.
    - *Sutura notha* (false) articulate by rough surfaces.
      - *Squamosa*, formed by thin bevelled margins, overlapping each other. As in squamo-parietal suture.
      - *Harmonia*, formed by the apposition of contiguous rough surfaces. As in intermaxillary suture.
  - *Schindylesis*.—Articulation formed by the reception of a thin plate of one bone into a fissure of another. As in articulation of rostrum of sphenoid with vomer.
  - *Gomphosis*.—Articulation formed by the insertion of a conical process into a socket. As in the teeth.
  - *Synchondrosis*.—When the connecting medium is cartilage, as in the occipito-sphenoid joint.
- *Amphiarthrosis*, Mixed Articulation.
  - *Symphysis*.—Surfaces connected by fibro-cartilage, not separated by synovial membrane, and having limited motion. As in joints between bodies of vertebræ.
  - *Syndesmosis*.—Surfaces united by an interosseous ligament. As in the inferior tibio-fibular articulation.
- *Diarthrosis*, Movable Joint.
  - *Ginglymus*.—Hinge-joint; motion limited to two directions, forwards and backwards. Articular surfaces fitted together so as to permit of movement in one plane. As in the interphalangeal joints and the joint between the humerus and the ulna.
  - *Trochoides or Pivot-joint*.—Articulation by a pivot process turning within a ring, or ring around a pivot. As in superior radio-ulnar articulation, and atlanto-axial joint.
  - *Condyloid*.—Ovoid head received into elliptical cavity. Movements in every direction except axial rotation. As the wrist-joint.
  - *Reciprocal Reception* (*Saddle-joint*).—Articular surfaces inversely convex in one direction and concave in the other. Movement in every direction except axial rotation. As in the carpo-metacarpal joint of the thumb.
  - *Enarthrosis*.—Ball-and-socket joint; capable of motion in all directions. Articulations by a globular head received into a cup-like cavity. As in hip- and shoulder-joints.
  - *Arthrodia*.—Gliding-joint; articulations by plane surfaces, which glide upon each other. As in carpal and tarsal articulations.

The Kinds of Movement admitted in Joints

The movements admissible in joints may be divided into four kinds: gliding, angular, circumduction, and rotation. These movements are often, however, more or less combined in the various joints, so as to produce an infinite variety, and it is seldom that we find only one kind of motion in any particular joint.

Gliding movement is the simplest kind of motion that can take place in a joint, one surface gliding or moving over another without any angular or rotatory movement. It is common to all movable joints; but in some, as in most of the articulations of the carpus and tarsus, it is the only motion permitted. This movement is not confined to plane surfaces, but may exist between any two contiguous surfaces, of whatever form, limited by the ligaments which enclose the articulation.

Angular movement occurs only between the long bones, and by it the angle between the two bones is increased or diminished. It may take place in four directions: forwards and backwards, constituting flexion and extension, or inwards and outwards, from the mesial line of the body (or in the fingers and toes from the middle line of the hand or foot), constituting adduction and abduction. The strictly ginglymoid or hinge-joints admit of flexion and extension only. Abduction and adduction, combined with flexion and extension, are met with in the more movable joints; as in the hip, shoulder, and metacarpal joint of the thumb, and partially in the wrist.

Circumduction is that degree of motion which takes place between the head of a bone and its articular cavity, while the limb is made to circumscribe a conical space, the base of which corresponds with the inferior extremity of the limb, the apex with the articular cavity; this kind of motion is best seen in the shoulder- and hip-joints.

Rotation is the movement of a bone around an axis; the latter may be formed by a separate bone, as in the case of the pivot formed by the odontoid process of the axis around which the atlas turns; or a bone may rotate around its own longitudinal axis, as in the rotation of the humerus and femur at the shoulder- and hip-joints respectively; or the axis of rotation may not be quite parallel to the long axis of the bone, as in the movement of the radius on the ulna during pronation and supination of the hand, where the axis of rotation is represented by a line connecting the centre of the head of the radius above with the centre of the head of the ulna below.

Ligamentous Action of Muscles.—The movements of the different joints of a limb are combined by means of the long muscles which pass over more than one joint, and which, when relaxed and stretched to their greatest extent, act as elastic ligaments in restraining certain movements of one joint, except when combined with corresponding movements of the other—these latter movements being usually in the opposite direction. Thus the shortness of the hamstring muscles prevents complete flexion of the hip, unless the knee-joint is also flexed, so as to bring their attachments nearer together. The uses of this arrangement are threefold. 1. It co-ordinates the kinds of movement which are the most habitual and necessary, and enables them to be performed with the least expenditure of power. 'Thus in the usual gesture of the arms, whether in grasping or rejecting, the shoulder and the elbow are flexed simultaneously, and simultaneously extended,' in consequence of the passage of the Biceps and Triceps cubiti over both joints. 2. It enables the short muscles which pass over only one joint to act upon more than one. 'Thus, if the Rectus femoris remain tonically of such length that, when stretched over the extended hip, it compels extension of the knee, then the Gluteus maximus becomes, not only an extensor of the hip, but an extensor of the knee as well.' 3. It provides the joints with ligaments which, while they are of very great power in resisting movements to an extent incompatible with the mechanism of the joint, at the same time spontaneously yield when necessary. 'Taxed beyond its strength a ligament will be ruptured, whereas a contracted muscle is easily relaxed; also, if neighbouring joints be united by ligaments, the amount of flexion or extension of each must remain in constant proportion to that of the other; while, if the union be by muscles, the separation of the points of attachment of those muscles may vary considerably in different varieties of movement, the muscles adapting themselves tonically to the length required.' The quotations are from a very interesting paper by Cleland in the 'Journal of Anatomy and Physiology,' No. 1, 1866, p. 85; by whom this important fact in the mechanism of joints was first clearly pointed out, though it was independently observed afterwards by other anatomists. W. W. Keen points out how important it is 'that the surgeon should remember this ligamentous action of muscles in making passive motion—for instance, at the wrist after Colles's fracture. If the fingers be extended,

the wrist can be flexed to a right angle. If, however, they be first flexed as in "making a fist," flexion at the wrist is quickly limited to from forty to fifty degrees in different persons, and is very painful beyond that point. Hence passive motion here should be made with the fingers extended. In the leg, when flexing the hip, the knee should be flexed.' Keen further points out that 'a beautiful illustration of this is seen in the perching of birds, whose toes are forced to clasp the perch by just such a passive ligamentous action so soon as they stoop. Hence they can go to sleep and not fall off the perch.'

The articulations may be grouped into those of the trunk, those of the upper extremity, and those of the lower extremity.

ARTICULATIONS OF THE TRUNK

These may be divided into the following groups, viz.:

I. Of the vertebral column.
II. Of the atlas with the axis.
III. Of the spine with the cranium.
IV. Of the lower jaw.
V. Of the ribs with the vertebræ.
VI. Of the cartilages of the ribs with the sternum, and with each other.
VII. Of the sternum.
VIII. Of the vertebral column with the pelvis.
IX. Of the pelvis.

I. ARTICULATIONS OF THE VERTEBRAL COLUMN

There are two distinct varieties of articulation in the vertebral column: 1. Those between the bodies of the vertebræ, which form a series of amphiarthrodial joints; these are termed the *intercentral joints*. 2. Those between the articular process, which form a series of arthrodial joints, and are termed *interneural*.

1. Intercentral Articulations

The intercentral articulations, or articulations between the bodies of the vertebræ, belong to the class of amphiarthrodial joints, and the individual vertebræ enjoy very little movement on each other. When, however, this slight degree of movement between the pairs of bones takes place in all the joints of the spine, the range of movement is very considerable. The ligaments of this articulation are the following:

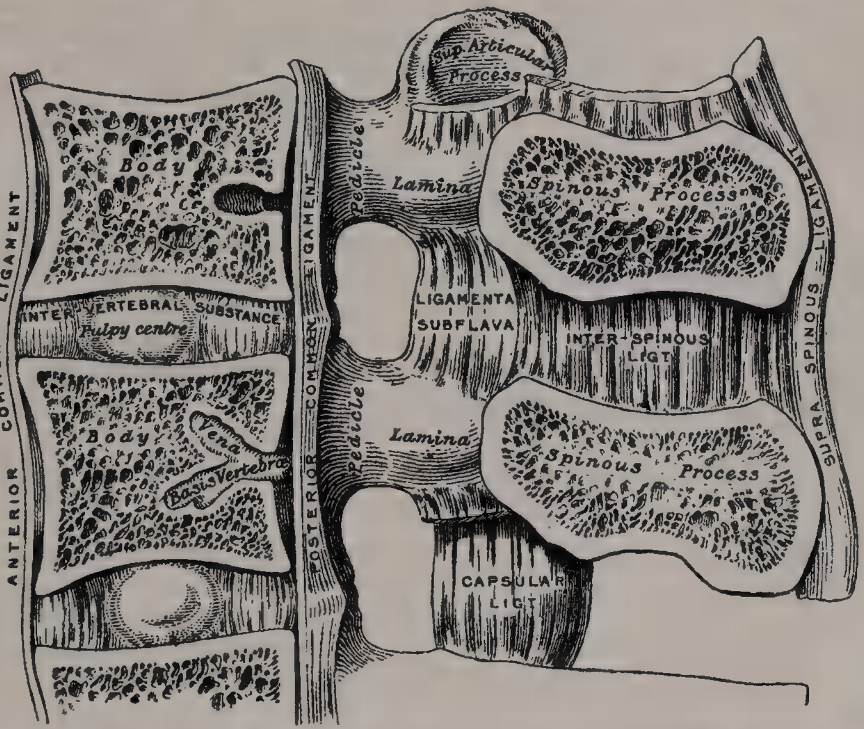
Anterior Common Ligament. Posterior Common Ligament.
Intervertebral Substance.

The **Anterior Common Ligament** (figs. 346, 347, 354, 358) is a broad and strong band of fibres, which extends along the anterior surface of the bodies of the vertebræ, from the axis to the sacrum. It is broader below than above, thicker in the dorsal than in the cervical or lumbar regions, and somewhat thicker opposite the front of the body of each vertebra than opposite the intervertebral substance. It is attached, above, to the body of the axis, where it is continuous with the anterior atlanto-axial ligament, and from this is continued upwards as a rounded cord, superficial to the anterior atlanto-axial ligament, to the under surface of the basilar process of the occipital bone. Here it is connected with the tendon of insertion of the Longus colli muscle. It extends down as far as the upper bone of the sacrum. It consists of dense longitudinal fibres, which are intimately adherent to the intervertebral substance, and the prominent margins of the vertebræ; but less closely to the middle parts of the bodies. In the latter situation the fibres are exceedingly thick, and serve to fill up the concavities on their front surface, and to make the anterior surface of the spine more even. This ligament is composed of several layers of fibres, which vary in length, but are closely interlaced with each other. The most superficial or longest fibres extend between four or five vertebræ. A second, subjacent set extend between two or three vertebræ; while a third set, the shortest and deepest, extend from one vertebra to the next. At the sides of the bodies the ligament consists of a few short fibres, which pass from one vertebra to the next, separated from the median portion by large oval apertures, for the passage of vessels.

The **Posterior Common Ligament** (figs. 346, 350) is situated within the spinal canal, and extends along the posterior surface of the bodies of the vertebræ, from the body of the axis, where it is continuous with the occipito-axial ligament, to the sacrum. It is broader above than below, and thicker in the dorsal than in the cervical or lumbar regions. In the situation of the intervertebral substance and contiguous margins of the vertebræ, where the ligament is more intimately adherent, it is broad, and presents a series of dentations with intervening concave margins; but it is narrow and thick over the centre of the bodies, from which it is separated by the *venæ basis vertebræ*. This ligament is composed of smooth, shining, longitudinal fibres, denser and more compact than those of the anterior ligament, and consists of a superficial layer occupying the interval between three or four vertebræ, and of a deeper layer which extends between one vertebra and the next adjacent to it. It is separated from the dura mater of the spinal cord by some loose connective tissue which is very liable to serous infiltration.

The **Intervertebral Substance** (figs. 346, 355) is a lenticular disc of composite structure interposed between the adjacent surfaces of the bodies of the vertebræ, from the axis to the sacrum, and forming the chief bond of connection between

FIG. 346.—Vertical section of two vertebræ and their ligaments, from the lumbar region.



these bones. The discs vary in shape, size, and thickness, in different parts of the spine. In *shape* they correspond with the surfaces of the bodies between which they are placed, except in the cervical region, where they are slightly smaller from side to side than the corresponding bodies. They are oval in the cervical and lumbar regions, and circular in the dorsal. Their *size* is greatest in the lumbar region. In *thickness* they vary not only in the different regions of the spine, but in different parts of the same disc: they are thicker in front than behind in the cervical and lumbar regions, and thus contribute to the anterior convexity of the column in these regions; while they are of nearly uniform thickness in the dorsal region, the anterior concavity in this region being almost entirely owing to the shape of the vertebral bodies. The intervertebral discs form about one-fourth of the spinal column, exclusive of the first two vertebræ; but this amount is not equally distributed between the various bones; the dorsal portion of the spine having, in proportion to its length, a much smaller amount than the cervical and lumbar regions, which necessarily gives to the latter parts greater pliancy and freedom of movement. The intervertebral discs are adherent, by their surfaces, to a thin layer of hyaline cartilage which covers

the upper and under surfaces of the bodies of the vertebræ, and in which, in early life, the epiphysial plate develops; and by their circumference are closely connected in front to the anterior, and behind to the posterior common ligament; while in the dorsal region they are joined laterally, by means of the interarticular ligament, to the heads of those ribs which articulate with two vertebræ: they consequently form part of the articular cavities in which the heads of these bones are received.

Structure of the Intervertebral Substance.—The intervertebral substance is composed, at its circumference, of laminæ of fibrous tissue and fibro-cartilage, forming the *annulus fibrosus*; and, at its centre, of a soft, pulpy, highly elastic substance, of a yellowish colour, which rises up considerably above the surrounding level when the disc is divided horizontally. This pulpy substance (*nucleus pulposus*) is especially well developed in the lumbar region, and is the remains of the chorda dorsalis. The laminæ are arranged concentrically one within the other, the outermost consisting of ordinary fibrous tissue, but the others and more numerous consist of white fibro-cartilage. These plates are not quite vertical in their direction, those near the circumference being curved outwards and closely approximated; while those nearest the centre curve in the opposite direction, and are somewhat more widely separated. The fibres of which each plate is composed are directed, for the most part, obliquely from above downwards; the fibres of adjacent plates passing in opposite directions and varying in every layer: so that the fibres of one layer are directed across those of another, like the limbs of the letter X. This laminar arrangement belongs to about the outer half of each disc. The pulpy substance presents no concentric arrangement, and consists of a fine fibrous matrix, containing angular cells, united to form a reticular structure.

2. Interneural Articulations

The interneural articulations, or articulations between the articular processes of the vertebræ, belong to the arthrodial variety of movable joints. The processes are connected together by capsular ligaments, and the joints are lined by synovial membranes; but in addition to these are a number of accessory ligaments, which connect together the laminæ, spinous and transverse processes. The ligaments of the interneural articulations are as follows:

Capsular. Supraspinous.
Ligamenta subflava. Interspinous.
Intertransverse.

The **Capsular Ligaments** (fig. 348) are thin and loose ligamentous sacs, attached to the contiguous margins of the articulating processes of each vertebra, through the greater part of their circumference, and completed internally by the ligamenta subflava. They are longer and looser in the cervical than in the dorsal or lumbar regions. The capsular ligaments are lined on their inner surface by **synovial membrane.**

The **Ligamenta Subflava** (fig. 346) are interposed between the laminæ of the vertebræ, from the axis to the first segment of the sacrum. They are most distinct when seen from the interior of the spinal canal: when viewed from the outer surface they appear short, being overlapped by the laminæ. Each ligament consists of two lateral portions, which commence on each side at the root of the articular process, and pass backwards to the point where the laminæ converge to form the spinous process, where their margins are in contact and to a certain extent united; slight intervals being left for the passage of small vessels. These ligaments consist of yellow elastic tissue, the fibres of which, almost perpendicular in direction, are attached to the anterior surface of the lamina above, some distance from its inferior margin, and to the posterior surface, as well as to the upper margin of the lamina below. In the cervical region they are thin in texture, but very broad and long; they become thicker in the dorsal region; and in the lumbar acquire very considerable thickness. Their highly elastic property serves to preserve the upright posture, and to assist the spine in resuming it, after it has been flexed. These ligaments do not exist between the occiput and atlas, or between the atlas and axis.

The **Supraspinous Ligament** (fig. 346) is a strong fibrous cord, which connects

together the apices of the spinous processes from the seventh cervical to the spinous processes of the sacrum. It is thicker and broader in the lumbar than in the dorsal region, and intimately blended, in both situations, with the neighbouring aponeurosis. The most superficial fibres of this ligament connect three or four vertebræ; those more deeply seated pass between two or three vertebræ; while the deepest connect the contiguous extremities of neighbouring vertebræ. It is continued upwards to the external occipital protuberance and occipital crest, as the ligamentum nuchæ, which, in the human subject, is thin, and forms merely an intermuscular septum.

The **Ligamentum nuchæ** is a fibrous membrane, which, in the neck, represents the supraspinous ligaments of the lower vertebræ. It extends from the external occipital protuberance and crest to the spinous process of the seventh cervical vertebra. From its anterior border a fibrous lamina is given off, which is attached to the posterior tubercle of the atlas, and the spinous process of each of the cervical vertebræ, so as to form a septum between the muscles on each side of the neck. In man it is merely the rudiment of an important elastic ligament, which, in some of the lower animals, serves to sustain the weight of the head.

The **Interspinous Ligaments** (fig. 346), thin and membranous, are interposed between the spinous processes. These ligaments extend from the root to the summit of each spinous process, connecting together their adjacent margins. They meet the ligamenta subflava in front and the supraspinous ligament behind. They are narrow and elongated in the dorsal region; broader, quadrilateral in form, and thicker in the lumbar region; and only slightly developed in the neck.

The **Intertransverse Ligaments** consist of bundles of fibres, interposed between the transverse processes. In the cervical region they consist of a few irregular, scattered fibres; in the dorsal, they are rounded cords intimately connected with the deep muscles of the back; in the lumbar region they are thin and membranous.

Actions.—The movements permitted in the spinal column are, Flexion, Extension, Lateral movement, Circumduction, and Rotation.

In *Flexion*, or movement of the spine forwards, the anterior common ligament is relaxed, and the intervertebral substances are compressed in front; while the posterior common ligament, the ligamenta subflava, and the inter- and supraspinous ligaments are stretched, as well as the posterior fibres of the intervertebral discs. The interspaces between the laminæ are widened, and the inferior articular processes of the vertebræ above glide upwards, upon the articular processes of the vertebræ below. Flexion is the most extensive of all the movements of the spine.

In *Extension*, or movement of the spine backwards, an exactly opposite disposition of the parts takes place. This movement is not extensive, being limited by the anterior common ligament, and by the approximation of the spinous processes.

Flexion and extension are free in the lower part of the lumbar region between the third and fourth and fourth and fifth lumbar vertebræ; above the third they are much diminished, and reach their minimum in the middle and upper part of the back. They increase again in the neck, the capability of motion backwards from the upright position being in this region greater than that of the motion forwards, whereas in the lumbar region the reverse is the case.

In *Lateral Movement*, the sides of the intervertebral discs are compressed, the extent of motion being limited by the resistance offered by the surrounding ligaments, and by the approximation of the transverse processes. This movement may take place in any part of the spine, but is freest in the neck and loins.

Circumduction is very limited, and is produced merely by a succession of the preceding movements.

Rotation is produced by the twisting of the intervertebral substances; this, although only slight between any two vertebræ, produces a considerable extent of movement, when it takes place in the whole length of the spine, the front of the upper part of the column being turned to one or the other side. This movement occurs only to a slight extent in the neck, but is freer in the upper part of the dorsal region, and is altogether absent in the lumbar region.

It is thus seen that the *cervical region* enjoys the greatest extent of each variety of movement, flexion and extension especially being very free. In the *dorsal region*, the three movements of flexion, extension, and circumduction are only permitted to a slight extent; while rotation is very free in the upper part

and ceases below. In the lumbar region there is free flexion, extension, and lateral movement, but no rotation.

As Humphry has pointed out, the movements permitted are mainly due to the shape and position of the articular processes. In the loins the inferior articular processes are turned outwards and embraced by the superior; this renders rotation in this region of the spine impossible, while there is nothing to prevent a sliding upwards and downwards of the surfaces on each other so as to allow of flexion and extension. In the dorsal region, on the other hand, the articulating processes, by their direction and mutual adaptation, especially at the upper part of the series, permit of rotation, but prevent extension and flexion; while in the cervical region the greater obliquity and lateral slant of the articular processes allow not only flexion and extension, but also rotation.

The principal muscles which produce *flexion* are the Sterno-mastoid, Rectus capitis anticus major, and Longus colli; the Scaleni; the abdominal muscles and the Psoas magnus. *Extension* is produced by the fourth layer of the muscles of the back, assisted in the neck by the Splenius, Semispinalis dorsi et colli, and the Multifidus spinæ. *Lateral* motion is produced by the fourth layer of the muscles of the back, by the Splenius and the Scaleni, the muscles of one side only acting; and *rotation* by the action of the following muscles of one side only, viz. the Sterno-mastoid, the Rectus capitis anticus major, the Scaleni, the Multifidus spinæ, the Complexus, and the abdominal muscles.

II. ARTICULATION OF THE ATLAS WITH THE AXIS

The articulation of the Atlas with the Axis is of a complicated nature, comprising no fewer than four distinct joints. There is a pivot articulation between the odontoid process of the axis and the ring formed between the anterior arch of the atlas and the transverse ligament (see fig. 349). Here there are two joints: one in front between the posterior surface of the anterior arch of the atlas and the front of the odontoid process; the other between the anterior surface of the transverse ligament and the back of the process. Between the articular processes of the two bones there is on either side an arthrodial or gliding joint. The ligaments which connect these bones are, the

Two Capsular.	Posterior Atlanto-axial.
Anterior Atlanto-axial.	Transverse.

The **Capsular Ligaments** are two thin and loose capsules, connecting the lateral masses of the atlas with the superior articular surfaces of the axis, the fibres being strengthened at the posterior and inner part of the articulation by a distinct ligamentous band, the *accessory ligament*, which is attached below to the body of the axis near the base of the odontoid process.

The **Anterior Atlanto-axial Ligament** (fig. 347) is a strong membranous layer, fixed, above, to the lower border of the anterior arch of the atlas; below, to the front of the body of the axis. It is strengthened in the middle line by a rounded cord, which is connected, above, to the tubercle on the anterior arch of the atlas, and below to the body of the axis, being a continuation upwards of the anterior common ligament of the spine. These ligaments are in relation, in front, with the Recti antici majores.

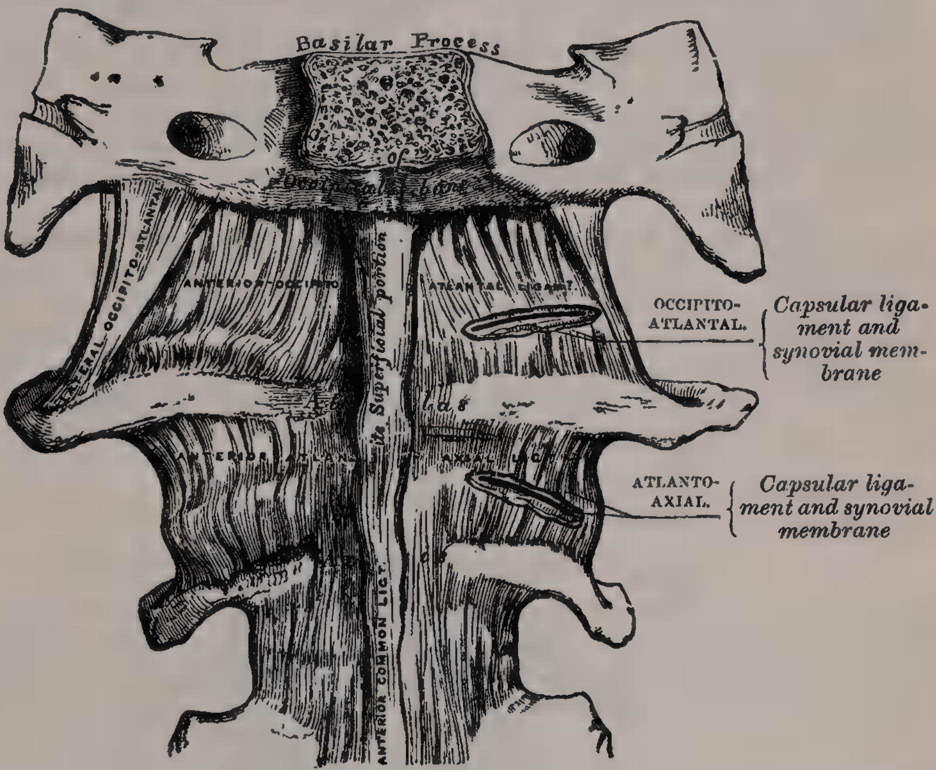
The **Posterior Atlanto-axial Ligament** (fig. 348) is a broad and thin membranous layer, attached, above, to the lower border of the posterior arch of the atlas; below, to the upper edge of the laminæ of the axis. This ligament supplies the place of the ligamenta subflava, and is in relation, behind, with the Inferior oblique muscles.

The **Transverse Ligament** * (figs. 349, 350) is a thick, strong band, which arches across the ring of the atlas, and serves to retain the odontoid process in firm connection with its anterior arch. This ligament is flattened from before backwards, broader and thicker in the middle than at either extremity, and

* It has been found necessary to describe the transverse ligament with those of the atlas and axis; but the student must remember that it is really a portion of the mechanism by which the movements of the head on the spine are regulated; so that the connections between the atlas and axis ought always to be studied in association with those between the latter bones and the skull.

firmly attached on each side to a small tubercle on the inner surface of the lateral mass of the atlas. As it crosses the odontoid process, a small fasciculus (*superior crus*) is prolonged upwards, and another (*inferior crus*) downwards, from the superficial or posterior fibres of the ligament: the former is inserted into the basilar process of the occipital bone, in close relation with the occipito-axial ligament; the latter descends, to be attached to the posterior surface of the body of the axis; hence, the whole ligament has received the name of *cruciform.* The transverse ligament divides the ring of the atlas into two unequal parts: of these, the posterior and larger serves for the transmission of the spinal cord and its membranes and the spinal accessory nerves; the anterior and smaller contains the odontoid process. Since the space between the anterior arch of the atlas and the transverse ligament is smaller at the lower part than the upper (because the transverse ligament embraces firmly the narrow neck of the odontoid process), this process is retained in firm connection with the atlas after all the other ligaments have been divided.

FIG. 347.—Occipito-atlantal and atlanto-axial ligaments. Front view.



There are *four* **Synovial Membranes** in this articulation: one lining the inner surface of each of the capsular ligaments; one between the anterior surface of the odontoid process and the anterior arch of the atlas, and one between the posterior surface of the odontoid process and the transverse ligament. The latter often communicates with those between the condyles of the occipital bone and the articular surfaces of the atlas.

Actions.—This joint allows the rotation of the atlas (and, with it, of the cranium) upon the axis, the extent of rotation being limited by the odontoid ligaments.

The principal muscles by which this action is produced are the Sterno-mastoid and Complexus of one side, acting with the Rectus capitis anticus major, Splenius, Trachelo-mastoid, Rectus capitis posticus major, and Inferior oblique of the other side.

III. ARTICULATIONS OF THE SPINE WITH THE CRANIUM

The ligaments connecting the spine with the cranium may be divided into two sets, those connecting the occipital bone with the atlas, and those connecting the occipital bone with the axis.

Ligaments connecting the Atlas with the Occipital Bone

The articulation between the atlas and the occipital bone is a double condyloid joint. Its ligaments are, the

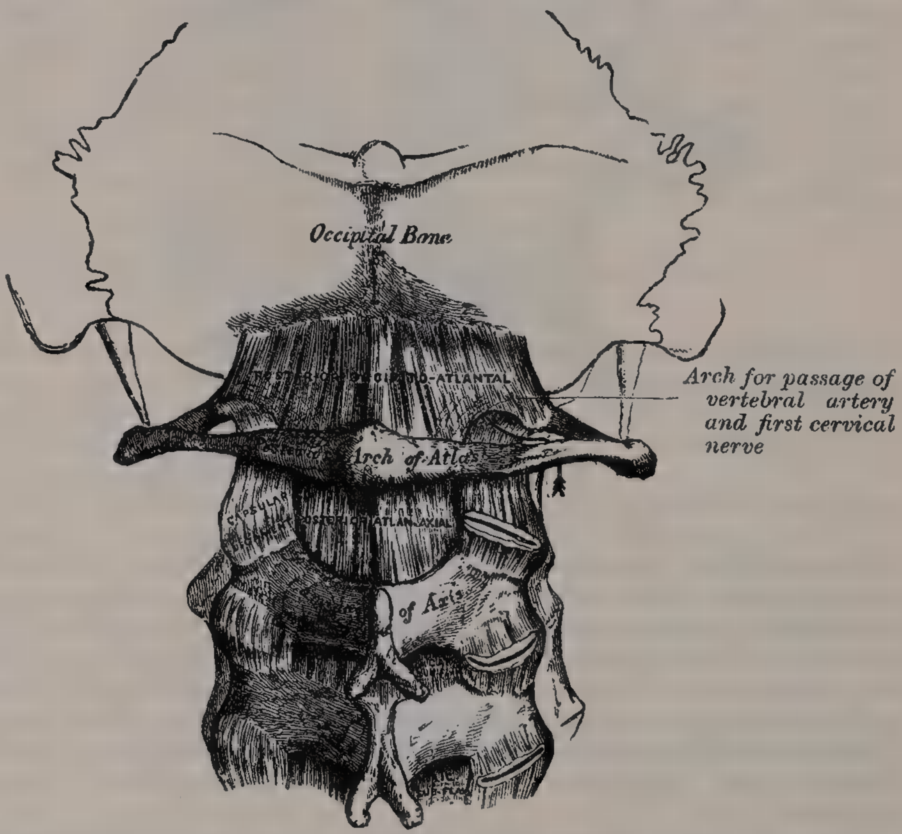
Two Capsular.	Posterior Occipito-atlantal.
Anterior Occipito-atlantal.	Two Lateral Occipito-atlantal.

The **Capsular Ligaments** surround the condyles of the occipital bone, and connect them with the articular processes of the atlas; they consist of thin and loose capsules, which are lined by synovial membrane.

The **Anterior Occipito-atlantal Ligament** (fig. 347) is a broad membranous layer, composed of densely woven fibres, which passes between the anterior margin of the foramen magnum above, and the whole length of the upper border of the anterior arch of the atlas below. Laterally, it is continuous with the capsular ligaments. In front, it is strengthened in the middle line by a strong, narrow, rounded cord, which is attached, above, to the basilar process of the occiput, and, below, to the tubercle on the anterior arch of the atlas. This ligament is in relation, in front, with the Recti antici minores; behind, with the odontoid ligaments.

The **Posterior Occipito-atlantal Ligament** (fig. 348) is a very broad but thin membranous lamina, intimately blended with the dura mater. It is connected, above, to the posterior margin of the foramen magnum; below, to the upper border of the posterior arch of the atlas. At each side this ligament is not attached to the bone, but presents a rounded inferior border, which forms, with

Fig. 348.—Occipito-atlantal and atlanto-axial ligaments. Posterior view.



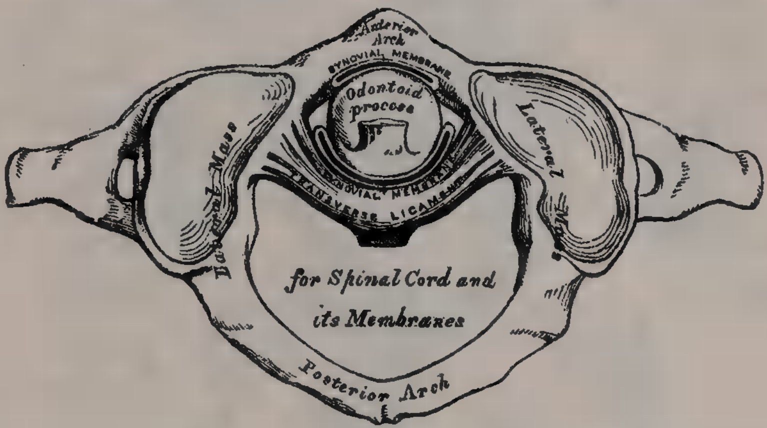
the superior intervertebral notch, an opening for the passage of the vertebral artery and suboccipital nerve. This free border, which arches over the artery and nerve, sometimes becomes ossified. It is in relation, behind, with the Recti postici minores and Obliqui superiores; in front, with the dura mater of the spinal canal, to which it is intimately adherent.

The **Lateral Ligaments** are thickened portions of the capsular ligament, reinforced by bundles of fibrous tissue, which are directed obliquely upwards and inwards, attached above to the jugular process of the occipital bone; below, to the base of the transverse process of the atlas.

Synovial Membranes.—There are two synovial membranes in this articulation: one lining the inner surface of each of the capsular ligaments. These occasionally communicate with that between the posterior surface of the odontoid process and the transverse ligament.

Actions.—The movements permitted in this joint are flexion and extension, which give rise to the ordinary forward and backward nodding of the head, besides slight lateral motion to one or the other side. When either of these actions is carried beyond a slight extent, the whole of the cervical portion of

FIG. 349.—Articulation between odontoid process and atlas.



the spine assists in its production. Flexion is mainly produced by the action of the Rectus capitis anticus major and minor and the Sterno-mastoid muscles; extension by the Rectus capitis posticus major and minor, the Superior oblique, the Complexus, Splenius, and upper fibres of the Trapezius. The Recti laterales are concerned in the lateral movement, assisted by the Trapezius, Splenius, Complexus, and the Sterno-mastoid of the same side, all acting together. According to Cruveilhier, there is a slight motion of rotation in this joint.

Ligaments connecting the Axis with the Occipital Bone

Occipito-axial. Three Odontoid.

To expose these ligaments, the spinal canal should be laid open by removing the posterior arch of the atlas, the laminæ and spinous process of the axis, and the portion of the occipital bone behind the foramen magnum, as seen in fig. 350.

The **Occipito-axial Ligament** (*membrana tectoria*) is situated within the spinal canal. It is a broad, strong band which covers the odontoid process and its ligaments, and appears to be a prolongation upwards of the posterior common ligament of the spinal column. It is attached, below, to the posterior surface of the body of the axis, and, becoming expanded as it ascends, is inserted into the basilar groove of the occipital bone, in front of the foramen magnum, where it blends with the dura mater of the skull.

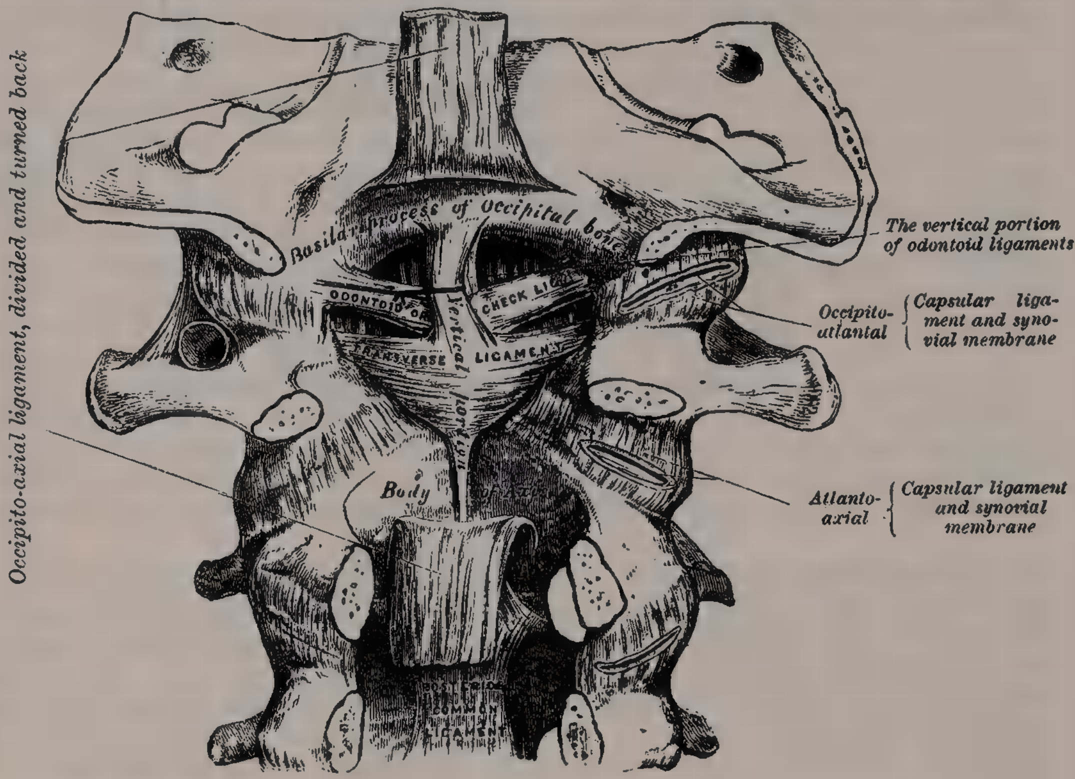
Relations.—By its anterior surface with the transverse ligament, by its posterior surface with the dura mater.

The **Odontoid** or **Check Ligaments** (*alar ligaments*) are strong, rounded, fibrous cords, which arise one on either side of the upper part of the odontoid process, and, passing obliquely upwards and outwards, are inserted into the rough depressions on the inner side of the condyles of the occipital bone. In the triangular interval left between these ligaments another fibrous cord (*ligamentum apicis dentis* or *middle odontoid ligament*) may be seen, which passes almost perpendicularly from the apex of the odontoid process to the anterior margin of the foramen magnum, being intimately blended with the deep portion of the anterior occipito-atlantal ligament, and upper fasciculus of the transverse ligament of the atlas. It is regarded as a rudimental intervertebral disc, and in it traces of the notochord may persist.

Actions.—The odontoid ligaments serve to limit the extent to which rotation of the cranium may be carried; hence they have received the name of *check ligaments*.

In addition to these ligaments which connect the atlas and axis to the skull, the ligamentum nuchæ must be regarded as one of the ligaments by which the spine is connected with the cranium. It has been described on page 355.

Fig. 350.—Occipito-axial and atlanto-axial ligaments. Posterior view, obtained by removing the arches of the vertebræ and the posterior part of the skull.



Surgical Anatomy.—The ligaments which unite the component parts of the vertebræ together are so strong, and these bones are so interlocked by the arrangement of their articulating processes, that dislocation is very uncommon, and, indeed, unless accompanied by fracture, rarely occurs, except in the upper part of the neck. Dislocation of the occiput from the atlas has only been recorded in one or two cases; but dislocation of the atlas from the axis, with rupture of the transverse ligament, is much more common: it is the mode in which death is produced in many cases of execution by hanging. In the lower part of the neck—that is, below the third cervical vertebra—dislocation unattended by fracture occasionally takes place.

IV. ARTICULATION OF THE LOWER JAW (TEMPORO-MANDIBULAR)

This is a ginglymo-arthrodial joint; the parts entering into its formation on each side are, above, the anterior part of the glenoid cavity of the temporal bone and the eminentia articularis; and, below, the condyle of the lower jaw. The ligaments are the following:

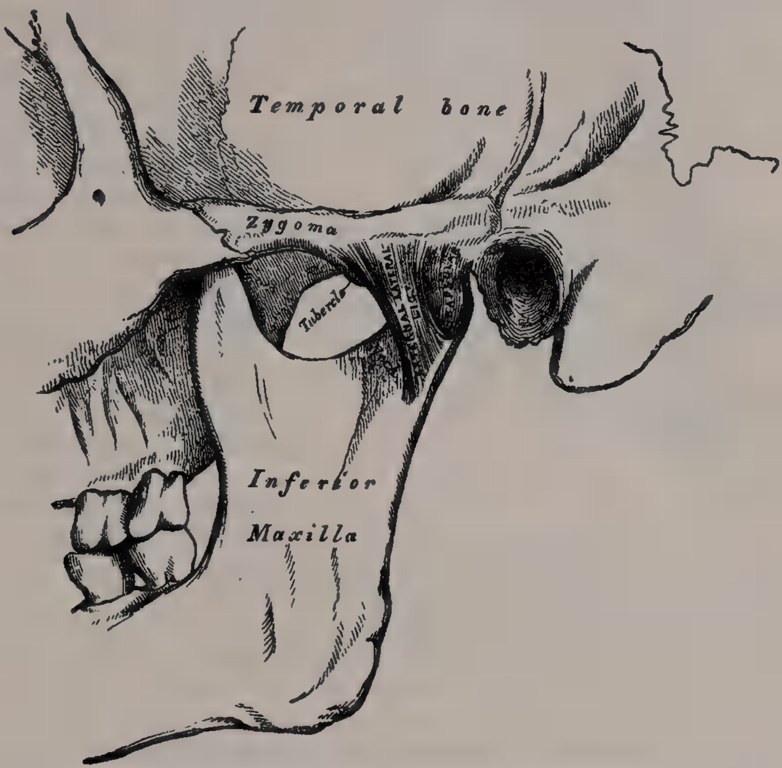
Capsular.	Internal Lateral.
External Lateral.	Interarticular Fibro-cartilage.
Stylo-mandibular.	

The **Capsular Ligament** forms a thin and loose, but distinct capsule, attached above to the circumference of the glenoid cavity and the articular surface immediately in front; below, to the neck of the condyle of the lower jaw. It is thinnest on the inner side.

The **External Lateral Ligament** (fig. 351) is an accessory band of the capsular ligament, and is not separable from it. It consists of two short, narrow fasciculi, one in front of the other, attached, above, to the outer surface of the zygoma and to the tubercle on its lower border; below, to the outer surface and posterior border of the neck of the lower jaw. It is broader above than below; its fibres

are parallel with one another, and directed obliquely downwards and backwards. Externally, it is covered by the parotid gland, and by the integument.

Fig. 351.—Temporo-mandibular articulation. External view.



The **Internal Lateral Ligament** (*spheno-mandibular*) (fig. 352) is not a true ligament, as it is developed from the fibrous covering of a part of Meckel's cartilage. It is a flat thin band which is attached above to the spinous process of the sphenoid bone, and, becoming broader as it descends, is inserted into the lingula of the dental foramen. Its outer surface is in relation, above, with the External pterygoid muscle; lower down, it is separated from the neck of the condyle by the internal maxillary artery; and still more inferiorly, the inferior dental vessels and nerve and a lobule of the parotid gland separate it from the ramus of the jaw. The inner surface is in relation with the Internal pterygoid muscle.

Fig. 352.—Temporo-mandibular articulation. Internal view.

The **Interarticular Fibro-cartilage** (fig. 353) is a thin plate of an oval form, placed horizontally between the condyle of the jaw and the glenoid cavity. Its upper surface is concavo-convex from before backwards, and a little convex transversely, to accommodate itself to the form of the glenoid cavity. Its under surface, where it is in contact with the condyle, is concave. Its circumference is connected to the capsular ligament; and in front to the tendon of the External pterygoid muscle. It is thicker at its circumference, especially behind, than at its centre. The fibres of which it is composed have a

concentric arrangement, more apparent at the circumference than at the centre. Its surfaces are smooth. It divides the joint into two cavities, each of which is furnished with a synovial membrane.

The **Synovial Membranes**, two in number, are placed one above, and the other below, the fibro-cartilage. The upper one, the larger and looser of the two, is continued from the margin of the cartilage covering the glenoid cavity and eminentia articularis on to the upper surface of the fibro-cartilage. The lower one passes from the under surface of the fibro-cartilage to the neck of the condyle of the jaw, being prolonged downwards a little farther behind than in front. The inter-articular cartilage is sometimes perforated in its centre, and the two synovial sacs then communicate with each other.

Fig. 353.—Vertical section of temporo-mandibular articulation.

The **Stylo-mandibular Ligament** is a specialised band of the cervical fascia, which extends from near the apex of the styloid process of the temporal bone to the angle and posterior border of the ramus of the lower jaw, between the Masseter and Internal pterygoid muscles. This ligament separates the parotid from the submaxillary gland, and has attached to its inner side part of the fibres of origin of the Stylo-glossus muscle. Although usually classed among the ligaments of the jaw, it can only be considered as an accessory to the articulation.

The *nerves* of this joint are derived from the auriculo-temporal and masseteric branches of the inferior maxillary. The *arteries* are derived from the temporal branch of the external carotid.

Actions.—The movements permitted in this articulation are very extensive. Thus, the jaw may be depressed or elevated, or it may be carried forwards or backwards. It must be borne in mind that there are two distinct joints in this articulation—that is to say, one between the condyle of the jaw and the interarticular fibro-cartilage, and another between the fibro-cartilage and the glenoid fossa; when the jaw is depressed, as in opening the mouth, the movements which take place in these two joints are not the same. In the lower compartment, that between the condyle and the fibro-cartilage, the movement is of a ginglymoid or hinge-like character, the condyle rotating on a transverse axis on the fibro-cartilage; while in the upper compartment the movement is of a gliding character, the fibro-cartilage, together with the condyle, gliding forwards on to the eminentia articularis. These two movements take place simultaneously, the condyle and fibro-cartilage move forwards on the eminence, and at the same time the condyle revolves on the fibro-cartilage. In the opposite movement of shutting the mouth the reverse action takes place; the fibro-cartilage glides back, carrying the condyle with it, and this at the same time revolves back to its former position. When the jaw is carried horizontally forwards, as in protruding the lower incisors in front of the upper, the movement takes place principally in the upper compartment of the joint, the fibro-cartilage, carrying with it the condyle, gliding forwards on the glenoid fossa. This is because the movement is mainly effected by the External pterygoid muscles, which are inserted into the condyles and interarticular fibro-cartilages. The grinding or chewing movement is produced by the alternate movement of one condyle, with its fibro-cartilage, forwards and backwards, while the other condyle moves simultaneously in the opposite direction; at the same time the condyle undergoes a vertical rotation on its own axis on the fibro-cartilage in the lower compartment. One condyle advances and rotates, the other condyle recedes and rotates, in alternate succession.

The lower jaw is *depressed* by its own weight, assisted by the Platysma, the Digastric, the Mylo-hyoid, and the Genio-hyoid. It is *elevated* by the anterior part of the Temporal, Masseter, and Internal pterygoid. It is drawn *forwards* by the simultaneous action of the External pterygoid, and the superficial fibres

of the Masseter; and it is drawn *backwards* by the deep fibres of the Masseter and the posterior fibres of the Temporal muscle. The grinding movement is caused by the alternate action of the two External pterygoids.

Surface Form.—The temporo-mandibular articulation is quite superficial, situated below the base of the zygoma, in front of the tragus and external auditory meatus, and behind the posterior border of the upper part of the Masseter muscle. Its exact position can be at once ascertained by feeling for the condyle of the jaw, the working of which can be distinctly felt in the movements of the lower jaw in opening and shutting the mouth. When the mouth is opened wide, the condyle advances out of the glenoid fossa on to the eminentia articularis, and a depression is felt in the situation of the joint.

Surgical Anatomy.—The lower jaw is dislocated only in one direction—viz. forwards. The accident is caused by violence or muscular action. When the mouth is open, the condyle is situated on the eminentia articularis, and any sudden violence, or even a sudden muscular spasm, as during a convulsive yawn, may displace the condyle forwards into the zygomatic fossa. The displacement may be unilateral or bilateral, according as one or both of the condyles are displaced. The latter of the two is the more common.

Sir Astley Cooper described a condition which he termed 'subluxation.' It occurs principally in delicate women, and is believed by some to be due to relaxation of the ligaments, permitting too free movement of the bone, and possibly some displacement of the fibro-cartilage. Others have believed that it is due to gouty or rheumatic changes in the joint.

In close relation to the condyle of the jaw is the external auditory meatus and the tympanum; any force, therefore, applied to the bone is liable to be attended with damage to these parts, or inflammation in the joint may extend to the ear, or on the other hand inflammation of the middle ear may involve the articulation and cause its destruction, thus leading to ankylosis of the joint. In children, arthritis of this joint may follow the exanthemata, and in adults occurs as the result of some constitutional conditions, as rheumatism or gout. The temporo-mandibular joint is also occasionally the seat of osteo-arthritis, leading to great suffering during efforts of mastication. A peculiar affection sometimes attacks the neck and condyle of the lower jaw, consisting in hypertrophy and elongation of these parts and consequent protrusion of the chin to the opposite side.

V. ARTICULATIONS OF THE RIBS WITH THE VERTEBRÆ

The articulations of the ribs with the vertebral column may be divided into two sets: 1. Those which connect the heads of the ribs with the bodies of the vertebræ (*costo-central*). 2. Those which connect the necks and tubercles of the ribs with the transverse processes (*costo-transverse*).

1. Costo-central Articulation (fig. 354)

These constitute a series of gliding joints, in which there is a certain hinge-like action, and hence may be characterised as ginglymo-arthrodial joints. They are formed by the articulation of the heads of the ribs with the cavities on the contiguous margins of the bodies of the dorsal vertebræ and the intervertebral substance between them, except in the case of the first, tenth, eleventh, and twelfth ribs, where the cavity is formed by a single vertebra. The bones are connected by the following ligaments:

Capsular. Anterior Costo-vertebral or Stellate.
Interarticular.

The **Capsular Ligament** surrounds and encloses the joint, being composed of short, strong fibres, which pass between the head of the rib and the circumference of the articular cavity formed by the intervertebral disc and the adjacent vertebræ. It is most distinct at the upper and lower parts of the articulation; and at its upper part some of its fibres pass through the intervertebral foramen to the back of the intervertebral disc, and, behind, it is continuous with the middle costo-transverse ligament.

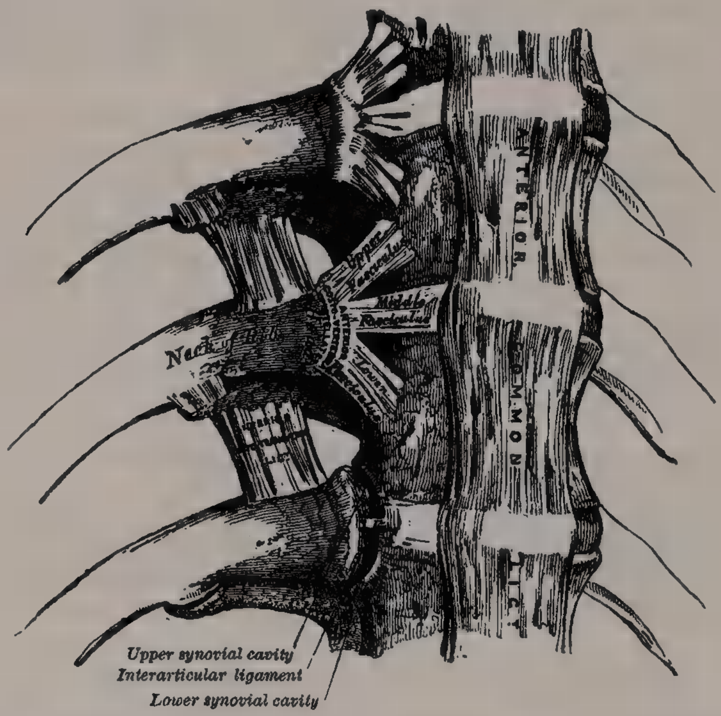
The **Anterior Costo-vertebral** or **Stellate Ligament** is a specialised part of the capsule, and connects the anterior part of the head of each rib with the sides of the bodies of two vertebræ, and the intervertebral disc between them. It consists of three flat bundles of ligamentous fibres, which are attached to the anterior part of the head of the rib, just beyond the articular surface. The superior bundle passes upwards to be connected with the body of the

vertebra above; the inferior one descends to the body of the vertebra below; and the middle one, the smallest and least distinct, passes horizontally inwards, to be attached to the intervertebral substance.

Relations.—In front, with the thoracic ganglia of the sympathetic, the pleura, and, on the right side, with the vena azygos major; behind, with the interarticular ligament and synovial membranes.

In the first rib, which articulates with a single vertebra, this ligament does not present a distinct division into three fasciculi; its fibres, however, radiate, and are attached to the body of the last cervical vertebra, as well as to the body of the vertebra with which the rib articulates. In the tenth, eleventh, and twelfth ribs, which also articulate with a single vertebra, the division does not exist; but the fibres of the ligament in each case radiate and are connected with the vertebra above, as well as that with which the rib articulates.

FIG. 354.—Costo-vertebral and costo-transverse articulations. Anterior view.



The **Interarticular Ligament** is situated in the interior of the joint. It consists of a short band of fibres, flattened from above downwards, attached by one extremity to the sharp crest which separates the two articular facets on the head of the rib, and by the other to the intervertebral disc. It divides the joint into two cavities, which have no communication with each other. In the first, tenth, eleventh, and twelfth ribs, the interarticular ligament does not exist; consequently, there is but one cavity. This ligament is the analogue of the *ligamentum conjugale* of some mammals, which unites the heads of opposite ribs across the back of the intervertebral disc.

The Synovial Membranes.—There are two synovial membranes in each of the articulations in which there is an interarticular ligament, one above and one below this structure: one only in those joints where there is a single cavity.

2. Costo-transverse Articulation (fig. 355)

The articular portion of the tubercle of the rib and adjacent transverse process form an arthrodial joint.

In the *eleventh* and *twelfth ribs* this articulation is wanting.

The ligaments connecting these parts are, the

Capsular.
Anterior Costo-transverse.
Middle Costo-transverse (Interosseous).
Posterior Costo-transverse.

The **Capsular Ligament** is a thin, membranous sac attached to the circumference of the articular surfaces, and enclosing a small synovial membrane.

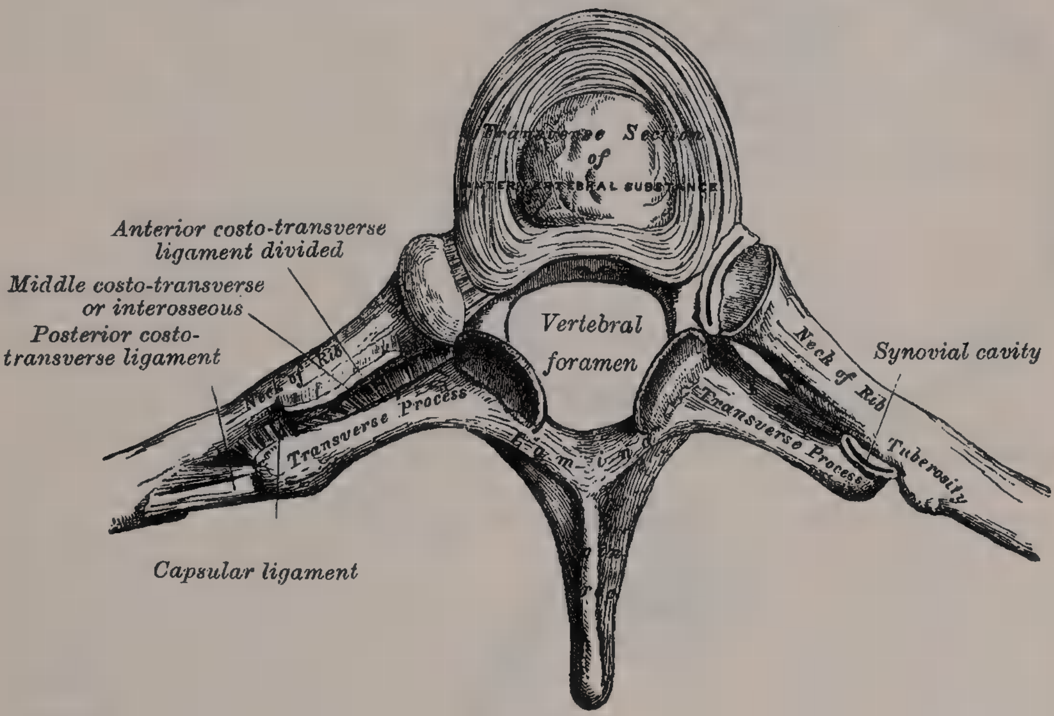
In the *eleventh* and *twelfth ribs* this ligament is absent.

The **Anterior** or **Superior Costo-transverse Ligament** consists of two sets of fibres: one (anterior) is attached below to the sharp crest on the upper border of the neck of each rib, and passes obliquely upwards and outwards, to the lower border of the transverse process immediately above; the other (posterior) is attached below to the neck of the rib, and passes upwards and inwards to the base of the transverse process and outer border of the lower articular process of the vertebra above. This ligament is in relation, in front, with the intercostal vessels and nerves; behind, with the Longissimus dorsi. Its *internal border* is thickened and free, and bounds an aperture which transmits the posterior branches of the intercostal vessels and nerves. Its *external border* is continuous with a thin aponeurosis, which covers the External intercostal muscle.

The *first rib* has no anterior costo transverse ligament.

The **Middle Costo-transverse** or **Interosseous Ligament** consists of short but strong fibres, which pass between the rough surface on the posterior part of the neck of each rib and the anterior surface of the adjacent transverse process. In

FIG. 355.—Costo-transverse articulation. Seen from above.



order fully to expose this ligament a horizontal section should be made across the transverse process and corresponding part of the rib; or the rib may be forcibly separated from the transverse process, and the fibres of the ligament put on the stretch.

In the *eleventh* and *twelfth ribs* this ligament is quite rudimentary or wanting.

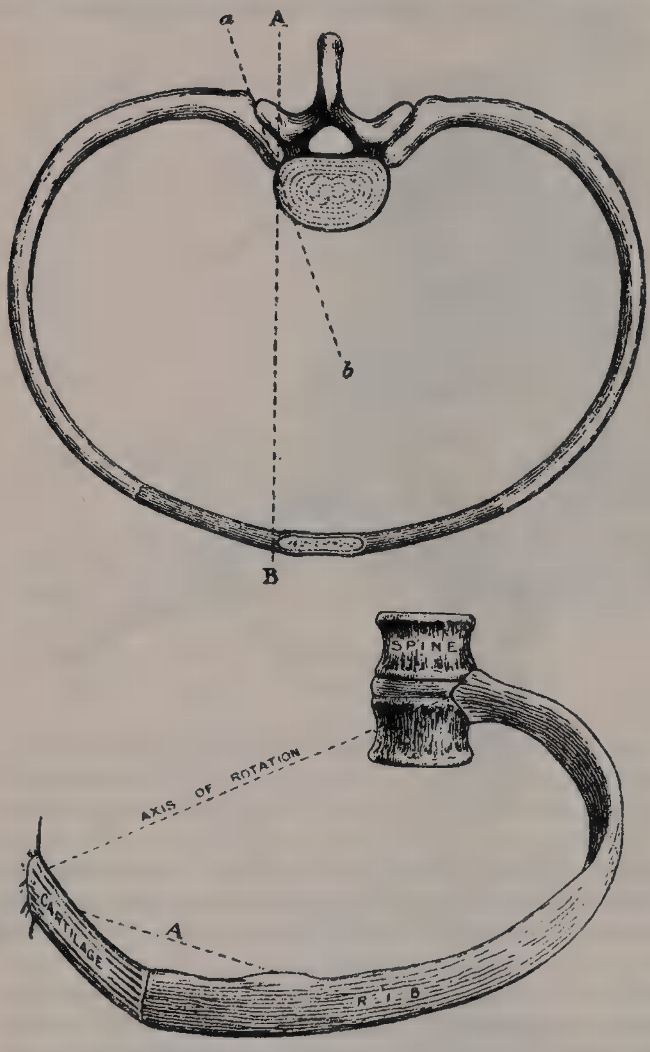
The **Posterior Costo-transverse Ligament** is a short but thick and strong fasciculus, which passes obliquely from the summit of the transverse process to the rough non-articular portion of the tubercle of the rib. This ligament is shorter and more oblique in the upper than in the lower ribs. Those corresponding to the superior ribs ascend, while those of the inferior ribs descend slightly.

In the *eleventh* and *twelfth ribs* this ligament is wanting.

Actions.—The heads of the ribs are so closely connected to the bodies of the vertebræ by the stellate and interarticular ligaments, and the necks and tubercles of the ribs to the transverse processes, that only a slight gliding movement of the articular surfaces on each other can take place in these articulations. The result of this gliding movement with respect to the six upper ribs, consists in an elevation of the front and middle portion of the rib, the hinder part being prevented from performing any upward movement by its close connection with the

spine. In this gliding movement the rib rotates on an axis corresponding with a line drawn through the two articulations, Costo-central and Costo-transverse, which the rib forms with the spine. With respect to the seventh, eighth, ninth, and tenth ribs, each one, besides rotating in a similar manner to the upper six, also rotates on an axis corresponding with a line drawn from the head of the rib to the sternum. By the first movement—that of rotation of the rib on an axis corresponding with a line drawn through the two articulations which this bone forms with the spine—an elevation of the anterior part of the rib takes place, and a consequent enlargement of the antero-posterior diameter of the chest. None of the ribs lie in the horizontal plane: they are all directed more or less obliquely, so that their anterior extremities lie on a lower level than their posterior, and this obliquity increases from the first to the seventh, and then again decreases. If any one rib is examined—say, that in which there is the greatest obliquity—it is obvious that as its sternal extremity is carried upwards, it must also be thrown forwards; so that the rib may be regarded as a radius, moving on the vertebral joint as a centre, and causing the sternal attachment to describe an arc of a circle in the vertical plane of the body. Since all the ribs are oblique and connected in front to the sternum by the elastic costal cartilages, they must have a tendency to thrust the sternum forwards, and so increase the antero-posterior diameter of the chest. By the second movement—that of the rotation of the rib on an axis corresponding with a line drawn from the head of the rib to the sternum—an elevation of the middle portion of the rib takes place, and consequently an increase in the transverse diameter of the chest. For the ribs not only slant downwards and forwards from their vertebral attachment, but they are also oblique in relation to their transverse plane—that is to say, their middle is on a lower level than either their vertebral or sternal extremities. It results from this that when the ribs are raised, the centre portion is thrust outwards, somewhat after the fashion in which the handle of a bucket is thrust away from the side when raised to a horizontal position, and the lateral diameter of the chest is increased (see fig. 356). The mobility of the different ribs varies very much. The first rib is more fixed than the others, on account of the weight of the upper extremity and the strain of the ribs beneath; but on the freshly dissected thorax it moves as freely as the rest. From the same causes the movement of the second rib is also not very extensive. In the other ribs, this mobility increases successively down to the last two, which are very movable. The ribs are generally more movable in the female than in the male.

Fig. 356.—Diagrams showing the axis of rotation of the ribs in the movements of respiration. The one axis of rotation corresponds with a line drawn through the two articulations which the rib forms with the spine (*a*, *b*), and the other with a line drawn from the head of the rib to the sternum (A, B). (From Kirke's 'Handbook of Physiology.')



VI. ARTICULATION OF THE CARTILAGES OF THE RIBS WITH THE STERNUM (CHONDRO-STERNAL) (fig. 357)

The articulations of the cartilages of the true ribs with the sternum are arthrodial joints, with the exception of the first, in which the cartilage is almost always directly united with the sternum, and which must, therefore, be regarded as a synarthrodial articulation. The ligaments connecting them are—

Capsular.	Interarticular Chondro-sternal.
Anterior Chondro-sternal.	Anterior Chondro-xiphoid.
Posterior Chondro-sternal.	Posterior Chondro-xiphoid.

The **Capsular Ligaments** surround the joints formed between the cartilages of the true ribs and the sternum. They are very thin, intimately blended with the anterior and posterior ligaments, and strengthened at the upper and lower parts of the articulations by a few fibres, which pass from the cartilage to the side of the sternum. These ligaments protect the synovial membranes.

The **Anterior Chondro-sternal Ligament** is an accessory part of the capsular ligament, and consists of a broad and thin membranous band that radiates from the front of the inner extremity of the cartilages of the true ribs to the anterior surface of the sternum. It is composed of fasciculi which pass in different directions. The *superior fasciculi* ascend obliquely, the *inferior* pass obliquely downwards, and the *middle fasciculi* horizontally. The superficial fibres of this ligament are the longest; they intermingle with the fibres of the ligaments above and below them, with those of the opposite side, and with the tendinous fibres of origin of the Pectoralis major, forming a thick fibrous membrane, which covers the surface of the sternum. This is more distinct at the lower than at the upper part.

The **Posterior Chondro-sternal Ligament** is also a part of the capsular ligament, but is less thick and distinct than the anterior; it is composed of fibres which radiate from the posterior surface of the sternal end of the cartilages of the true ribs to the posterior surface of the sternum, becoming blended with the periosteum.

The **Interarticular Chondro-sternal Ligaments.**—These are only found constantly between the second costal cartilages and the sternum. The cartilage of the *second rib* is connected with the sternum by means of an interarticular ligament, attached by one extremity to the cartilage of the second rib, and by the other extremity to the cartilage which unites the first and second pieces of the sternum. This articulation is provided with two synovial membranes. Occasionally the cartilage of the *third rib* is connected with the sternum by means of an interarticular ligament which is attached by one extremity to the cartilage of the third rib, and by the other extremity to the point of junction of the second and third pieces of the sternum. Still more rarely a similar condition is found in the other four joints of the series. In the lower two the ligament sometimes completely obliterates the cavity, so as to convert it into a synarthrosis.

The **Anterior Chondro-xiphoid.**—This is a band of ligamentous fibres, which connects the anterior surface of the seventh costal cartilage, and occasionally also that of the sixth, to the anterior surface of the ensiform appendix. It varies in length and breadth in different subjects.

The **Posterior Chondro-xiphoid** is a similar band of fibres on the internal or posterior surface, though less thick and distinct.

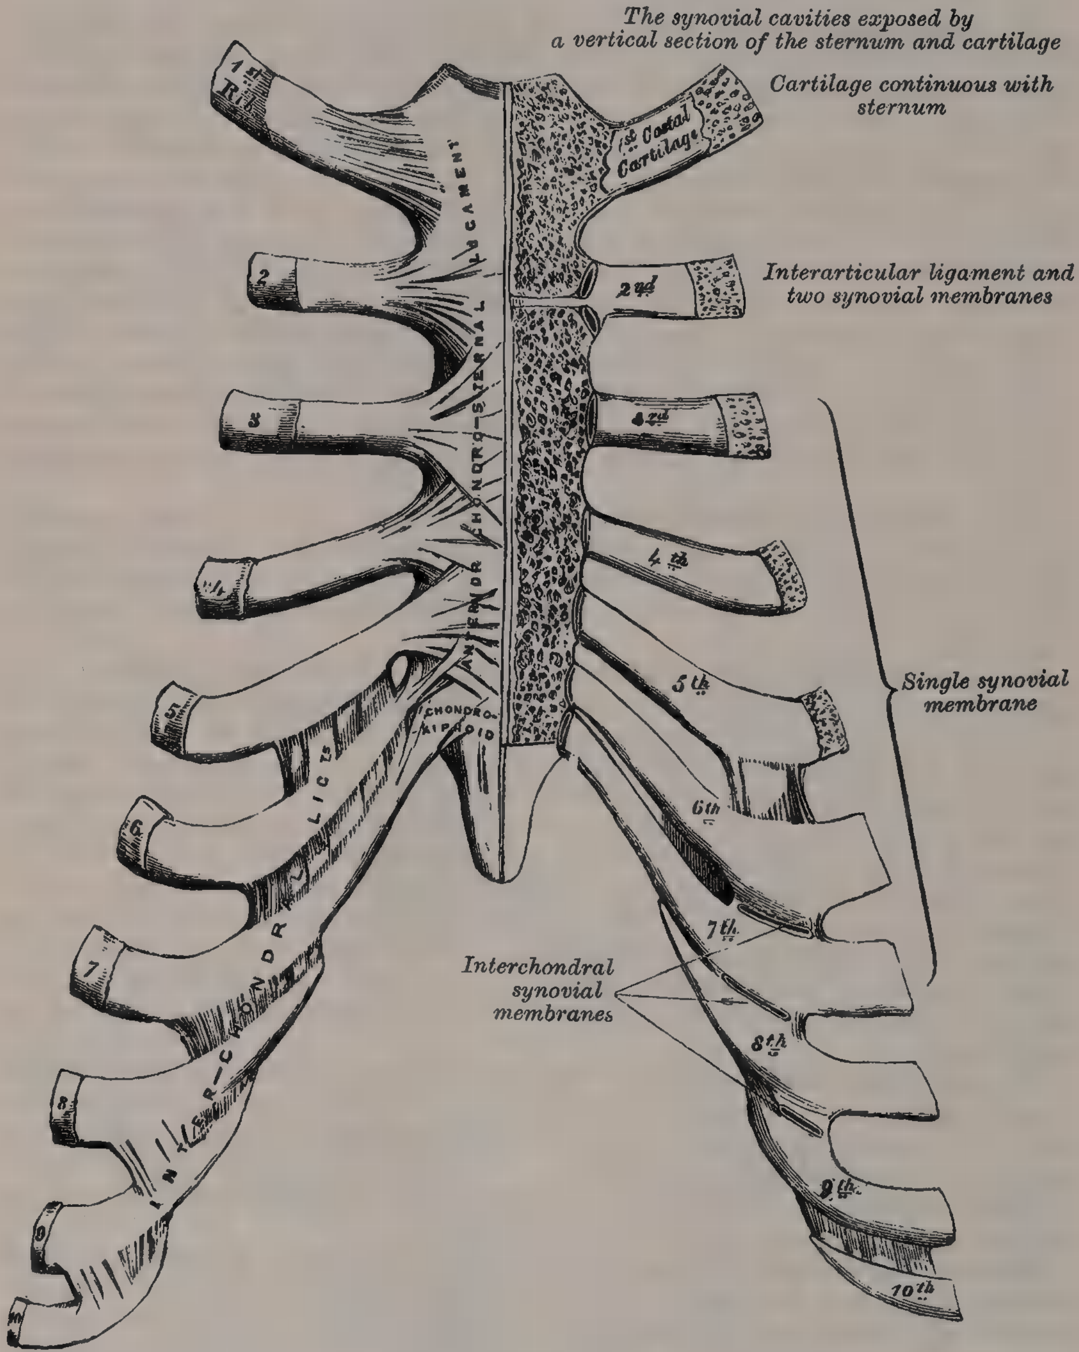
Synovial Membranes.—There is no synovial membrane between the first costal cartilage and the sternum, as this cartilage is directly continuous with the sternum. There are two synovial membranes in the articulation of the second costal cartilages to the sternum. There is generally one synovial membrane in each of the joints between the third, fourth, fifth, sixth, and seventh costal cartilages to the sternum; but it is sometimes absent in the sixth and seventh chondro-sternal joints. If an interarticular ligament exists in any of these joints, there are two synovial cavities. After middle life the articular surfaces lose their polish, become roughened, and the synovial membranes appear to be wanting. In old age, the articulations do not exist, the cartilages of most of the ribs becoming continuous with the sternum.

Actions.—The movements which are permitted in the chondro-sternal articulations are limited to elevation and depression, and these only to a slight extent.

Articulations of the Cartilages of the Ribs with each other (Interchondral) (fig. 357)

The contiguous borders of the sixth, seventh, and eighth, and sometimes the ninth and tenth, costal cartilages articulate with each other by small, smooth,

Fig. 357.—Chondro-sternal, chondro-xiphoid, and interchondral articulations. Anterior view.



oblong-shaped facets. Each articulation is enclosed in a thin *capsular ligament* lined by *synovial membrane*, and strengthened externally and internally by ligamentous fibres (*interchondral ligaments*) which pass from one cartilage to the other. Sometimes the fifth costal cartilage, more rarely that of the ninth, articulates, by its lower border, with the adjoining cartilage by a small oval facet; more frequently they are connected together by a few ligamentous fibres. Occasionally, the articular surfaces above mentioned are wanting.

Articulations of the Ribs with their Cartilages (Costo-chondral) (fig. 357)

The outer extremity of each costal cartilage is received into a depression in the sternal end of the rib, and the two are held together by the periosteum.

VII. ARTICULATIONS OF THE STERNUM

The first piece of the sternum is united to the second either by an amphiarthrodial joint—a single piece of true fibro-cartilage uniting the segments—or by a diarthrodial joint, in which each bone is clothed with a distinct lamina of cartilage, adherent on one side, free on the other. In the latter case, the cartilage covering the gladiolus is continued without interruption on to the cartilages of the second ribs. Rivington has found the diarthrodial form of joint in about one-third of the specimens examined by him, Maisonneuve more frequently. It appears to be rare in childhood, and is formed, in Rivington's opinion, from the amphiarthrodial form, by absorption. The diarthrodial joint seems to have no tendency to ossify at any age, while the amphiarthrodial is more liable to do so, and has been found ossified as early as thirty-four years of age. The two segments are further connected by an

Anterior Intersternal Ligament.
Posterior Intersternal Ligament.

The **Anterior Intersternal Ligament** consists of a layer of fibres, having a longitudinal direction; it blends with the fibres of the anterior chondro-sternal ligaments on both sides, and with the tendinous fibres of origin of the Pectoralis major. This ligament is rough, irregular, and much thicker below than above.

The **Posterior Intersternal Ligament** is disposed in a somewhat similar manner on the posterior surface of the articulation.

VIII. ARTICULATION OF THE VERTEBRAL COLUMN WITH THE PELVIS

The ligaments connecting the last lumbar vertebra with the sacrum are similar to those which connect the movable segments of the spine with each other—viz.: 1. The continuation downwards of the anterior and posterior common ligaments. 2. The intervertebral substance connecting the flattened oval surfaces of the two bones and forming an amphiarthrodial joint. 3. Ligamenta subflava, connecting the arch of the last lumbar vertebra with the posterior border of the sacral canal. 4. Capsular ligaments connecting the articulating processes and forming a double arthrodia. 5. Inter- and supra-spinous ligaments.

Two additional ligaments connect the pelvis with the spine; these are the lumbo-sacral and ilio-lumbar.

The **Lumbo-sacral Ligament** (fig. 358) is a short, thick, triangular fasciculus, which is connected above to the lower and front part of the transverse process of the last lumbar vertebra, passes obliquely outwards, and is attached below to the lateral surface of the base of the sacrum, becoming blended with the anterior sacro-iliac ligament. The ligament is in relation, in front, with the Psoas muscle.

The **Ilio-lumbar Ligament** (fig. 358), the thickened lower edge of the anterior lamella of the lumbar fascia, passes horizontally outwards from the apex of the transverse process of the last lumbar vertebra to the crest of the ilium immediately in front of the sacro-iliac articulation. It is of a triangular form, thick and narrow internally, broad and thinner externally. It is in relation, in front, with the Psoas muscle; behind, with the muscles occupying the vertebral groove; above, with the Quadratus lumborum.

IX. ARTICULATIONS OF THE PELVIS

The ligaments connecting the bones of the pelvis with each other may be divided into four groups: 1. Those connecting the sacrum and ilium. 2. Those passing between the sacrum and ischium. 3. Those connecting the sacrum and coccyx. 4. Those between the two pubic bones.

FIG. 358.—Articulations of pelvis and hip. Anterior view.

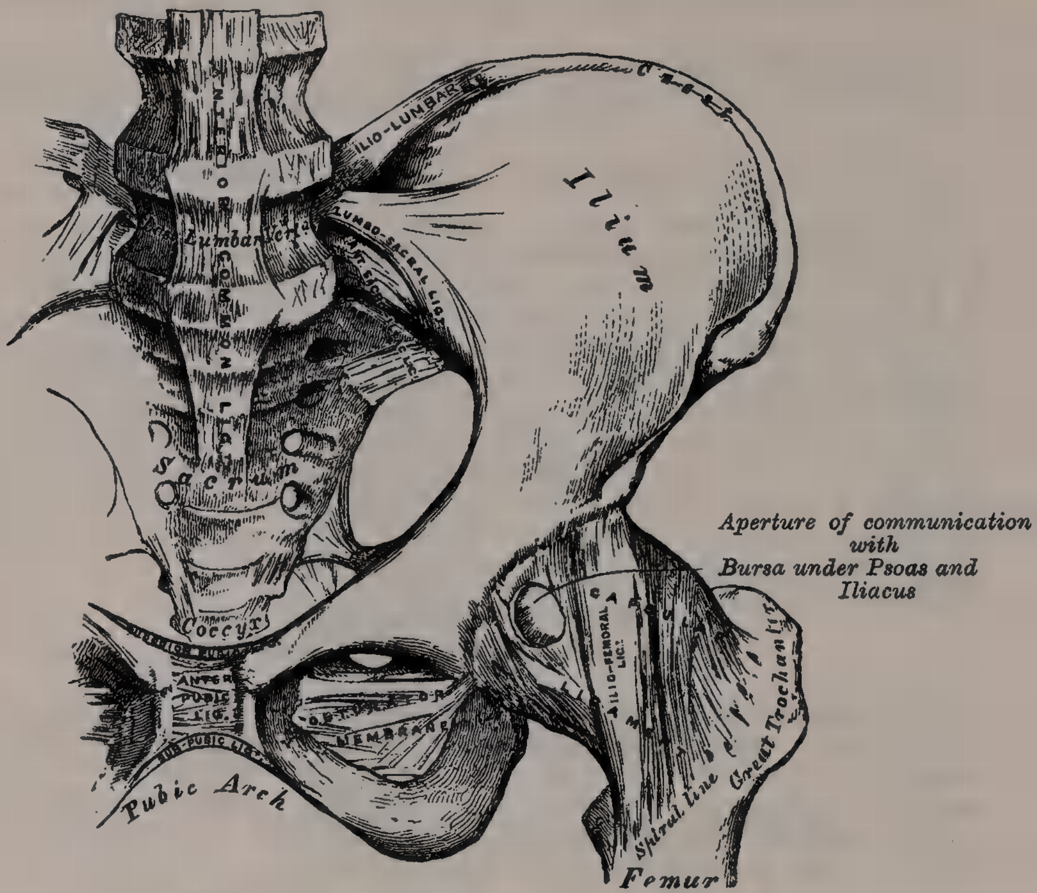


FIG. 359.—Articulations of pelvis and hip. Posterior view.

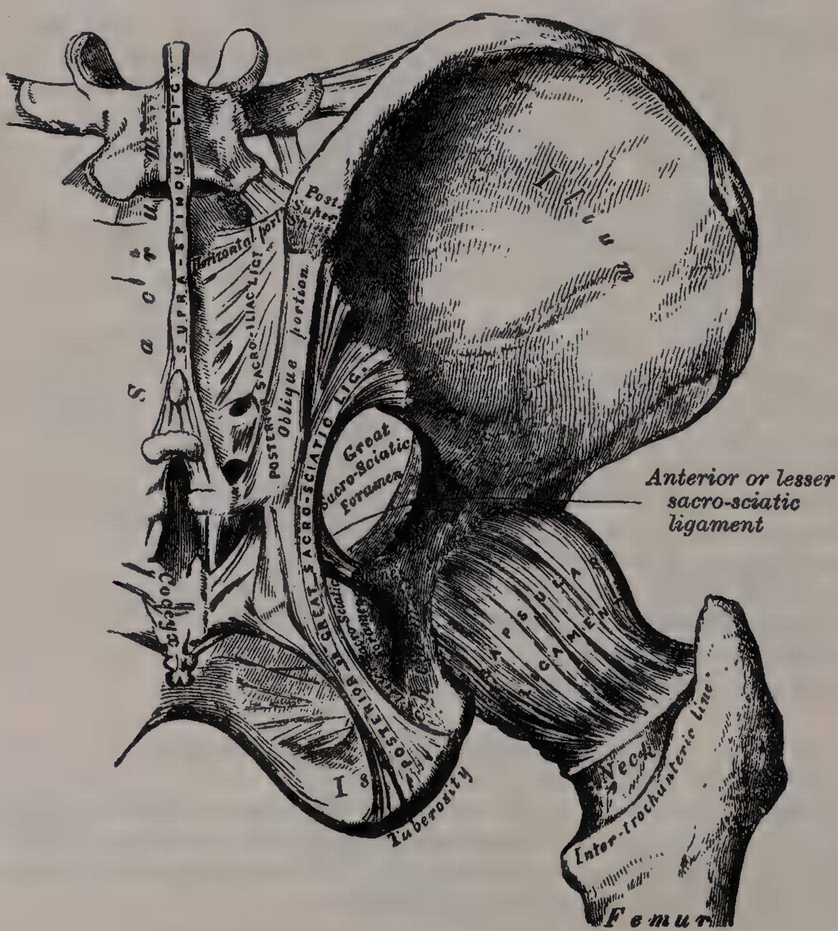


1. Articulation of the Sacrum and Ilium (Sacro-iliac joint)

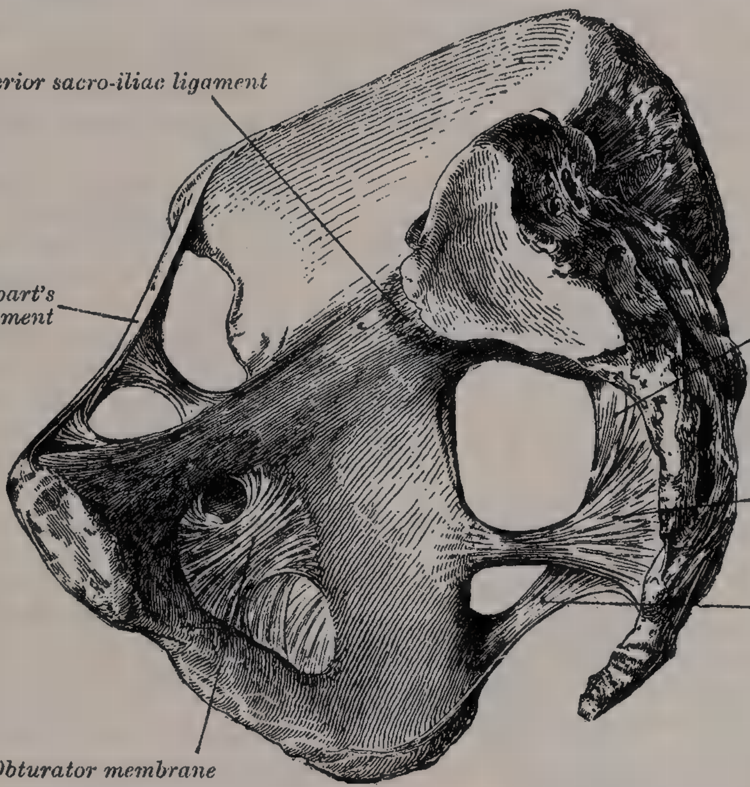
The sacro-iliac articulation is an amphiarthrodial joint, formed between the lateral surfaces of the sacrum and the ilium. The articular, ear-shaped surface of each bone is covered with a thin plate of cartilage, thicker on the sacrum than on the ilium. These are in close contact with each other, and to a certain extent united together by irregular patches of softer fibro-cartilage, and at their upper and posterior part by fine fibres of interosseous fibrous tissue. In a considerable part of their extent, especially in advanced life, they are not connected together, but are separated by a space containing a synovial-like fluid, and hence the joint presents the characters of a diarthrosis.

The ligaments connecting these surfaces are the anterior and posterior sacro-iliac.

The **Anterior Sacro-iliac Ligament** (fig. 358) consists of numerous thin bands, which connect the anterior surfaces of the sacrum and ilium.

The **Posterior Sacro-iliac** (fig. 359) is a strong interosseous ligament, situated in a deep depression between the sacrum and ilium behind, and forming the

Fig. 360.—Side view of pelvis, showing the great and lesser sacro-sciatic ligaments.



chief bond of connection between those bones. It consists of numerous strong fasciculi, which pass between the bones in various directions. Three of these are of large size; the *two superior*, nearly horizontal in direction, arise from the first and second transverse tubercles on the posterior surface of the sacrum, and are inserted into the rough, uneven surface at the posterior part of the inner surface of the ilium. The third fasciculus, oblique in direction, is attached by one extremity to the third transverse tubercle on the posterior surface of the sacrum, and by the other to the posterior superior spine of the ilium; it is sometimes called the *oblique sacro-iliac ligament.*

The position of the sacro-iliac joint is indicated by the posterior superior spine of the ilium. This process is immediately behind the centre of the articulation.

2. Ligaments passing between the Sacrum and Ischium (fig. 360)

The Great Sacro-sciatic (Posterior).
The Lesser Sacro-sciatic (Anterior).

The **Great** or **Posterior Sacro-sciatic Ligament** is situated at the lower and back part of the pelvis. It is flat, and triangular in form; narrower in the

middle than at the extremities; attached by its broad base to the posterior inferior spine of the ilium, to the fourth and fifth transverse tubercles of the sacrum, and to the lower part of the lateral margin of that bone and the coccyx. Passing obliquely downwards, outwards, and forwards, it becomes narrow and thick, but at its insertion into the inner margin of the tuberosity of the ischium, it increases in breadth, and is prolonged forwards along the inner margin of the ramus, forming what is known as the *falciform ligament*, the free concave edge of which gives attachment to the obturator fascia. One of its surfaces is turned towards the perinæum, the other towards the Obturator internus muscle. The lower border of the ligament is directly continuous with the tendon of origin of the long head of the Biceps muscle, and by many is believed to be the proximal end of this muscle, cut off by the projection of the tuberosity of the ischium.

The *posterior surface* of this ligament gives origin, by its whole extent, to fibres of the Gluteus maximus. Its *anterior surface* is united to the lesser sacro-sciatic ligament. Its *external border* forms, above, the posterior boundary of the great sacro-sciatic foramen, and, below, the posterior boundary of the lesser sacro-sciatic foramen. Its *lower border* forms part of the boundary of the perinæum. It is pierced by the coccygeal branch of the sciatic artery and coccygeal nerve.

The **Lesser** or **Anterior Sacro-sciatic Ligament**, much shorter and smaller than the preceding, is thin, triangular in form, attached by its apex to the spine of the ischium, and internally, by its broad base, to the lateral margin of the sacrum and coccyx, anterior to the attachment of the great sacro-sciatic ligament with which its fibres are intermingled.

It is in relation, *anteriorly*, with the Coccygeus muscle, to which it is closely connected; *posteriorly*, it is covered by the great sacro-sciatic ligament, and crossed by the internal pudic vessels and nerve. Its *superior border* forms the lower boundary of the great sacro-sciatic foramen; its *inferior border*, part of the lesser sacro-sciatic foramen.

These two ligaments convert the sacro-sciatic notches into foramina. The *superior* or *great* sacro-sciatic foramen is bounded, in front and above, by the posterior border of the os innominatum; behind, by the great sacro-sciatic ligament; and below, by the lesser sacro-sciatic ligament. It is partially filled up, in the recent state, by the Pyriformis muscle which passes through it. Above this muscle, the gluteal vessels and superior gluteal nerve emerge from the pelvis; and below it, the sciatic vessels and nerves, the internal pudic vessels and nerve, the inferior gluteal nerve, and the nerves to the obturator internus and quadratus femoris also make their exit from the pelvis. The *inferior* or *lesser* sacro-sciatic foramen is bounded, in front, by the tuber ischii; above, by the spine and lesser sacro-sciatic ligament; behind, by the greater sacro-sciatic ligament. It transmits the tendon of the Obturator internus muscle, its nerve, and the internal pudic vessels and nerve.

3. Articulation of the Sacrum and Coccyx

This articulation is an amphiarthrodial joint, formed between the oval surface at the apex of the sacrum, and the base of the coccyx. It is analogous to the joints between the bodies of the vertebræ, and is connected by similar ligaments. They are the

Anterior Sacro-coccygeal. Lateral Sacro-coccygeal.
Posterior Sacro-coccygeal. Interposed Fibro-cartilage.
Interarticular.

The **Anterior Sacro-coccygeal Ligament** consists of a few irregular fibres, which descend from the anterior surface of the sacrum to the front of the coccyx, becoming blended with the periosteum.

The **Posterior Sacro-coccygeal Ligament** is a flat band, of a pearly tint, which arises from the margin of the lower orifice of the sacral canal, and descends to be inserted into the posterior surface of the coccyx. This ligament completes the lower and back part of the sacral canal. Its superficial fibres are much longer than the more deeply seated. This ligament is in relation, behind, with the Gluteus maximus.

The **Lateral Sacro-coccygeal Ligaments** connect the transverse processes of the coccyx to the lower lateral angles of the sacrum.

A **Fibro-cartilage** is interposed between the contiguous surfaces of the sacrum and coccyx; it differs from that interposed between the bodies of the vertebræ in being thinner, and its central part firmer in texture. It is somewhat thicker in front and behind than at the sides. Occasionally, a synovial membrane is found when the coccyx is freely movable, which is more especially the case during pregnancy.

The **Interarticular Ligaments** are thin bands of ligamentous tissue, which unite the cornua of the two bones.

The different segments of the coccyx are connected together by an extension downwards of the anterior and posterior sacro-coccygeal ligaments, a thin annular disc of fibro-cartilage being interposed between each segment. In the adult male, all the pieces become ossified; but in the female, this does not commonly occur until a later period of life. The separate segments of the coccyx are first united, and at a more advanced age the joint between the sacrum and coccyx is obliterated.

Actions.—The movements which take place between the sacrum and coccyx, and between the different pieces of the latter bone, are forwards and backwards; they are very limited. Their extent increases during pregnancy.

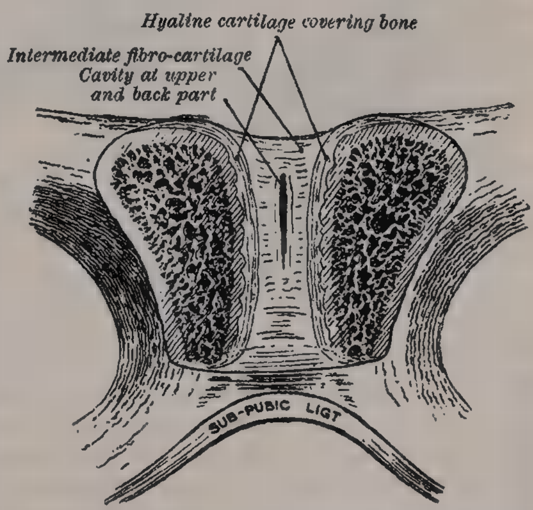
4. Articulation of the Ossa Pubis (Symphysis Pubis)

The articulation between the pubic bones is an amphiarthrodial joint, formed by the junction of the two oval articular surfaces of the ossa pubis. The ligaments of this articulation are, the

Anterior Pubic.	Superior Pubic.
Posterior Pubic.	Subpubic.
Interpubic Disc.	

The **Anterior Pubic Ligament** (fig. 358) consists of several superimposed layers, which pass across the front of the articulation. The superficial fibres pass obliquely from one bone to the other, decussating and forming an interlacement with the fibres of the aponeurosis of the External oblique and the tendon of the Rectus muscles. The deep fibres pass transversely across the symphysis, and are blended with the fibro-cartilage.

Fig. 361.—Vertical section of the symphysis pubis. Made near its posterior surface.



The **Posterior Pubic Ligament** consists of a few thin, scattered fibres, which unite the two pubic bones posteriorly.

The **Superior Pubic Ligament** is a band of fibres, which connects together the two pubic bones superiorly.

The **Subpubic Ligament** is a thick, triangular arch of ligamentous fibres, connecting together the two pubic bones below, and forming the upper boundary of the pubic arch. Above, it is blended with the interarticular fibro-cartilage; laterally, it is united with the descending rami of the ossa pubis; below, it is free, and is separated from the triangular ligament of the perinæum by the opening through which the dorsal vein of the penis passes into the pelvis. Its fibres are closely connected, and have an arched direction.

The **Interpubic Disc** connects the pubic bones in front. Each of the two bony surfaces is covered by a thin layer of hyaline cartilage, which is firmly connected to the bone by a series of nipple-like processes which accurately fit within corresponding depressions on the osseous surfaces. These opposed cartilaginous surfaces are connected together by an intermediate lamina of fibro-cartilage which varies in thickness in different subjects. It often contains a cavity in its centre, probably formed by the softening and absorption of the fibro-cartilage, since it rarely appears before the tenth year of life, and is not lined by synovial

membrane. It is larger in the female than in the male, but it is very doubtful whether it enlarges, as was formerly supposed, during pregnancy. It is most frequently limited to the upper and back part of the joint; but it occasionally reaches to the front, and may extend the entire length of the cartilage. This cavity may be easily demonstrated by making a transverse vertical section of the symphysis pubis near its posterior surface (fig. 361).

The **Obturator Membrane** is more properly regarded as analogous to the muscular fasciæ, with which it will be described.

ARTICULATIONS OF THE UPPER EXTREMITY

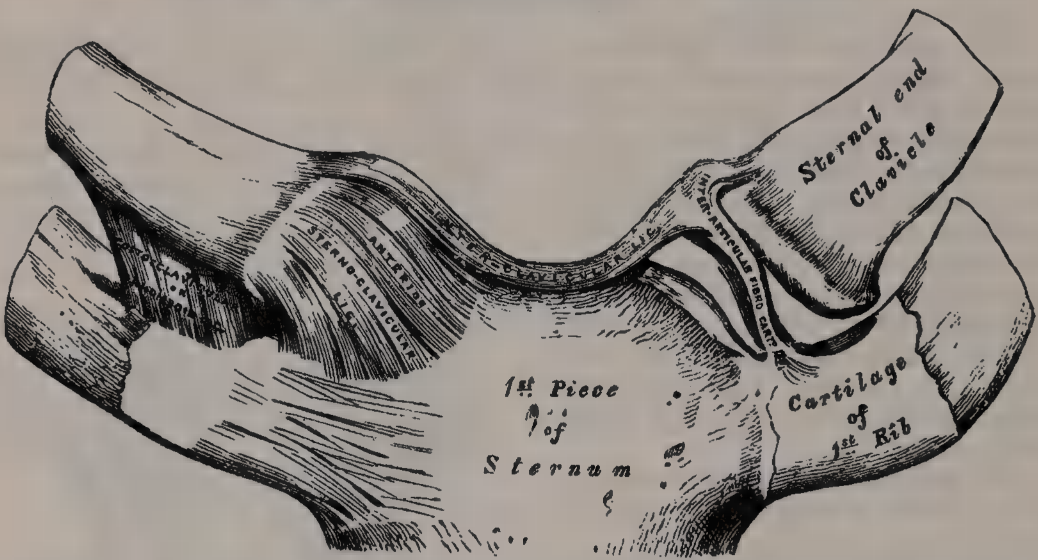
The articulations of the Upper Extremity may be arranged as follows:

I. Sterno-clavicular.
II. Acromio-clavicular.
III. Scapular ligaments.
IV. Shoulder.
V. Elbow.
VI. Radio-ulnar.
VII. Wrist.
VIII. Carpal.
IX. Carpo-metacarpal.
X. Metacarpo-phalangeal.
XI. Phalangeal.

I. STERNO-CLAVICULAR ARTICULATION (fig. 362).

The **Sterno-clavicular** is regarded by most anatomists as an arthrodial joint; but Cruveilhier considers it to be an articulation by reciprocal reception. Probably the former opinion is the correct one; the varied movements, which the joint enjoys, being due to the interposition of an interarticular fibro-cartilage between

Fig. 362.—Sterno-clavicular articulation. Anterior view.



the joint surfaces. The parts entering into its formation are the sternal end of the clavicle, the upper and lateral part of the first piece of the sternum, and the cartilage of the first rib. The articular surface of the clavicle is much larger than that of the sternum, and is invested with a layer of cartilage,* which is considerably thicker than that on the latter bone. The ligaments of this joint are, the

Capsular.
Anterior Sterno-clavicular.
Posterior Sterno-clavicular.
Interclavicular.
Costo-clavicular (rhomboid).
Interarticular fibro-cartilage.

The **Capsular Ligament** completely surrounds the articulation, consisting of fibres of varying degrees of thickness and strength. Those in front and behind are of considerable thickness, and form the anterior and posterior sterno-clavicular ligaments; but those above and below, especially in the latter situation, are thin and scanty, and partake more of the character of connective tissue than true fibrous tissue.

* According to Bruch, the sternal end of the clavicle is covered by a tissue, which is rather fibrous than cartilaginous in structure.

The **Anterior Sterno-clavicular Ligament** is a part of the capsular ligament. It is a broad band of fibres, which covers the anterior surface of the articulation, being attached, above, to the upper and front part of the inner extremity of the clavicle; and, passing obliquely downwards and inwards, is attached, below, to the front of the upper part of the first piece of the sternum. This ligament is covered by the sternal portion of the Sterno-cleido-mastoid and the integument; behind, it is in relation with the interarticular fibro-cartilage and the two synovial membranes.

The **Posterior Sterno-clavicular Ligament**, also a part of the capsular ligament, is a similar band of fibres, which covers the posterior surface of the articulation, being attached, above, to the upper and back part of the inner extremity of the clavicle; and, passing obliquely downwards and inwards, is attached, below, to the back of the upper part of the first piece of the sternum. It is in relation, in front, with the interarticular fibro-cartilage and synovial membranes; behind, with the Sterno-hyoid and Sterno-thyroid muscles.

The **Interclavicular Ligament** is a flattened band, which varies considerably in form and size in different individuals; it passes in a curved direction from the upper part of the inner extremity of one clavicle to the other, and is also attached to the upper margin of the sternum. It is in relation, in front, with the integument; behind, with the Sterno-thyroid muscles.

The **Costo-clavicular Ligament (rhomboid)** is short, flat, and strong: it is of a rhomboid form, attached, below, to the upper and inner part of the cartilage of the first rib, it ascends obliquely backwards and outwards, and is attached, above, to the rhomboid depression on the under surface of the clavicle. It is in relation, in front, with the tendon of origin of the Subclavius; behind, with the subclavian vein.

The **Interarticular Fibro-cartilage** is a flat and nearly circular disc, interposed between the articulating surfaces of the sternum and clavicle. It is attached, above, to the upper and posterior border of the articular surface of the clavicle; below, to the cartilage of the first rib, at its junction with the sternum; and by its circumference to the anterior and posterior sterno-clavicular and interclavicular ligaments. It is thicker at the circumference, especially its upper and back part, than at its centre, or below. It divides the joint into two cavities, each of which is furnished with a separate synovial membrane.

Of the two **Synovial Membranes** found in this articulation, one is reflected from the sternal end of the clavicle, over the adjacent surface of the fibro-cartilage, and cartilage of the first rib; the other is placed between the articular surface of the sternum and adjacent surface of the fibro-cartilage; the latter is the larger of the two.

Actions.—This articulation is the centre of the movements of the shoulder, and admits of a limited amount of motion in nearly every direction—upwards, downwards, backwards, forwards, as well as circumduction. When these movements take place in the joint, the clavicle in its motion carries the scapula with it, this bone gliding on the outer surface of the chest. This joint therefore forms the centre from which all movements of the supporting arch of the shoulder originate, and is the only point of articulation of this part of the skeleton with the trunk. 'The movements attendant on elevation and depression of the shoulder take place between the clavicle and the interarticular fibro-cartilage, the bone rotating upon the ligament on an axis drawn from before backwards through its own articular facet. When the shoulder is moved forwards and backwards, the clavicle, with the interarticular fibro-cartilage, rolls to and fro on the articular surface of the sternum, revolving, with a sliding movement, round an axis drawn nearly vertically through the sternum. In the circumduction of the shoulder, which is compounded of these two movements, the clavicle revolves upon the interarticular fibro-cartilage, and the latter, with the clavicle, rolls upon the sternum.'* Elevation of the clavicle is principally limited by the costo-clavicular ligament; depression, by the interclavicular ligament and interarticular fibro-cartilage. The muscles which *raise* the clavicle, as in shrugging the shoulders, are the upper fibres of the Trapezius, the Levator anguli scapulæ, the clavicular head of the Sterno-mastoid, assisted to a certain extent by the two Rhomboids, which pull the vertebral border of the Scapula backwards and

* Humphry, *On the Human Skeleton*, page 402.

upwards and so raise the clavicle. The *depression* of the clavicle is principally effected by gravity, assisted by the Subclavius, Pectoralis minor, and lower fibres of the Trapezius. It is drawn *backwards* by the Rhomboids and the middle and lower fibres of the Trapezius, and *forwards* by the Serratus magnus and Pectoralis minor.

Surface Form.—The position of the sterno-clavicular joint may be easily ascertained by feeling the enlarged sternal end of the collar-bone just external to the long, cord-like, sternal origin of the Sterno-mastoid muscle. If this muscle is relaxed by bending the head forwards, a depression just internal to the end of the clavicle, and between it and the sternum, can be felt, indicating the exact position of the joint, which is subcutaneous. When the arm hangs by the side, the cavity of the joint is V-shaped. If the arm is raised, the bones become more closely approximated, and the cavity becomes a mere slit.

Surgical Anatomy.—The strength of this joint mainly depends upon its ligaments, and it is owing to this, and to the fact that the force of the blow is usually transmitted along the long axis of the clavicle, that dislocation rarely occurs, and that the bone is broken rather than displaced. When dislocation does occur, the course which the displaced bone takes depends more upon the direction in which the violence is applied than upon the anatomical construction of the joint; it may be either forwards, backwards, or upwards. The chief point worthy of note, as regards the construction of the joint, in connection with dislocation, is the fact that, owing to the shape of the articular surfaces, and the strength of the joint mainly depending upon the ligaments, the displacement when reduced is very liable to recur, and hence it is extremely difficult to keep the end of the bone in its proper place.

II. ACROMIO-CLAVICULAR ARTICULATION (fig. 363)

The **Acromio-clavicular** is an arthrodial joint, formed between the outer extremity of the clavicle and the inner margin of the acromion process of the scapula. Its ligaments are, the

Capsular.	Interarticular Fibro-cartilage.
Superior Acromio-clavicular.	Coraco-clavicular { Trapezoid and Conoid.
Inferior Acromio-clavicular.	

The **Capsular Ligament** completely surrounds the articular margins, and is specially strong above and below, where it forms the superior and inferior acromio-clavicular ligaments. It consists of fibres arranged parallel to each other and passing between the adjacent borders of the two bones.

The **Superior Acromio-clavicular Ligament** is a quadrilateral band, a part of the capsular ligament, which covers the superior part of the articulation, extending between the upper part of the outer end of the clavicle and the adjoining part of the upper surface of the acromion. It is composed of parallel fibres, which interlace with the aponeurosis of the Trapezius and Deltoid muscles; below, it is in contact with the interarticular fibro-cartilage (when it exists) and the synovial membranes.

The **Inferior Acromio-clavicular Ligament**, also a part of the capsular ligament, is somewhat thinner than the preceding; it covers the under part of the articulation, and is attached to the adjoining surfaces of the two bones. It is in relation, above, with the synovial membranes, and in rare cases with the interarticular fibro-cartilage; below, with the tendon of the Supraspinatus.

The **Interarticular Fibro-cartilage** is frequently absent in this articulation. When it exists, it generally only partially separates the articular surfaces, and occupies the upper part of the articulation. More rarely, it completely separates the joint into two cavities.

The Synovial Membrane.—There is usually only one synovial membrane in this articulation, but when a complete interarticular fibro-cartilage exists, there are two.

The **Coraco-clavicular Ligament** serves to connect the clavicle with the coracoid process of the scapula. It does not properly belong to this articulation, but as it forms a most efficient means in retaining the clavicle in contact with the acromial process, it is usually described with it. It consists of two fasciculi, called the *trapezoid* and *conoid ligaments*.

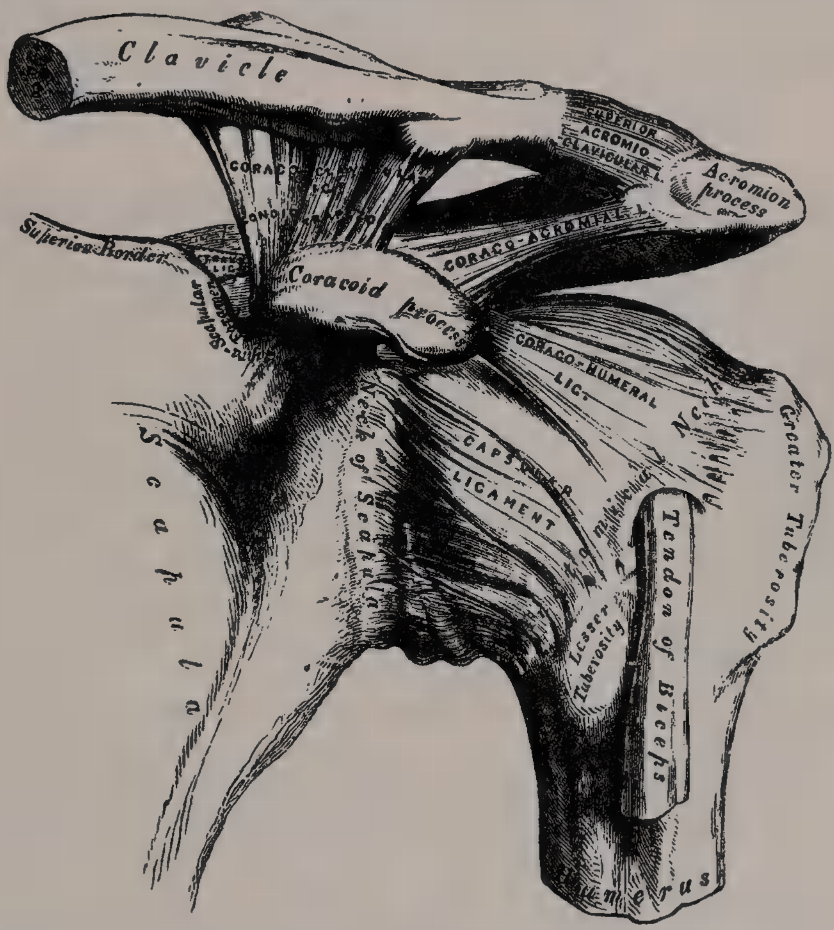
The *Trapezoid Ligament*, the anterior and external fasciculus, is broad, thin, and quadrilateral: it is placed obliquely between the coracoid process and the

clavicle. It is attached, below, to the upper surface of the coracoid process; above, to the oblique line on the under surface of the clavicle. Its anterior border is free; its posterior border is joined with the conoid ligament: the two forming, by their junction, a projecting angle.

The *Conoid Ligament*, the posterior and internal fasciculus, is a dense band of fibres, conical in form, the base being directed upwards, the summit downwards. It is attached by its apex to a rough impression at the base of the coracoid process, internal to the preceding; above, by its expanded base, to the conoid tubercle on the under surface of the clavicle, and to a line proceeding internally from it for half an inch. These ligaments are in relation, in front, with the Subclavius and Deltoid; behind, with the Trapezius. They serve to limit rotation of the scapula; the Trapezoid limiting rotation forwards, and the Conoid backwards.

Actions.—The movements of this articulation are of two kinds. 1. A gliding motion of the articular end of the clavicle on the acromium. 2. Rotation of the

Fig. 363.—The left shoulder-joint, acromio-clavicular articulation, and proper ligaments of scapula.



scapula forwards and backwards upon the clavicle, the extent of this rotation being limited by the two portions of the coraco-clavicular ligament.

The acromio-clavicular joint has important functions in the movements of the upper extremity. It has been well pointed out by Humphry, that if there had been no joint between the clavicle and scapula, the circular movement of the scapula on the ribs (as in throwing the shoulders backwards or forwards) would have been attended with a greater alteration in the direction of the shoulder than is consistent with the free use of the arm in such positions, and it would have been impossible to give a blow straight forwards with the full force of the arm; that is to say, with the combined force of the scapula, arm, and fore-arm. 'This joint,' as he happily says, 'is so adjusted as to enable either bone to turn in a hinge-like manner upon a vertical axis drawn through the other, and it permits the surfaces of the scapula, like the baskets in a roundabout swing, to look the same way in every position, or nearly so.' Again, when the whole arch formed by the clavicle and scapula rises and falls (in elevation or depression of

the shoulders), the joint between these two bones enables the scapula still to maintain its lower part in contact with the ribs.

Surface Form.—The position of the acromio-clavicular joint can generally be ascertained by the slightly enlarged extremity of the outer end of the clavicle, which causes it to project above the level of the acromion process of the scapula. Sometimes this enlargement is so considerable as to form a rounded eminence, which is easily to be felt. The joint lies in the plane of a vertical line passing up the middle of the front of the arm.

Surgical Anatomy.—The acromio-clavicular joint owes its security mainly to the coraco-clavicular ligament, which limits the amount of movement of the outer end of the clavicle either upwards, backwards, or forwards. Owing to the slanting shape of the articular surfaces of this joint, dislocation generally occurs downwards: that is to say, the acromion process of the scapula is dislocated under the outer end of the clavicle; but dislocation in the opposite direction has been described. The displacement is often incomplete, on account of the strong coraco-clavicular ligaments, which remain untorn. The same difficulty exists, as in the sterno-clavicular dislocation, in maintaining the ends of the bone in position after reduction.

III. PROPER LIGAMENTS OF THE SCAPULA (fig. 363)

The proper ligaments of the scapula are, the

Coraco-acromial. Transverse.
Spino-glenoid.

The **Coraco-acromial Ligament** is a strong triangular band, extending between the coracoid and acromial processes. It is attached, by its apex, to the summit of the acromion just in front of the articular surface for the clavicle; and by its broad base to the whole length of the outer border of the coracoid process. Its posterior fibres are directed inwards, its anterior fibres forwards and inwards. This ligament completes the vault formed by the coracoid and acromion processes for the protection of the head of the humerus. It is in relation, above, with the clavicle and under surface of the Deltoid; below, with the tendon of the Supra-spinatus muscle, a bursa being interposed. Its outer border is continuous with a dense lamina that passes beneath the Deltoid upon the tendons of the Supra- and Infra-spinatus muscles. This ligament is sometimes described as consisting of two marginal bands and a thinner intervening portion, the two bands being attached respectively to the apex and base of the coracoid process, and joining together at their attachment into the acromion process. When the Pectoralis minor is inserted, as occasionally is the case, into the capsule of the shoulder-joint instead of into the coracoid process, it passes between these two bands, and the intervening portion is then deficient.

The **Transverse** or **Suprascapular Ligament** converts the suprascapular notch into a foramen. It is a thin and flat fasciculus, narrower at the middle than at the extremities, attached by one end to the base of the coracoid process, and by the other to the inner extremity of the scapular notch. The suprascapular nerve passes through the foramen; the suprascapular vessels pass over the ligament. This ligament is sometimes ossified.

The **Spino-glenoid Ligament** consists of a band of fibres, situated on the posterior surface of the neck of the scapula and stretching from the outer border of the spine to the margin of the glenoid cavity. It forms an arch under which the suprascapular vessels and nerve pass as they enter the infraspinous fossa.

Movements of Scapula.—The scapula is capable of being moved upwards and downwards, forwards and backwards, or, by a combination of these movements, circumducted on the wall of the chest. The muscles which *raise* the scapula are the upper fibres of the Trapezius, the Levator anguli scapulæ, and the two Rhomboids; those which *depress* it are the lower fibres of the Trapezius, the Pectoralis minor, and, through the clavicle, the Subclavius. The scapula is drawn *backwards* by the Rhomboids and the middle and lower fibres of the Trapezius, and *forwards* by the Serratus magnus and Pectoralis minor, assisted, when the arm is fixed, by the Pectoralis major. The mobility of the scapula is very considerable, and greatly assists the movements of the arm at the shoulder-joint. Thus, in raising the arm from the side, the Deltoid and Supraspinatus can only lift it to a right angle with the trunk, the further elevation of the limb being effected by the Trapezius and Serratus magnus moving the scapula on the

wall of the chest. This mobility is of special importance in ankylosis of the shoulder-joint, the movements of this bone compensating to a very great extent for the immobility of the joint.

IV. SHOULDER-JOINT (fig. 363)

The **Shoulder** is an enarthrodial or ball-and-socket joint. The bones entering into its formation are the large globular head of the humerus, which is received into the shallow glenoid cavity of the scapula, an arrangement which permits of very considerable movement, while the joint itself is protected against displacement by the tendons which surround it and by atmospheric pressure. The ligaments do not maintain the joint surfaces in apposition, because when they alone remain the humerus can be separated to a considerable extent from the glenoid cavity; their use, therefore, is to limit the amount of movement. Above, the joint is protected by an arch, formed by the under surface of the coracoid and acromion processes, and the coraco-acromial ligament. The articular surfaces are covered by a layer of cartilage: that on the head of the humerus is thicker at the centre than at the circumference, the reverse being the case in the glenoid cavity. The ligaments of the shoulder are, the

Capsular. Gleno-humeral.
Coraco-humeral. Transverse Humeral.
Glenoid.*

The **Capsular Ligament** completely encircles the articulation, being attached, above, to the circumference of the glenoid cavity beyond the glenoid ligament; below, to the anatomical neck of the humerus, approaching nearer to the articular cartilage above than in the rest of its extent. It is thicker above and below than elsewhere, and is remarkably loose and lax, and much larger and longer than is necessary to keep the bones in contact, allowing them to be separated from each other more than an inch, an evident provision for that extreme freedom of movement which is peculiar to this articulation. It is strengthened, above, by the Supraspinatus; below, by the long head of the Triceps; behind, by the tendons of the Infraspinatus and Teres minor; and in front, by the tendon of the Subscapularis. The capsular ligament usually presents three openings: one anteriorly, below the coracoid process, establishes a communication between the synovial membrane of the joint and a bursa beneath the tendon of the Subscapularis muscle. The second, which is not constant, is at the posterior part, where a communication sometimes exists between the joint and a bursal sac under the tendon of the Infraspinatus muscle. The third is seen between the tuberosities of the humerus, for the passage of the long tendon of the Biceps muscle.

The **Coraco-humeral** is a broad band which strengthens the upper part of the capsular ligament. It arises from the outer border of the coracoid process, and passes obliquely downwards and outwards to the front of the great tuberosity of the humerus, being blended with the tendon of the Supraspinatus muscle. This ligament is intimately united to the capsular ligament by its hinder and lower border; but its superior and anterior border presents a free edge, which overlaps the capsular ligament.

Gleno-humeral Ligaments.—In addition to the coraco-humeral ligament, the capsular ligament is strengthened by three supplemental bands in the interior of the joint, which are named the *gleno-humeral ligaments*. These may be best seen by opening the capsule at the back of the joint and removing the head of the humerus. One of them is situated on the inner side of the joint, and passes from the inner edge of the glenoid cavity to the lower part of the lesser tuberosity of the humerus. This is sometimes known as *Flood's ligament*. A second is situated at the lower part of the joint, and passes from the under edge of the glenoid cavity to the under part of the anatomical neck of the humerus, and is known as *Schlemm's ligament*. A third is situated at the upper part of the joint, and is fixed above to the apex of the glenoid

* The long tendon of origin of the Biceps muscle also acts as one of the ligaments of this joint. See the observations on page 351, on the function of the muscles passing over more than one joint.

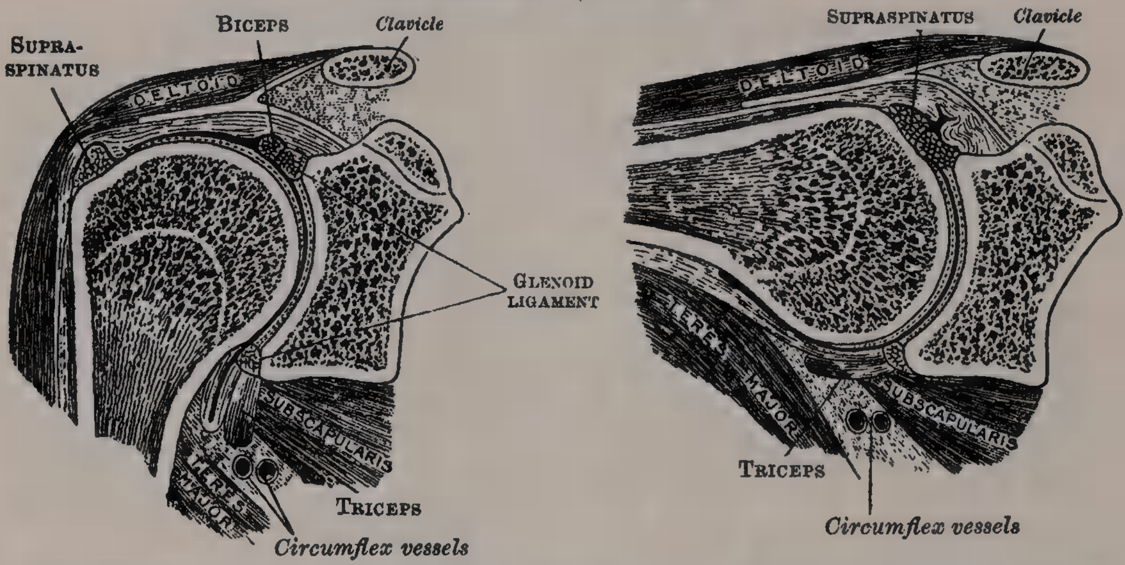
cavity close to the root of the coracoid process, and passing downwards along the inner edge of the tendon of the Biceps, is attached below to the lesser tuberosity of the humerus. In addition to these, the capsule is strengthened externally on its anterior aspect by two bands derived from the tendons of the Pectoralis major and Teres major respectively.

The Transverse Humeral Ligament.—This is a broad band of fibrous tissue passing from the lesser to the greater tuberosity of the humerus, and always limited to that portion of the bone which lies above the epiphysial line. It converts the bicipital groove into an osseo-aponeurotic canal, and is the analogue of the strong process of bone which connects the summits of the two tuberosities in the musk ox.

The **Glenoid Ligament** is a fibro-cartilaginous rim attached round the margin of the glenoid cavity. It is triangular on section, the thickest portion being fixed to the circumference of the cavity, the free edge being thin and sharp. It is continuous above with the long tendon of the Biceps muscle, which gives off two fasciculi, to blend with the fibrous tissue of the ligament. This ligament deepens the cavity for articulation, and protects the edges of the bone.

The **Synovial Membrane** is reflected from the margin of the glenoid cavity over the glenoid ligament which surrounds it; it is then reflected over the

FIG. 364.—Vertical sections through the shoulder-joint, the arm being vertical and horizontal. (After Henle.)



internal surface of the capsular ligament, and covers the lower part and sides of the anatomical neck of the humerus as far as the cartilage covering the head of the bone. The long tendon of the Biceps muscle which passes through the capsular ligament is enclosed in a tubular sheath of synovial membrane, which is reflected upon it at the point where it perforates the capsule, and is continued around it as far as the summit of the glenoid cavity. The tendon of the Biceps thus traverses the articulation, but it is not contained in the interior of the synovial cavity.

Bursæ.—The bursæ in the neighbourhood of the shoulder-joint are the following: (1) A constant bursa is situated between the tendon of the Subscapularis muscle and the capsule of the joint, which communicates with the synovial membrane through an opening in the front of the capsular ligament: (2) a bursa is sometimes found between the tendon of the Infraspinatus and the capsule, which occasionally communicates with the joint: (3) a large bursa exists between the under surface of the Deltoid muscle and the capsule, which does not communicate with the joint; this bursa is prolonged under the acromion process and coraco-acromial ligament, and intervenes between these structures and the capsule of the joint: (4) a large bursa mucosa is situated on the summit of the acromion: (5) a bursa is frequently found between the coracoid process and the capsule of the joint: (6) there is a bursa beneath the Coraco-brachialis muscle; (7) one between the Teres major and the long

head of the Triceps; (8) one in front of, and another behind the tendon of the Latissimus dorsi.

The *Muscles* in relation with the joint are, above, the Supraspinatus; below, the long head of the Triceps; in front, the Subscapularis; behind, the Infraspinatus and Teres minor; within, the long tendon of the Biceps. The Deltoid is placed most externally, and covers the articulation on its outer side, as well as in front and behind.

The *Arteries* supplying the joint are articular branches of the anterior and posterior circumflex, and suprascapular.

The *Nerves* are derived from the circumflex and suprascapular.

Actions.—The shoulder-joint is capable of movement in every direction, forwards, backwards, abduction, adduction, circumduction, and rotation. The humerus is drawn *forwards* by the Pectoralis major, anterior fibres of the Deltoid, Coraco-brachialis, and by the Biceps, when the forearm is flexed; *backwards* by the Latissimus dorsi, Teres major, posterior fibres of the Deltoid, and by the Triceps when the forearm is extended; it is *abducted* (elevated) by the Deltoid and Supraspinatus; it is *adducted* (depressed) by the Subscapularis, Pectoralis major, Latissimus dorsi, and Teres major, and by the weight of the limb; it is *rotated outwards* by the Infraspinatus and Teres minor; and it is *rotated inwards* by the Subscapularis, Latissimus dorsi, Teres major, and Pectoralis major.

The most striking peculiarities in this joint are: 1. The large size of the head of the humerus in comparison with the depth of the glenoid cavity, even when supplemented by the glenoid ligament. 2. The looseness of the capsule of the joint. 3. The intimate connection of the capsule with the muscles attached to the head of the humerus. 4. The peculiar relation of the Biceps tendon to the joint.

It is in consequence of the relative size of the two articular surfaces, and the looseness of the capsular ligament, that the joint enjoys such free movement in every possible direction. When these movements of the arm are arrested in the shoulder-joint by the contact of the bony surfaces, and by the tension of the corresponding fibres of the capsule, together with that of the muscles acting as accessory ligaments, they can be carried considerably farther by the movements of the scapula, involving, of course, motion at the acromio- and sterno-clavicular joints. These joints are therefore to be regarded as accessory structures to the shoulder-joint (see page 377). The extent of these movements of the scapula is very considerable, especially in extreme elevation of the arm, which movement is best accomplished when the arm is thrown somewhat forwards and outwards, because the margin of the head of the humerus is by no means a true circle; its greatest diameter is from the bicipital groove, downwards, inwards, and backwards, and the greatest elevation of the arm can be obtained by rolling its articular surface in the direction of this measurement. The great width of the central portion of the humeral head also allows of very free horizontal movement when the arm is raised to a right angle, in which movement the arch formed by the acromion, the coracoid process, and the coraco-acromial ligament, constitutes a sort of supplemental articular cavity for the head of the bone.

The looseness of the capsule is so great that the arm will fall about an inch from the scapula when the muscles are dissected from the capsular ligament, and an opening made in it to counteract the atmospheric pressure. The movements of the joint, therefore, are not regulated by the capsule so much as by the surrounding muscles and by the pressure of the atmosphere, an arrangement which 'renders the movements of the joint much more easy than they would otherwise have been, and permits a swinging, pendulum-like vibration of the limb when the muscles are at rest' (Humphry). The fact, also, that in all ordinary positions of the joint the capsule is not put on the stretch, enables the arm to move freely in all directions. Extreme movements are checked by the tension of appropriate portions of the capsule, as well as by the interlocking of the bones. Thus it is said that 'abduction is checked by the contact of the great tuberosity with the upper edge of the glenoid cavity; adduction by the tension of the coraco-humeral ligament' (Beaunis et Bouchard). Cleland * maintains that the

* *Journ. of Anat. and Phys.* No. 1, 1886, p. 85.

limitations of movement at the shoulder-joint are due to the structure of the joint itself, the glenoid ligament fitting, in different positions of the elevated arm, into the anatomical neck of the humerus.

Cathcart * has pointed out that in abducting the arm and raising it above the head, the scapula rotates throughout the whole movement with the exception of a short space at the beginning and at the end; that the humerus moves on the scapula not only from the hanging to the horizontal position but also in passing upwards as it approaches the vertical above; that the clavicle moves not only during the second half of the movement but in the first as well, though to a less extent—i.e. the scapula and clavicle are concerned in the first stage as well as in the second; and that the humerus is partly involved in the second as well as chiefly in the first.

The intimate union of the tendons of the four short muscles with the capsule converts these muscles into elastic and spontaneously acting ligaments of the joint, and it is regarded as being also intended to prevent the folds into which all portions of the capsule would alternately fall in the varying positions of the joint from being driven between the bones by the pressure of the atmosphere.

The peculiar relations of the Biceps tendon to the shoulder-joint appear to subserve various purposes. In the first place, by its connection with both the shoulder and elbow the muscle harmonises the action of the two joints, and acts as an elastic ligament in all positions, in the manner previously adverted to (see page 351). Next, it strengthens the upper part of the articular cavity, and prevents the head of the humerus from being pressed up against the acromion process, when the Deltoid contracts, instead of forming the centre of motion in the glenoid cavity. By its passage along the bicipital groove it assists in rendering the head of the humerus steady in the various movements of the arm. When the arm is raised from the side it assists the Supra- and Infra-spinatus in rotating the head of the humerus in the glenoid cavity. It also holds the head of the bone firmly in contact with the glenoid cavity, and prevents its slipping over its lower edge, or being displaced by the action of the Latissimus dorsi and Pectoralis major, as in climbing and many other movements.

Surface Form.—The direction and position of the shoulder-joint may be indicated by a line drawn from the middle of the coraco-acromial ligament, in a curved direction, with its convexity inwards, to the innermost part of that portion of the head of the humerus which can be felt in the axilla when the arm is forcibly abducted from the side. When the arm hangs by the side, not more than one-third of the head of the bone is in contact with the glenoid cavity, and three-quarters of its circumference is in front of a vertical line drawn from the anterior border of the acromion process.

Surgical Anatomy.—Owing to the construction of the shoulder-joint and the freedom of movement which it enjoys, as well as in consequence of its exposed situation, it is more frequently dislocated than any other joint in the body. Dislocation occurs when the arm is abducted, and when, therefore, the head of the humerus presses against the lower and front part of the capsule, which is the thinnest and least supported part of the ligament. The rent in the capsule almost invariably takes place in this situation, and through it the head of the bone escapes, so that the dislocation in most instances is primarily subglenoid. The head of the bone does not usually remain in this situation, between the tendons of the Subscapularis and the Triceps, but generally assumes some other position, which varies according to the direction and amount of force producing the dislocation and the relative strength of the muscles in front and behind the joint. In consequence of the muscles at the back being stronger than those in front, and especially on account of the long head of the Triceps preventing the bone passing backwards, dislocation forwards is much more common than backwards. The most frequent position which the head of the humerus ultimately assumes is on the front of the neck of the scapula, beneath the coracoid process, and hence named subcoracoid dislocation. Occasionally, in consequence probably of a greater amount of force being brought to bear on the limb, the head is driven farther inwards, and rests on the upper part of the front of the chest, beneath the clavicle (subclavicular). Sometimes it remains in the position in which it was primarily displaced, resting on the axillary border of the scapula (subglenoid), and rarely it passes backwards and remains in the infraspinatus fossa, beneath the spine (subspinous).

The shoulder-joint is sometimes the seat of all those inflammatory affections, both acute and chronic, which attack joints, though perhaps less frequently than some other articulations of equal size and importance. Acute synovitis may result from injury, rheumatism, or pyæmia, or may follow secondarily on acute epiphysitis of infants. It is attended with

* *Journ. of Anat. and Phys.* vol. xviii. 1884.

effusion into the joint, and when this occurs the capsule is evenly distended, and the contour of the joint rounded. Special projections may occur at the site of the openings in the capsular ligament. Thus a swelling may appear just in front of the joint, internal to the lesser tuberosity, from effusion into the bursa beneath the Subscapularis muscle; or, again, a swelling which is sometimes bilobed may be seen in the interval between the Deltoid and Pectoralis major muscles, from effusion into the diverticulum, which runs down the bicipital groove with the tendon of the Biceps. The effusion into the synovial membrane can be best ascertained by examination from the axilla, where a soft, elastic, fluctuating swelling can usually be felt. In cases of septic synovitis, where incision is required, the opening should be made in front, over the most prominent point of the swelling. After the pus has been evacuated, a counter-opening should be made behind, so as to ensure efficient drainage.

Tuberculous arthritis not infrequently attacks the shoulder-joint, and may lead to total destruction of the articulation, when ankylosis may result, or long-protracted suppuration may necessitate excision. This joint is also one of those which is most liable to be the seat of osteo-arthritis, and may also be affected in gout and rheumatism; or in locomotor ataxy, when it becomes the seat of Charcot's disease.

Ankylosis is occasionally met with in the shoulder-joint, as the result of destructive changes. The ankylosis usually takes place with the arm in a dependent position, and any attempt to raise the arm is attended by a rotation of the scapula on the wall of the chest.

Excision of the shoulder-joint may be required in cases of arthritis (especially the tuberculous form) which have gone on to destruction of the articulation; in compound dislocations and fractures, particularly those arising from gunshot injuries, in which there has been extensive injury to the head of the bone; in some cases of old unreduced dislocation, where there is much pain; and possibly in some few cases of growth connected with the upper end of the bone. The operation is best performed by making an incision from the middle of the coraco-acromial ligament down the arm for about three inches: this will expose the bicipital groove and the tendon of the Biceps, which may be either divided or hooked out of the way, according as to whether it is implicated in the disease or not. The capsule is freely opened, and the muscles attached to the greater and lesser tuberosities of the humerus divided. The head of the bone can then be thrust out of the wound and sawn off; or divided with a narrow saw *in situ* and subsequently removed. The section should be made, if possible, just below the articular surface, so as to leave the bone as long as possible. The glenoid cavity must then be examined, and gouged if carious.

V. ELBOW-JOINT (figs. 365, 366)

The **Elbow** is a *ginglymus* or hinge-joint. The bones entering into its formation are the trochlea of the humerus, which is received into the greater sigmoid cavity of the ulna, and admits of the movements peculiar to this joint, viz. flexion and extension; while the lesser, or radial, head of the humerus articulates with the cup-shaped depression on the head of the radius; the circumference of the head of the radius articulates with the lesser sigmoid cavity of the ulna, allowing of the movement of rotation of the radius on the ulna, the chief action of the superior radio-ulnar articulation. The articular surfaces are covered with a thin layer of cartilage, and connected together by a capsular ligament of unequal thickness, being especially thickened on its two sides, and, to a less extent, in front and behind. These thickened portions are usually described as distinct ligaments under the following names:

Anterior.	Internal Lateral.
Posterior.	External Lateral.

The **Anterior Ligament** (fig. 365) is a broad and thin fibrous layer, which covers the anterior surface of the joint. It is attached to the front of the internal epicondyle and to the front of the humerus immediately above the coronoid and radial fossæ; below, to the anterior surface of the coronoid process of the ulna and orbicular ligament, being continuous on each side with the lateral ligaments. Its superficial fibres pass obliquely from the inner condyle of the humerus outwards to the orbicular ligament. The middle fibres, vertical in direction, pass from the upper part of the coronoid depression and become partly blended with the preceding, but mainly inserted into the anterior surface of the coronoid process. The deep or transverse set intersects these at right angles. This ligament is in relation, in front, with the Brachialis anticus, except at its outermost part; behind, with the synovial membrane.

The **Posterior Ligament** (fig. 366) is thin and membranous, and consists of transverse and oblique fibres. Above, it is attached to the humerus immediately behind the capitellum and close to the inner margin of the trochlear surface, to the lateral margins of the olecranon fossa, and to the back of the external condyle some little distance from the trochlear surface. Below, it is fixed to the upper and outer aspects of the olecranon process, to the posterior part of the orbicular ligament, and to the ulna behind the lesser sigmoid cavity. The transverse fibres form a strong band which bridges across the olecranon fossa; under cover of this band a pouch of synovial membrane and a pad of fat project into the upper part of the fossa when the joint is extended In the fat are a few scattered fibrous bundles, which pass from the deep aspect of the transverse band to the upper part of the fossa. This ligament is in relation, behind, with the tendon of the Triceps and the Anconeus; in front, with the synovial membrane.

Fig. 365.—Left elbow-joint, showing anterior and internal ligaments.

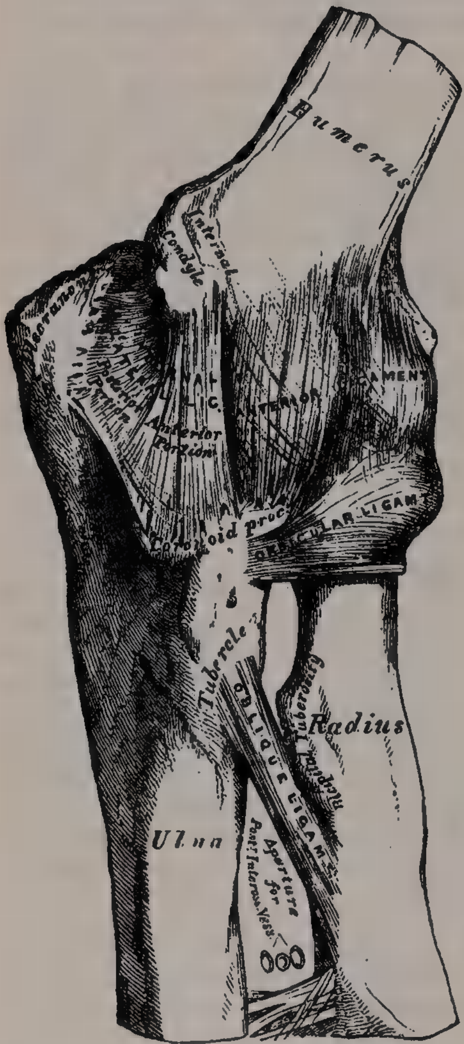


Fig. 366.—Left elbow-joint, showing posterior and external ligaments.

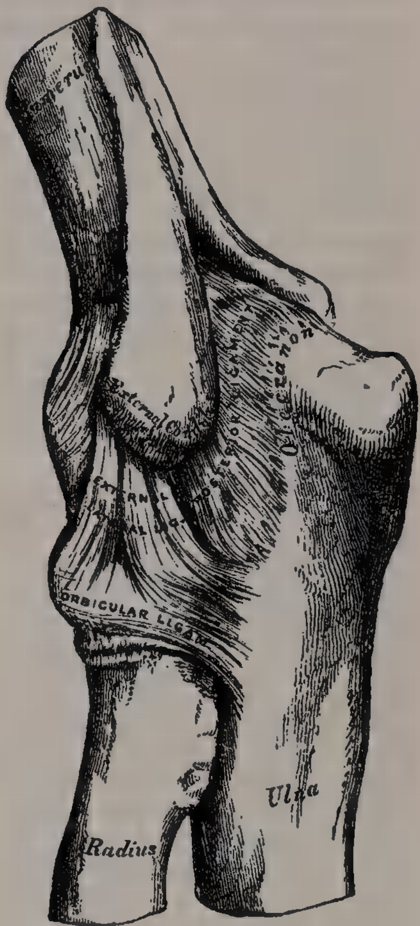

The **Internal Lateral Ligament** (fig. 365) is a thick triangular band consisting of two portions, an anterior and posterior, united by a thinner intermediate portion. The *anterior portion*, directed obliquely forwards, is attached, above, by its apex, to the front part of the internal epicondyle of the humerus; and, below, by its broad base, to the inner margin of the coronoid process. The *posterior portion*, also of triangular form, is attached, above, by its apex, to the lower and back part of the internal epicondyle; below, to the inner margin of the olecranon. Between these two bands a few intermediate fibres descend from the internal epicondyle to blend with a *transverse band* of ligamentous tissue which bridges across the notch between the olecranon and coronoid processes. This ligament is in relation, internally, with the Triceps and Flexor carpi ulnaris muscles, and the ulnar nerve, and gives origin to part of the Flexor sublimis digitorum.

The **External Lateral Ligament** (fig. 366) is a short and narrow fibrous band, less distinct than the internal, attached, above, to a depression below the external epicondyle of the humerus; below, to the orbicular ligament, some of its most posterior fibres passing over that ligament, to be inserted into the outer margin of the ulna. This ligament is intimately blended with the tendon of origin of the Supinator brevis muscle.

The **Synovial Membrane** is very extensive. It extends from the margin of the articular surface of the humerus, and lines the coronoid and olecranon fossæ on that bone: from these points, it is reflected over the anterior, posterior, and lateral ligaments; and forms a pouch between the lesser sigmoid cavity, the internal surface of the orbicular ligament, and the circumference of the head of the radius. Projecting into the cavity is a crescentic fold of synovial membrane, between the radius and ulna, suggesting the division of the joint into two: one the humero-radial, the other the humero-ulnar.

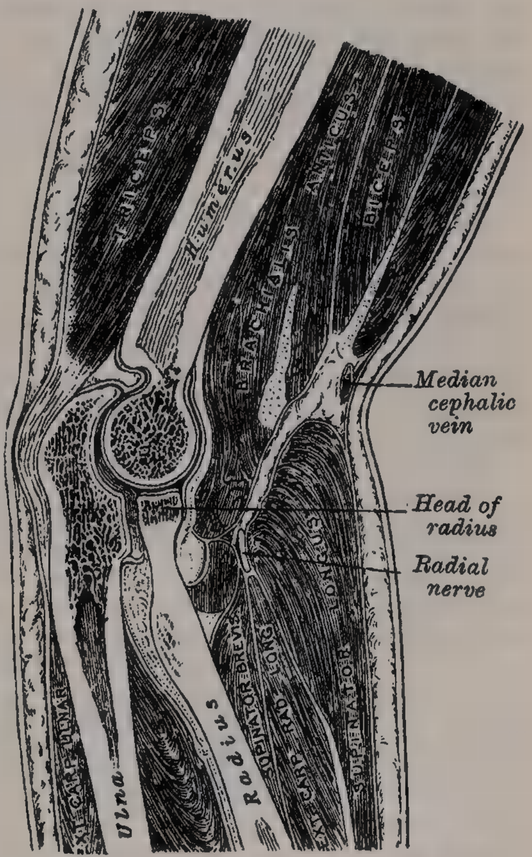

FIG. 367.—Sagittal section of the right elbow-joint, taken somewhat obliquely and seen from the radial aspect. (After Braune.)

Between the capsular ligament and the synovial membrane are three masses of fat: one, the largest, over the olecranon fossa, which is pressed into the fossa by the Triceps during flexion; a second, over the coronoid fossa; and a third over the radial fossa. These are pressed into their respective fossæ during extension.

The *Muscles* in relation with the joint are, in front, the Brachialis anticus; behind, the Triceps and Anconeus; externally, the Supinator brevis, and the common tendon of origin of the Extensor muscles; internally, the common tendon of origin of the Flexor muscles, and the Flexor carpi ulnaris, with the ulnar nerve (fig. 367).

The *Arteries* supplying the joint are derived from the anastomosis between the superior profunda, inferior profunda, and anastomotic branches of the brachial, with the anterior, posterior, and interosseous recurrent branches of the ulnar, and the recurrent branch of the radial. These vessels form a complete chain of inosculation around the joint.

The *Nerves* are derived from the ulnar, as it passes between the internal condyle and the olecranon; a filament from the musculo-cutaneous (Rüdinger), and two from the median (Macalister).

Actions.—The elbow-joint comprises three different portions, viz.: the joint between the ulna and humerus, that between the head of the radius and the humerus, and the superior radio-ulnar articulation, described below. All these articular surfaces are invested by a common synovial membrane, and the movements of the whole joint should be studied together. The combination of the movements of flexion and extension of the forearm with those of pronation and supination of the hand, which is ensured by the two being performed at the same joint, is essential to the accuracy of the various minute movements of the hand.

The portion of the joint between the ulna and humerus is a simple hinge-joint, and allows of movements of flexion and extension only. Owing to the obliquity of the trochlear surface of the humerus, this movement does not take place in a straight line; so that when the forearm is extended and supinated, the axes of the arm and forearm are not in the same line, the upper portion of the

limb forming an angle with the lower, and the hand, with the forearm, being directed outwards. During flexion, on the other hand, the forearm and the hand tend to approach the middle line of the body, and thus enable the hand to be easily carried to the face. The shape of the trochlear surface of the humerus, with its prominences and depressions, accurately adapted to the great sigmoid cavity, prevents any lateral movement. *Flexion* is produced by the action of the Biceps and Brachialis anticus, assisted by the muscles arising from the internal condyle of the humerus and the Supinator longus; *extension*, by the Triceps and Anconeus, assisted by the Extensors of the wrist and by the Extensor communis digitorum and Extensor minimi digiti.

The joint between the head of the radius and the capitellum or radial head of the humerus is an arthrodial joint. The bony surfaces would of themselves constitute an enarthrosis and allow of movement in all directions, were it not for the orbicular ligament by which the head of the radius is bound down firmly to the sigmoid cavity of the ulna, and which prevents any separation of the two bones laterally. It is to the same ligament that the head of the radius owes its security from dislocation, which would otherwise occur, as a consequence of the shallowness of the cup-like surface on the head of the radius. In fact, but for this ligament, the tendon of the Biceps would be liable to pull the head of the radius out of the joint.* In complete extension, the head of the radius glides so far backwards that its edge is plainly felt at the back of the articulation. Flexion and extension of the elbow-joint are limited by the tension of the structures on the front and back of the joint; the limitation of flexion being also aided by the soft structures of the arm and forearm coming into contact.

In combination with any position of flexion or extension, the head of the radius can be rotated in the upper radio-ulnar joint, carrying the hand with it. The hand is directly articulated to the lower surface of the radius only, and the concave or sigmoid surface on the lower end of the radius travels round the lower end of the ulna. The latter bone is excluded from the wrist-joint by the inter-articular fibro-cartilage. Thus, rotation of the head of the radius round an axis which passes through the centre of the radial head of the humerus imparts circular movement to the hand through a very considerable arc.

Surface Form.—If the forearm be slightly flexed on the arm, a curved crease or fold with its convexity downwards may be seen running across the front of the elbow, extending from one condyle to the other. The centre of this fold is some slight distance above the line of the joint. The position of the radio-humeral portion of the joint can be at once ascertained by feeling for a slight groove or depression between the head of the radius and the capitellum of the humerus at the back of the articulation.

Surgical Anatomy.—From the great breadth of the joint, and the manner in which the articular surfaces are interlocked, and also on account of the strong lateral ligaments and the support which the joint derives from the mass of muscles attached to each condyle of the humerus, lateral displacement of the bones is very uncommon; whereas antero-posterior dislocation, on account of the shortness of the antero-posterior diameter, the weakness of the anterior and posterior ligaments, and the want of support of muscles, occurs much more frequently. Dislocation backwards takes place when the forearm is in a position of extension, and forwards when in a position of flexion. For, in the former position, that of extension, the coronoid process is not interlocked into the coronoid fossa, and loses its grip to a certain extent, whereas the olecranon process is in the olecranon fossa, and entirely prevents displacement forwards. On the other hand, during flexion, the coronoid process is in the coronoid fossa, and prevents dislocation backwards, while the olecranon loses its grip and is not so efficient, as during extension, in preventing a forward displacement. When lateral dislocation does take place it is generally incomplete.

Dislocation of the elbow-joint is of common occurrence in children, far more common than dislocation of any other articulation, for, as a rule, fracture of a bone more frequently takes place, under the application of any severe violence, in young persons, than dislocation. In lesions of this joint there is often very great difficulty in ascertaining the exact nature of the injury.

The elbow-joint is occasionally the seat of acute synovitis. The joint cavity then becomes distended with fluid, the bulging showing itself principally around the olecranon process, that is to say, on its inner and outer sides and above, in consequence of the laxness of the posterior ligament. Sometimes a well-marked triangular projection may be seen on the outer side of the olecranon, from bulging of the synovial membrane

---

* Humphry, *op. cit.* p. 419.

beneath the Anconeus muscle. Again, there is often some swelling just above the head of the radius, in the line of the radio-humeral joint. There is not generally much swelling at the front of the joint, though sometimes deep-seated fulness beneath the Brachialis anticus may be noted. When suppuration occurs the abscess usually points at one or other border of the Triceps muscle; occasionally the pus discharges itself in front, near the insertion of the Brachialis anticus muscle. In cases of suppurative synovitis, incisions should be made into the joint on either side of the olecranon, care being observed on the inner side to avoid wounding the ulnar nerve. Chronic synovitis, usually of tuberculous origin, is of common occurrence in the elbow-joint: under these circumstances the forearm tends to assume the position of semiflexion, which is that of greatest ease and relaxation of ligaments. It should be borne in mind, that should ankylosis occur in this or the extended position, the limb will not be nearly so useful as if ankylosed in a position of rather less than a right angle. Loose cartilages are sometimes met with in the elbow-joint, not so commonly, however, as in the knee; nor do they, as a rule, give rise to such urgent symptoms, and rarely require operative interference. The elbow-joint is also sometimes affected with osteo-arthritis, but this affection is less common in this articulation than in some other of the larger joints.

Excision of the elbow is principally required for three conditions—viz. tuberculous arthritis, injury and its results, and faulty ankylosis—but may be necessary for some other rarer conditions, such as disorganising arthritis after pyæmia, unreduced dislocations, and osteo-arthritis. The results of the operation are, as a rule, more favourable than those of excision of any other joint, and it is one, therefore, that the surgeon should never hesitate to perform, especially in the first three of the conditions mentioned above. The operation is best performed by a single vertical incision down the back of the joint; a transverse incision, over the outer condyle, being added if the parts are much thickened and fixed. A straight incision is made about four inches long, the mid-point of which is on a level with and a little to the inner side of the tip of the olecranon. This incision is made down to the bone, through the substance of the Triceps muscle. The operator with the point of his knife, and guarding the soft parts with his thumb-nail, separates them from the bone. In doing this there are two structures which he should carefully avoid: the ulnar nerve, which lies parallel to his incision, but a little internal, as it courses down between the internal condyle and the olecranon process; and the prolongation of the Triceps into the deep fascia of the forearm over the Anconeus muscle. Having cleared the bones and divided the lateral and posterior ligaments, the forearm is strongly flexed and the ends of the bones turned out and sawn off. The turning out of the ends of the bones is rendered easier by first cutting off the olecranon process with a pair of cutting bone forceps. The section of the humerus should be through the base of the condyles, that of the ulna and radius should be just below the level of the lesser sigmoid cavity of the ulna and the neck of the radius. In this operation the object is to obtain such union as shall allow free motion of the bones of the forearm; and, therefore, passive motion must be commenced early—that is to say, about the tenth day.

VI. RADIO-ULNAR ARTICULATIONS

The articulation of the radius with the ulna is effected by ligaments, which connect together both extremities as well as the shafts of these bones. They may, consequently, be subdivided into three sets: 1. The superior radio-ulnar articulation; 2. the middle radio-ulnar union; and, 3. the inferior radio-ulnar articulation.

1. Superior Radio-ulnar Articulation

This articulation is a trochoid or pivot-joint. The parts entering into its formation are the inner side of the circumference of the head of the radius and the lesser sigmoid cavity of the ulna. Its only ligament is the *annular* or *orbicular*.

The **Orbicular Ligament** (fig. 366) is a strong band of ligamentous fibres, which surrounds the head of the radius, and retains it in firm connection with the lesser sigmoid cavity of the ulna. It forms about four-fifths of an osseo-fibrous ring, attached by each end to the extremities of the lesser sigmoid cavity, and is smaller at the lower part of its circumference than above, by which means the head of the radius is more securely held in its position. Its upper border blends with the anterior and posterior ligaments of the elbow, while its *outer surface* is strengthened by the external lateral ligament of the elbow, and affords origin to part of the Supinator brevis muscle. Its *inner surface* is smooth, and lined by synovial membrane. The synovial membrane is continuous with that which lines the elbow-joint.

Actions.—The movement which takes place in this articulation is limited to rotation of the head of the radius within the ring formed by the orbicular ligament, and the lesser sigmoid cavity of the ulna; rotation forwards being called *pronation*; rotation backwards, *supination*. Supination is performed by the Biceps and Supinator brevis, assisted to a slight extent by the Extensor muscles of the thumb and, in certain positions, by the Supinator longus. Pronation is performed by the Pronator radii teres and the Pronator quadratus, assisted, in some positions, by the Supinator longus.

Surface Form.—The position of the superior radio-ulnar joint is marked on the surface of the body by the little dimple on the back of the elbow which indicates the position of the head of the radius.

Surgical Anatomy.—Dislocation of the head of the radius alone is not an uncommon accident, and occurs most frequently in young persons from falls on the hand when the forearm is extended and supinated, the head of the bone being displaced forward. It is attended by rupture of the orbicular ligament. Occasionally a peculiar injury, which is supposed to be a subluxation, occurs in young children in lifting them from the ground by the hand or forearm. It is believed that the head of the radius is displaced downwards in the orbicular ligament, the upper border of which becomes folded over the head of the radius, between it and the capitellum of the humerus. The forearm becomes fixed in a position of semiflexion, midway between supination and pronation, and great pain is complained of upon any attempt to move the joint.

2. Middle Radio-ulnar Union

The shafts of the radius and ulna are connected by the

Oblique ligament and the Interosseous membrane.

The **Oblique** or **Round Ligament** (fig. 365) is a small, flattened, fibrous band, which extends obliquely downwards and outwards, from the tubercle of the ulna at the base of the coronoid process to the radius a little below the bicipital tuberosity. Its fibres run in the opposite direction to those of the interosseous ligament; and it appears to be placed as a substitute for it in the upper part of the interosseous interval. This ligament is sometimes wanting.

The **Interosseous Membrane** is a broad and thin plane of fibrous tissue descending obliquely downwards and inwards, from the interosseous ridge on the radius to that on the ulna. It is deficient above, commencing about an inch beneath the tubercle of the radius; is broader in the middle than at either extremity; and presents an oval aperture just above its lower margin for the passage of the anterior interosseous vessels to the back of the forearm. This ligament serves to connect the bones, and to increase the extent of surface for the attachment of the deep muscles. Between its upper border and the oblique ligament an interval exists, through which the posterior interosseous vessels pass. Two or three fibrous bands are occasionally found on the posterior surface of this membrane, which descend obliquely from the ulna towards the radius, and which have consequently a direction contrary to that of the other fibres. It is in relation, *in front*, by its upper three-fourths, with the Flexor longus pollicis on the outer side, and with the Flexor profundus digitorum on the inner, lying in the interval between which are the anterior interosseous vessels and nerve; by its lower fourth with the Pronator quadratus; *behind*, with the Supinator brevis, Extensor ossis metacarpi pollicis, Extensor brevis pollicis, Extensor longus pollicis, Extensor indicis; and, near the wrist, with the anterior interosseous artery and posterior interosseous nerve.

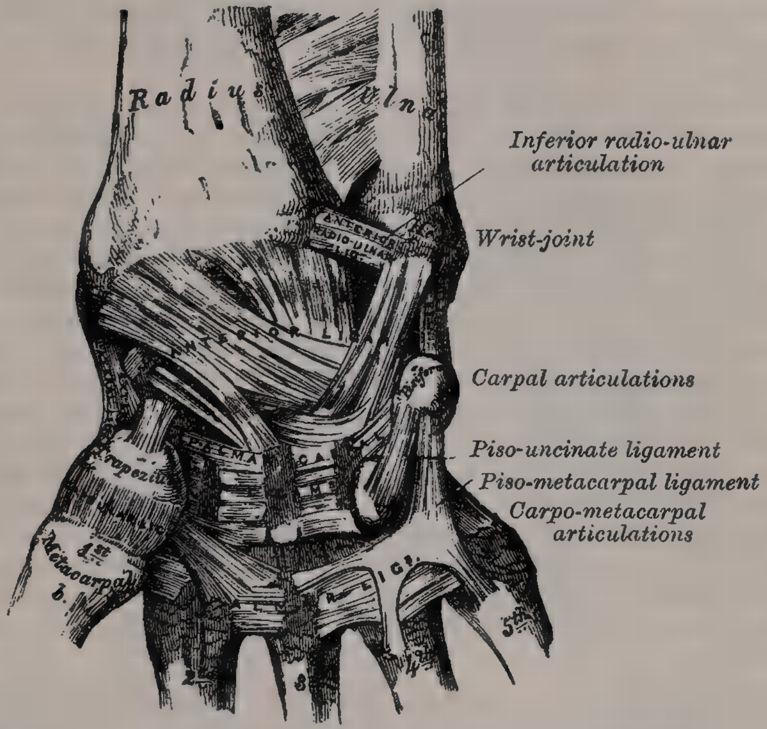
3. Inferior Radio-ulnar Articulation

This is a pivot-joint, formed by the head of the ulna received into the sigmoid cavity at the inner side of the lower end of the radius. The articular surfaces are covered by a thin layer of cartilage, and connected together by the following ligaments:

Anterior Radio-ulnar. Posterior Radio-ulnar.
Interarticular Fibro-cartilage.

The **Anterior Radio-ulnar Ligament** (fig. 368) is a narrow band of fibres extending from the anterior margin of the sigmoid cavity of the radius to the anterior surface of the head of the ulna.

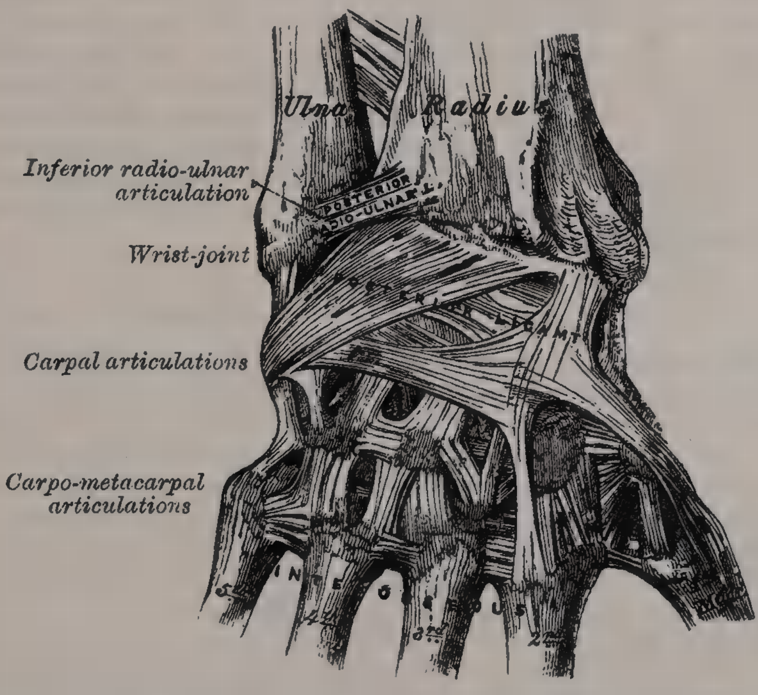
FIG. 368.—Ligaments of wrist and hand. Anterior view.



The **Posterior Radio-ulnar Ligament** (fig. 369) extends between similar points on the posterior surface of the articulation.

The **Interarticular Fibro-cartilage** (fig. 371) is triangular in shape, and is placed transversely beneath the head of the ulna, binding the lower end of this

FIG. 369.—Ligaments of wrist and hand. Posterior view.



bone and the radius firmly together. Its periphery is thicker than its centre, which is thin and occasionally perforated. It is attached by its apex to a depression which separates the styloid process of the ulna from the head of that bone; and by its base, which is thin, to the prominent edge of the radius, which

separates the sigmoid cavity from the carpal articulating surface. Its margins are united to the ligaments of the wrist-joint. Its *upper surface*, smooth and concave, articulates with the head of the ulna, forming an arthrodial joint; its *under surface*, also concave and smooth, forms part of the wrist-joint and articulates with the cuneiform and inner part of the semilunar bones. Both surfaces are lined by a synovial membrane: the upper surface, by one peculiar to the radio-ulnar articulation; the under surface, by the synovial membrane of the wrist.

The **Synovial Membrane** (fig. 371) of this articulation has been called, from its extreme looseness, the *membrana sacciformis*; it extends horizontally inwards between the head of the ulna and the interarticular fibro-cartilage, and upwards between the radius and the ulna, forming here a very loose *cul-de-sac*. The quantity of synovia which it contains is usually considerable.

Actions.—The movement in the inferior radio-ulnar articulation is just the reverse of that in the superior radio-ulnar joint. It consists of a movement of rotation of the lower end of the radius round an axis which corresponds to the centre of the head of the ulna. When the radius rotates forwards, *pronation* of the forearm and hand is the result; and when backwards, *supination*. It will thus be seen that in pronation and supination of the forearm and hand the radius describes a segment of a cone, the axis of which extends from the centre of the head of the radius to the middle of the head of the ulna. In this movement, however, the ulna is not quite stationary, but rotates a little in the opposite direction. So that it also describes the segment of a cone, though of smaller size than that described by the radius. The movement which causes this alteration in the position of the head of the ulna takes place principally at the shoulder-joint by a rotation of the humerus, but possibly also to a slight extent at the elbow-joint.*

Surface Form.—The position of the inferior radio-ulnar joint may be ascertained by feeling for a slight groove at the back of the wrist, between the prominent head of the ulna and the lower end of the radius, when the forearm is in a state of almost complete pronation.

VII. RADIO-CARPAL OR WRIST-JOINT

The **Wrist** is a condyloid articulation. The parts entering into its formation are the lower end of the radius and under surface of the interarticular fibro-cartilage on the one hand; and the scaphoid, semilunar, and cuneiform bones on the other. The articular surface of the radius and the under surface of the interarticular fibro-cartilage form together a transversely elliptical concave surface, the receiving cavity. The articular surfaces of the scaphoid, semilunar, and cuneiform bones present a smooth, convex surface, the *condyle*, which is received into the concavity above mentioned. All the bony surfaces of the articulation are covered with cartilage, and connected together by a capsule, which is divided into the following ligaments:

External Lateral.	Anterior.
Internal Lateral.	Posterior.

The **External Lateral Ligament** (*radio-carpal*) (fig. 368) extends from the summit of the styloid process of the radius to the outer side of the scaphoid, some of its fibres being prolonged to the trapezium and annular ligament. It has in relation with it the radial artery, which separates the ligament from the tendons of the Extensor ossis metacarpi and Extensor brevis pollicis.

The **Internal Lateral Ligament** (*ulno-carpal*) is a rounded cord, attached, above, to the extremity of the styloid process of the ulna; and dividing below into two fasciculi, one of which is attached to the inner side of the cuneiform bone, the other to the pisiform bone and annular ligament.

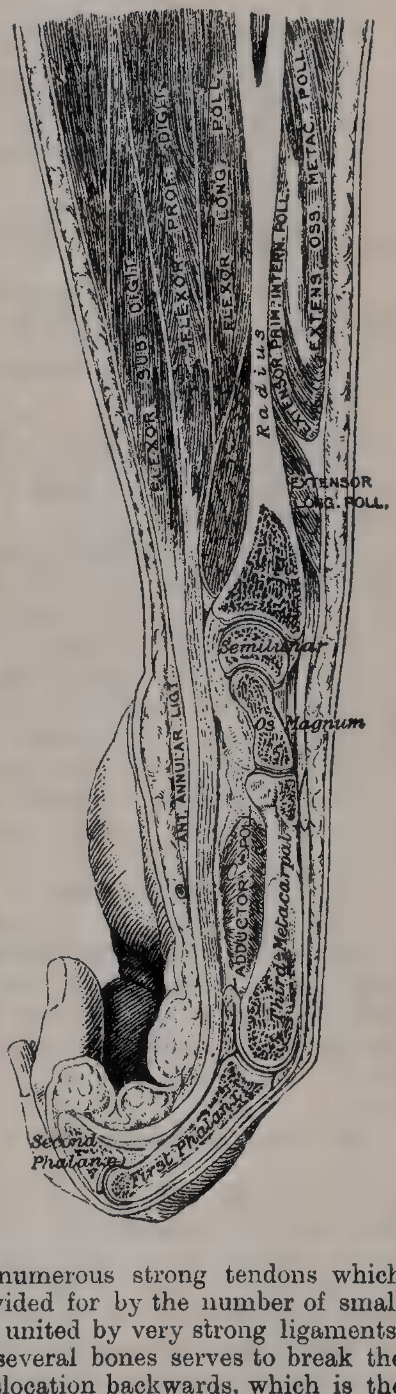
The **Anterior Ligament** is a broad membranous band, attached, above, to the anterior margin of the lower end of the radius, to its styloid process and to the ulna; its fibres pass downwards and inwards to be inserted into the palmar surface of the scaphoid, semilunar, and cuneiform bones, some of the fibres being continued to the os magnum. In addition to this broad membrane, there

* See *Journ. of Anat. and Phys.* vol. xix. parts ii., iii. and iv.

is a distinct rounded fasciculus, superficial to the rest, which passes from the base of the styloid process of the ulna to the semilunar and cuneiform bones. This ligament is perforated by numerous apertures for the passage of vessels, and is in relation, in front, with the tendons of the Flexor profundus digitorum and Flexor longus pollicis; behind, with the synovial membrane of the wrist-joint, where it is closely adherent to the anterior border of the triangular fibro-cartilage of the inferior radio-ulnar articulation.

The **Posterior Ligament** (fig. 369), less thick and strong than the anterior, is attached, above, to the posterior border of the lower end of the radius; its fibres pass obliquely downwards and inwards, to be attached to the dorsal surface of the scaphoid, semilunar, and cuneiform bones, being continuous with those of the dorsal carpal ligaments. This ligament is in relation, behind, with the Extensor tendons of the fingers; in front, with the synovial membrane of the wrist, where it is blended with the triangular fibro-cartilage.

Fig. 370.—Longitudinal section of the right forearm, hand, and third finger, viewed from the ulnar aspect. (After Braune.)



The **Synovial Membrane** (fig. 371) lines the inner surface of the ligaments above described, extending from the lower end of the radius and interarticular fibro-cartilage above to the articular surfaces of the carpal bones below. It is loose and lax, and presents numerous folds, especially behind.

Relations.—The wrist-joint is covered in front by the Flexor, and behind by the Extensor tendons; it is also in relation with the radial and ulnar arteries.

The *Arteries* supplying the joint are the anterior and posterior carpal branches of the radial and ulnar, the anterior and posterior interosseous, and some ascending branches from the deep palmar arch.

The *Nerves* are derived from the ulnar and posterior interosseous.

Actions.—The movements permitted in this joint are flexion, extension, abduction, adduction, and circumduction. Its actions will be further studied with those of the carpus, with which they are combined.

Surface Form.—On the front of the lower part of the forearm three transverse furrows may be generally seen: the uppermost is on a level with the styloid process of the ulna; the middle corresponds fairly accurately with the wrist-joint; and the lowest indicates the position of the mid-carpal articulation.

Surgical Anatomy.—The wrist-joint is rarely dislocated, its strength depending mainly upon the numerous strong tendons which surround the articulation. Its security is further provided for by the number of small bones of which the carpus is made up, and which are united by very strong ligaments. The slight movement which takes place between the several bones serves to break the jars that result from falls or blows on the hand. Dislocation backwards, which is the more common, simulates to a considerable extent Colles's fracture of the radius, and is liable to be mistaken for it. The diagnosis can be easily made out by observing the relative position of the styloid processes of the radius and the ulna. In the natural condition the styloid process of the radius is on a lower level, i.e. nearer the ground, when the arm hangs by the side, than that of the ulna, and the same would be the case in dislocation. In Colles's fracture, on the other hand, the styloid process of the radius is on the same, or even a higher level than that of the ulna.

The wrist-joint is occasionally the seat of acute synovitis, the result of traumatism, or

arising in the rheumatic or pyæmic state. When the synovial sac is distended with fluid, the swelling is greatest on the dorsal aspect of the wrist, showing a general fulness, with some bulging between the tendons. The inflammation is prone to extend to the intercarpal joints and to attack also the sheaths of the tendons in the neighbourhood. Chronic inflammation of the wrist is generally tuberculous, and often leads to similar disease in the synovial sheaths of adjacent tendons and of the intercarpal joints. The disease, therefore, when progressive, frequently leads to necrosis of the carpal bones, and the result is often unsatisfactory.

VIII. ARTICULATIONS OF THE CARPUS

These articulations may be subdivided into three sets:

1. The Articulations of the First Row of Carpal Bones.
2. The Articulations of the Second Row of Carpal Bones.
3. The Articulations of the Two Rows with each other.

1. Articulations of the First or Proximal Row of Carpal Bones

These are arthrodial joints. The ligaments connecting the scaphoid, semilunar, and cuneiform bones are—

Dorsal. Palmar.
Two Interosseous.

The **Dorsal Ligaments,** two in number, are placed transversely behind the bones of the first row; they connect the scaphoid and semilunar, and the semilunar and cuneiform.

The **Palmar Ligaments,** also two, connect the scaphoid and semilunar, and the semilunar and cuneiform bones; they are less strong than the dorsal, and placed very deeply below the Flexor tendons and the anterior ligament of the wrist.

The **Interosseous Ligaments** (fig. 371) are two narrow bundles of fibrous tissue, connecting the semilunar bone, on one side with the scaphoid, and on the other with the cuneiform. They are on a level with the superior surfaces of these bones, and their upper surfaces are smooth, and form with the bones which they connect, the convex articular surface of the wrist-joint.

The ligaments connecting the pisiform bone are—

Capsular. Two Palmar.

The **Capsular Ligament** is a thin membrane which connects the pisiform bone to the cuneiform. It is lined with a separate synovial membrane.

The **two Palmar Ligaments** are strong fibrous bands which connect the pisiform to the unciform, the *piso-unciform*, and to the base of the fifth metacarpal bone, the *piso-metacarpal ligament* (fig. 368). These ligaments are, in reality, prolongations of the tendon of the Flexor carpi ulnaris.

2. Articulations of the Second or Distal Row of Carpal Bones

These also are arthrodial joints. The articular surfaces are covered with cartilage, and connected by the following ligaments:

Dorsal. Palmar.
Three Interosseous.

The **Dorsal Ligaments,** three in number, extend transversely from one bone to another on the dorsal surface, connecting the trapezium with the trapezoid, the trapezoid with the os magnum, and the os magnum with the unciform.

The **Palmar Ligaments,** also three, have a similar arrangement on the palmar surface.

The **three Interosseous Ligaments,** much thicker than those of the first row, are placed one between the os magnum and the unciform, a second between the os magnum and the trapezoid, and a third between the trapezium and trapezoid. The first of these is much the strongest, and the third is sometimes wanting.

3. Articulations of the Two Rows of Carpal Bones with each other

The joint between the scaphoid, semilunar, and cuneiform on the one hand, and the second row of the carpus on the other, is named the *mid-carpal joint*, and is made up of three distinct portions; in the centre the head of the os magnum and the superior surface of the unciform articulate with the deep cup-shaped cavity formed by the scaphoid and semilunar bones, and constitute a sort of ball-and-socket joint. On the outer side the trapezium and trapezoid articulate with the scaphoid, and on the inner side the unciform articulates with the cuneiform, forming gliding joints.

The ligaments are—

Anterior or Palmar.	External Lateral.
Posterior or Dorsal.	Internal Lateral.

The **Anterior** or **Palmar Ligament** consists of short fibres, which pass, for the most part, from the palmar surface of the bones of the first row to the front of the os magnum.

The **Posterior** or **Dorsal Ligament** consists of short, irregular bundles of fibres passing between the bones of the first and second row on the dorsal surface of the carpus.

The **Lateral Ligaments** are very short: one is placed on the radial, the other on the ulnar side of the carpus; the former, the stronger and more distinct, connecting the scaphoid and trapezium, the latter the cuneiform and unciform; they are continuous with the lateral ligaments of the wrist-joint. In addition to these ligaments, a slender interosseous band sometimes connects the os magnum and the scaphoid.

The **Synovial Membrane of the Carpus** is very extensive; it passes from the under surface of the scaphoid, semilunar, and cuneiform bones to the upper surface of the bones of the second row, sending upwards two prolongations—between the scaphoid and semilunar, and the semilunar and cuneiform—sending downwards three prolongations between the four bones of the second row. The prolongation between the trapezium and trapezoid, or that between the trapezoid and os magnum, is often continued onwards, through the absence of the interosseous ligament, into the carpo-metacarpal joints, sometimes of the four inner metacarpal bones; sometimes of the second and third metacarpal bones only. In the latter condition, the carpo-metacarpal joints of the fourth and fifth metacarpal bones have a separate synovial membrane. The synovial membranes of these joints are prolonged for a short distance between the metacarpal bones. There is a separate synovial membrane between the pisiform and cuneiform bones.

Actions.—The articulation of the hand and wrist, considered as a whole, is divided into three parts: (1) the radius and the interarticular fibro-cartilage; (2) the meniscus, formed by the scaphoid, semilunar, and cuneiform—the pisiform bone having no essential part in the movement of the hand; (3) the hand proper, the metacarpal bones with the four carpal bones on which they are supported, viz. the trapezium, trapezoid, os magnum, and unciform. These three elements form two joints: (1) the superior (wrist-joint proper), between the meniscus and bones of the forearm; (2) the inferior, between the hand and meniscus (transverse or mid-carpal joint).

(1) The articulation between the forearm and carpus is a true condyloid articulation, and therefore all movements but rotation are permitted. Flexion and extension are the most free, and of these a greater amount of extension than flexion is permitted on account of the articulating surfaces extending farther on the dorsal than on the palmar aspect of the carpal bones. In this movement the carpal bones rotate on a transverse axis drawn between the tips of the styloid processes of the radius and ulna. A certain amount of adduction (or ulnar flexion) and abduction (or radial flexion) is also permitted. Of these the former is considerably greater in extent than the latter, on account of the shorter length of the styloid process of the ulna, abduction being limited by the contact of the styloid process of the radius with the trapezium. In this movement the carpus revolves upon an antero-posterior axis drawn through the centre of the wrist. Finally, circumduction is permitted by the consecutive movements of adduction, extension, abduction, and flexion, with intermediate movements

between them. There is no rotation, but this is provided for by the supination and pronation of the radius on the ulna. The movement of *flexion* is performed by the Flexor carpi radialis, the Flexor carpi ulnaris, and the Palmaris longus; *extension* by the Extensor carpi radialis longior et brevior and the Extensor carpi ulnaris; *adduction* (ulnar flexion) by the Flexor carpi ulnaris and the Extensor carpi ulnaris; and *abduction* (radial flexion) by the Extensors of the thumb, and the Extensor carpi radialis longior and brevior and the Flexor carpi radialis.

(2) The chief movements permitted in the transverse or mid-carpal joint are flexion and extension and a slight amount of rotation. In flexion and extension, which is the movement most freely enjoyed, the trapezium and trapezoid on the radial side and the unciform on the ulnar side glide forwards and backwards on the scaphoid and cuneiform respectively, while the head of the os magnum and the superior surface of the unciform rotate in the cup-shaped cavity of the scaphoid and semilunar. Flexion at this joint is freer than extension. A very trifling amount of rotation is also permitted, the head of the os magnum rotating round a vertical axis drawn through its own centre, while at the same time a slight gliding movement takes place in the lateral portions of the joint.

IX. CARPO-METACARPAL ARTICULATIONS

1. Articulation of the Metacarpal Bone of the Thumb with the Trapezium

This is a joint of reciprocal reception, and enjoys great freedom of movement, on account of the configuration of its articular surfaces, which are saddle-shaped, so that, on section, each bone appears to be received into a cavity in the other, according to the direction in which they are cut. The joint is surrounded by a capsular ligament.

The **Capsular Ligament** is thick but loose, and passes from the circumference of the upper extremity of the metacarpal bone to the rough edge bounding the articular surface of the trapezium; it is thickest externally and behind, and lined by a separate *synovial membrane.*

Movements.—In the articulation of the metacarpal bone of the thumb with the trapezium, the movements permitted are flexion, extension, adduction, abduction, and circumduction. When the joint is flexed, the metacarpal bone is moved inwards and forwards, and the thumb is opposed to the fingers. It is by this peculiar movement of *opposition* that the tip of the thumb is brought into contact with the palmar surfaces of the slightly flexed fingers one after another.

2. Articulations of the Metacarpal Bones of the Four Inner Fingers with the Carpus

The joints formed between the carpus and four inner metacarpal bones are arthrodial joints. The ligaments are—

Dorsal. Palmar.
Interosseous.

The **Dorsal Ligaments,** the strongest and most distinct, connect the carpal and metacarpal bones on their dorsal surface. The second metacarpal bone receives two fasciculi, one from the trapezium, the other from the trapezoid; the third metacarpal receives two, one from the trapezoid, and one from the os magnum; the fourth two, one from the os magnum, and one from the unciform; the fifth receives a single fasciculus from the unciform bone, which is continuous with a similar ligament on the palmar surface, forming an incomplete capsule.

The **Palmar Ligaments** have a somewhat similar arrangement on the palmar surface, with the exception of the third metacarpal, which has three ligaments, an external one from the trapezium, situated above the sheath of the tendon of the Flexor carpi radialis; a middle one from the os magnum; and an internal one from the unciform.

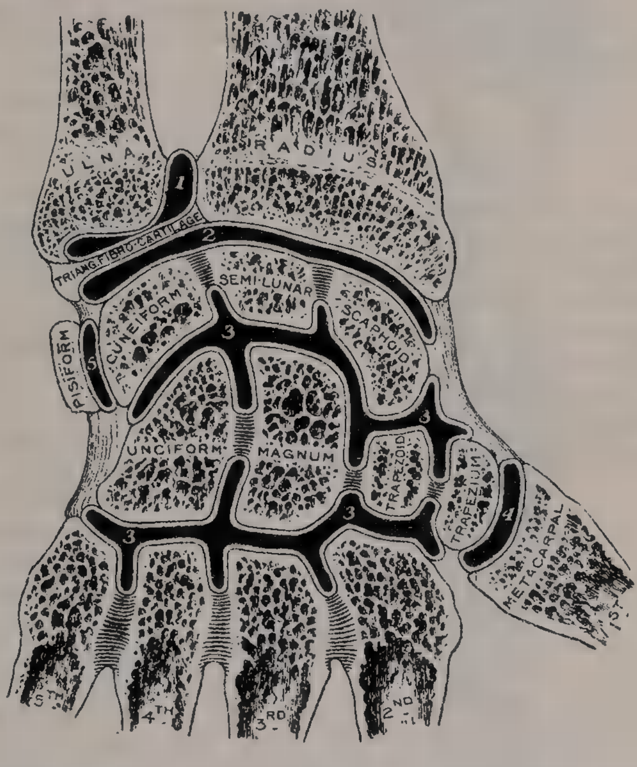
The **Interosseous Ligaments** consist of short, thick fibres, which are limited to one part of the carpo-metacarpal articulation; they connect the contiguous

inferior angles of the os magnum and unciform with the adjacent surfaces of the third and fourth metacarpal bones.

The **Synovial Membrane** is frequently a continuation of that between the two rows of carpal bones. Occasionally, the articulation of the unciform with the fourth and fifth metacarpal bones has a separate synovial membrane.

The synovial membranes of the wrist and carpus (fig. 371) are thus seen to be five in number. The *first*, the *membrana sacciformis*, passes from the lower end of the ulna to the sigmoid cavity of the radius, and lines the upper surface of the interarticular fibro-cartilage. The *second* passes from the lower end of the radius and interarticular fibro-cartilage above, to the bones of the first row below. The *third*, the most extensive, passes between the contiguous margins of the two rows of carpal bones, and sometimes, in the event of one of the interosseous ligaments being absent, between the bones of the second row to the carpal extremities of the four inner metacarpal bones. The *fourth*, from the margin of the trapezium to the metacarpal bone of the thumb. The *fifth*, between the adjacent margins of the cuneiform and pisiform bones. Occasionally the carpo-metacarpal joints have a separate synovial membrane (see page 393).

Fig. 371.—Vertical section through the articulations at the wrist, showing the five synovial membranes.



Actions.—The movement permitted in the carpo-metacarpal articulations of the four inner fingers is limited to a slight gliding of the articular surfaces upon each other, the extent of which varies in the different joints. Thus the articulation of the metacarpal bone of the little finger is most movable, then that of the ring-finger. The metacarpal bones of the index and middle fingers are almost immovable.

3. Articulations of the Metacarpal Bones with each other

The carpal extremities of the four inner metacarpal bones articulate with one another at each side by small surfaces covered with cartilage, and connected together by dorsal, palmar, and interosseous ligaments.

The **Dorsal** and **Palmar Ligaments** pass transversely from one bone to another on the dorsal and palmar surfaces. The *Interosseous Ligaments* pass between their contiguous surfaces, just beneath their lateral articular facets.

The **Synovial Membrane** between the lateral facets is a reflection from that between the two rows of carpal bones.

The **Transverse Metacarpal Ligament** (fig. 372) is a narrow fibrous band,

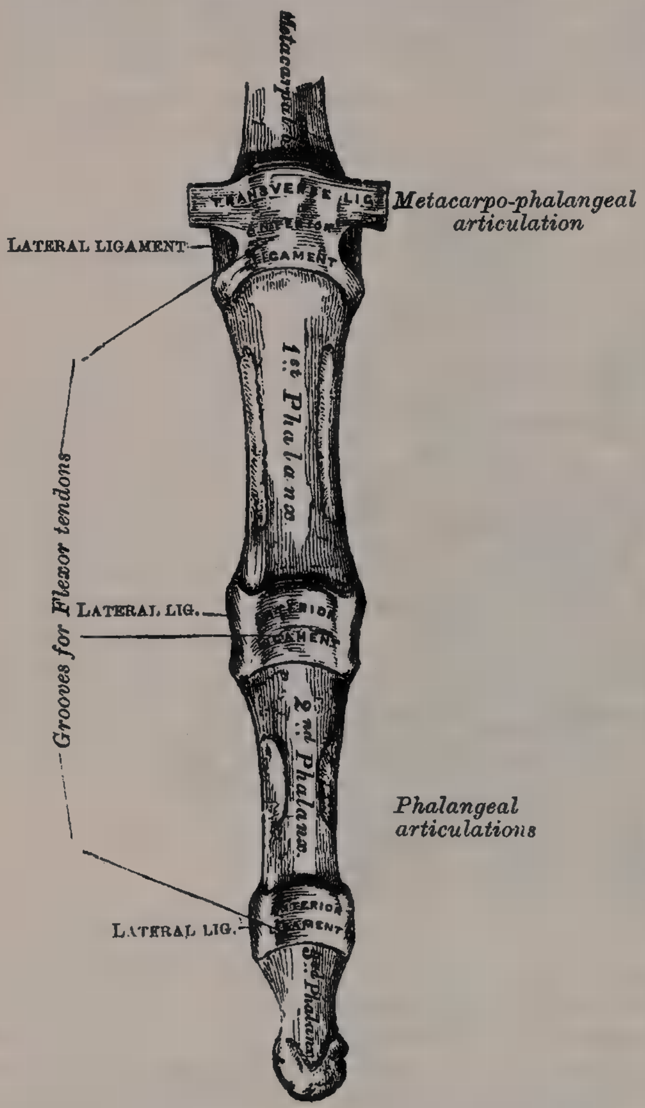
which passes transversely across the anterior surfaces of the digital extremities of the four inner metacarpal bones, connecting them together. It is blended anteriorly with the anterior (glenoid) ligament of the metacarpo-phalangeal articulations. To its posterior border is connected the fascia which covers the Interossei muscles. Its anterior surface is concave where the Flexor tendons pass over it. Behind it the tendons of the Interossei muscles pass to their insertion.

X. METACARPO-PHALANGEAL ARTICULATIONS (fig. 372)

These articulations are of the condyloid kind, formed by the reception of the rounded head of the metacarpal bone into a shallow cavity in the extremity of the first phalanx, with the exception of that of the thumb, which presents more of the characters of a ginglymoid joint. The ligaments are—

Anterior.
Two Lateral.

FIG. 372.—Articulations of the phalanges.



The **Anterior Ligaments** (*Glenoid Ligaments* of Cruveilhier) are thick, dense, fibro-cartilaginous structures, placed upon the palmar surface of the joints in the intervals between the lateral ligaments, to which they are connected; they are loosely united to the metacarpal bone, but are very firmly attached to the base of the first phalanx. Their palmar surfaces are intimately blended with the transverse metacarpal ligament, and present a groove for the passage of the Flexor tendons, the sheath surrounding which is connected to each side of the groove. By their deep surfaces, they form part of the articular facets for the heads of the metacarpal bones, and are lined by synovial membranes.

The **Lateral Ligaments** are strong, rounded cords, placed one on each side of the joint, and attached by one extremity to the posterior tubercle and adjacent depression on the side of the head of the metacarpal bone, and by the other to the contiguous extremity of the phalanx.

Actions.—The movements which occur in these joints are flexion, extension, adduction, abduction, and circumduction; the lateral movements are very limited.

Surface Form.—The prominences of the knuckles do not correspond to the position of the joints either of the metacarpo-phalangeal or interphalangeal articulations. These prominences are invariably formed by the distal ends of the proximal bone of each joint, and the line indicating the position of the joint must be sought considerably in front of the middle of the knuckle. The usual rule for finding these joints is to flex the distal phalanx on the proximal one to a right angle; the position of the joint is then indicated by an imaginary line drawn along the middle of the lateral aspect of the proximal phalanx.

XI. ARTICULATIONS OF THE PHALANGES

These are hinge joints. The ligaments are—

Anterior. Two Lateral.

The arrangement of these ligaments is similar to those in the metacarpo-phalangeal articulations; the Extensor tendon supplies the place of a posterior ligament.

Actions.—The only movements permitted in the phalangeal joints are flexion and extension; these movements are more extensive between the first and second phalanges than between the second and third. The movement of flexion is very considerable, but extension is limited by the anterior and lateral ligaments.

ARTICULATIONS OF THE LOWER EXTREMITY

The articulations of the Lower Extremity comprise the following:

I. Hip.
II. Knee.
III. Tibia with Fibula.
IV. Ankle.
V. Tarsal.
VI. Tarso-metatarsal.
VII. Metatarsal.
VIII. Metatarso-phalangeal.
IX. Phalangeal.

I. HIP-JOINT (fig. 373)

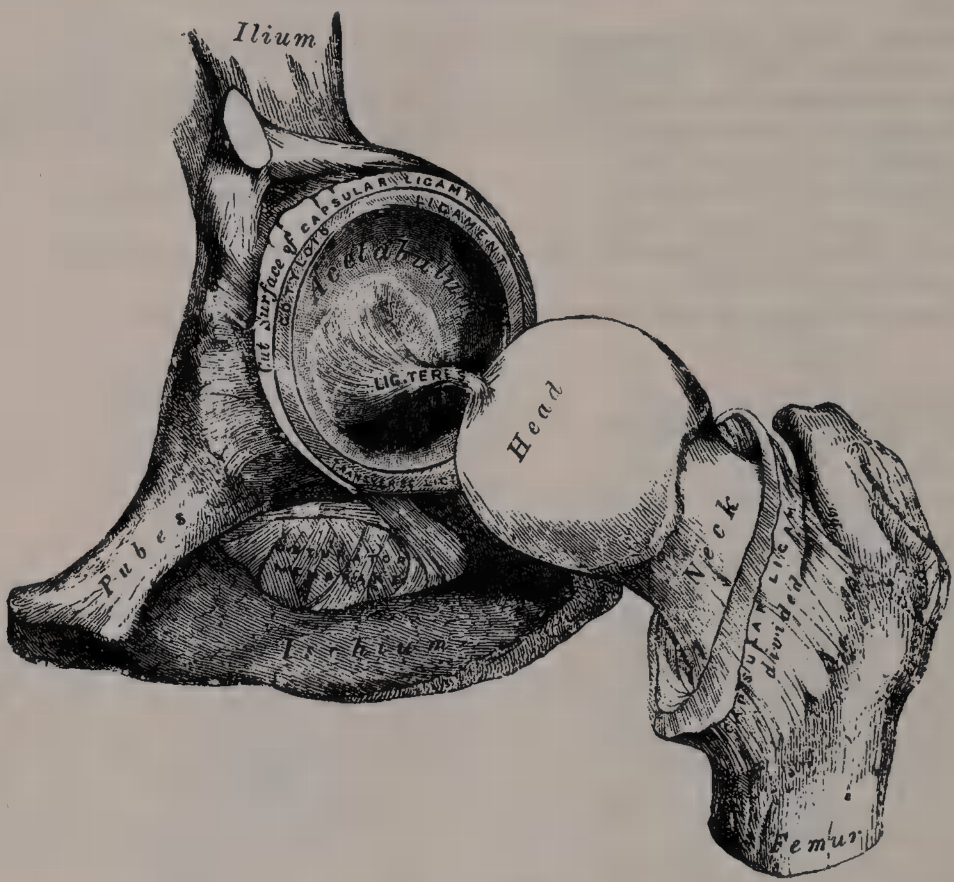
This articulation is an enarthrodial, or ball-and-socket joint, formed by the reception of the head of the femur into the cup-shaped cavity of the acetabulum. The articulating surfaces are covered with cartilage, that on the head of the femur being thicker at the centre than at the circumference, and covering the entire surface with the exception of a depression just below its centre for the ligamentum teres; that covering the acetabulum is much thinner at the centre than at the circumference. It forms an incomplete cartilaginous ring, of a horse-shoe shape, being deficient below, where there is a circular depression, which is occupied in the recent state by a mass of fat, covered by synovial membrane. The ligaments of the joint are, the

Capsular. Teres.
Ilio-femoral. Cotyloid.
Transverse.

The **Capsular Ligament** is a strong, dense, ligamentous capsule, embracing the margin of the acetabulum above, and surrounding the neck of the femur below. Its *upper circumference* is attached to the acetabulum, two or three lines external to the cotyloid ligament, above and behind; but in front, it is attached to the outer margin of the ligament, and opposite to the notch where the margin of the cavity is deficient, it is connected to the transverse ligament, and by a few fibres to the edge of the obturator foramen. Its *lower circumference* surrounds the neck of the femur, being attached, in front, to the spiral or anterior intertrochanteric line; above, to the base of the neck; behind, to the neck of the bone, about half an inch above the posterior intertrochanteric line; below, to the lower part of the neck of the femur, close to the lesser trochanter. From this insertion some of the fibres are reflected upwards over the neck of the femur as longitudinal bands, termed *retinacula*. The capsule is much thicker at the upper and fore part of the joint, where the greatest amount of resistance is required, than below and internally, where it is thin, loose, and longer than in any other part. It consists of two sets of fibres, circular and longitudinal. The circular fibres (*zona orbicularis*) are most abundant at the lower and back part of the capsule, and form a sling or collar around the neck of the femur. Anteriorly they blend with the deep surface of the ilio-femoral ligament, and through its medium reach the anterior inferior spine of the ilium. The longitudinal fibres are greatest in amount at the upper and front part of the capsule, where they form distinct bands, or accessory ligaments, of which the most important is the

ilio-femoral. The other accessory bands are known as the *pubo-femoral,* passing from the ilio-pectineal eminence and obturator crest to the front of the capsule, where some of its fibres blend with the lower segment of the ilio-femoral ligament; and *ischio-capsular,* passing from the ischium, just below the acetabulum, to blend with the circular fibres at the lower part of the joint. The external

Fig. 373.—Left hip-joint laid open.



surface (fig. 358, page 370) is rough, covered by numerous muscles, and separated in front from the Psoas and Iliacus by a synovial bursa, which not infrequently communicates, by a circular aperture, with the cavity of the joint. It differs from the capsular ligament of the shoulder in being much less loose and lax, and in not being perforated for the passage of a tendon.

The **Ilio-femoral Ligament** (figs. 358 and 374) is a band of great strength which lies in front of the joint; it is intimately connected with the capsular ligament, and serves to strengthen it in this situation. It is attached, above, to the lower part of the anterior inferior spine of the ilium; and, diverging below, forms two bands, of which one passes downwards to be inserted into the lower part of the anterior intertrochanteric line; the other passes downwards and outwards to be inserted into the upper part of the same line. Between the two bands is a thinner part of the capsule. In some joints there is no division, and the ligament spreads out into a flat triangular band which is attached below into the whole length of the anterior intertrochanteric line. This ligament is frequently called the Y-shaped ligament of Bigelow; and the outer or upper of the two bands is sometimes described as a separate ligament, under the name of the *ilio-trochanteric ligament.*

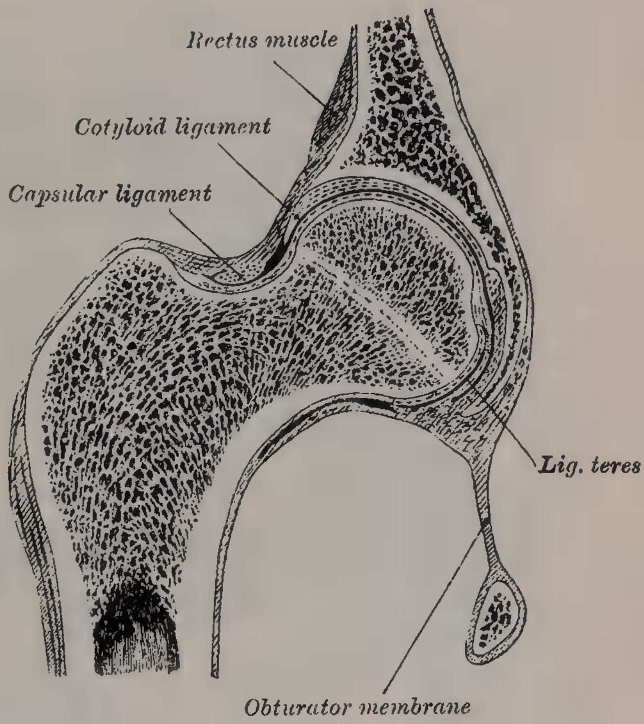
The **Ligamentum Teres** is a triangular, somewhat flattened band implanted by its apex into the depression a little behind and below the centre of the head of the femur, and by its broad base into the margins of the cotyloid notch, becoming blended with the transverse ligament. It is formed of connective tissue, surrounded by a tubular sheath of synovial membrane. Occasionally only the synovial fold exists, or the ligament may be altogether absent. The ligament is made tense when the hip is semiflexed, and the limb then adducted or rotated outwards; it is, on the other hand, relaxed when the limb is abducted. It has,

however, but little influence as a ligament, though it may to a certain extent limit movement.

The **Cotyloid Ligament** is a fibro-cartilaginous rim attached to the margin of the acetabulum, the cavity of which it deepens; at the same time it protects the edge of the bone, and fills up the inequalities on its surface. It bridges over the notch as the *transverse ligament*, and thus forms a complete circle, which closely surrounds the head of the femur, and assists in holding it in its place. It is prismoid on section, its base being attached to the margin of the acetabulum, and its opposite edge being free and sharp; while its two surfaces are invested by synovial membrane, the external one being in contact with the capsular ligament, the internal one being inclined inwards so as to narrow the acetabulum, and embrace the cartilaginous surface of the head of the femur. It is much thicker above and behind than below and in front, and consists of close compact fibres, which arise from different points of the circumference of the acetabulum, and interlace with each other at very acute angles.

Fig. 374.—Hip-joint, showing the ilio-femoral ligament. (After Bigelow.)

Fig. 375.—Vertical section through hip-joint. (Henle.)



The **Transverse Ligament** is in reality a portion of the cotyloid ligament, though differing from it in having no cartilage cells among its fibres. It consists of strong, flattened fibres, which cross the notch at the lower part of the acetabulum, and convert it into a foramen. Thus an interval is left beneath the ligament for the passage of nutrient vessels to the joint.

The **Synovial Membrane** is very extensive. Commencing at the margin of the cartilaginous surface of the head of the femur, it covers all that portion of the neck which is contained within the joint; from the neck it is reflected on the internal surface of the capsular ligament, covers both surfaces of the cotyloid ligament and the mass of fat contained in the depression at the bottom of the acetabulum, and is prolonged in the form of a tubular sheath around the ligamentum teres, as far as the head of the femur. It sometimes communicates through a hole in the capsular ligament between the inner band of the Y-shaped ligament and the pubo-femoral ligament with a bursa situated on the under surface of the Ilio-psoas muscle.

The muscles in relation with the joint are, in front, the Psoas and Iliacus, separated from the capsular ligament by a synovial bursa; above, the reflected

head of the Rectus and Gluteus minimus, the latter being closely adherent to the capsule; internally, the Obturator externus and Pectineus; behind, the Pyriformis, Gemellus superior, Obturator internus, Gemellus inferior, Obturator externus, and Quadratus femoris (fig. 376).

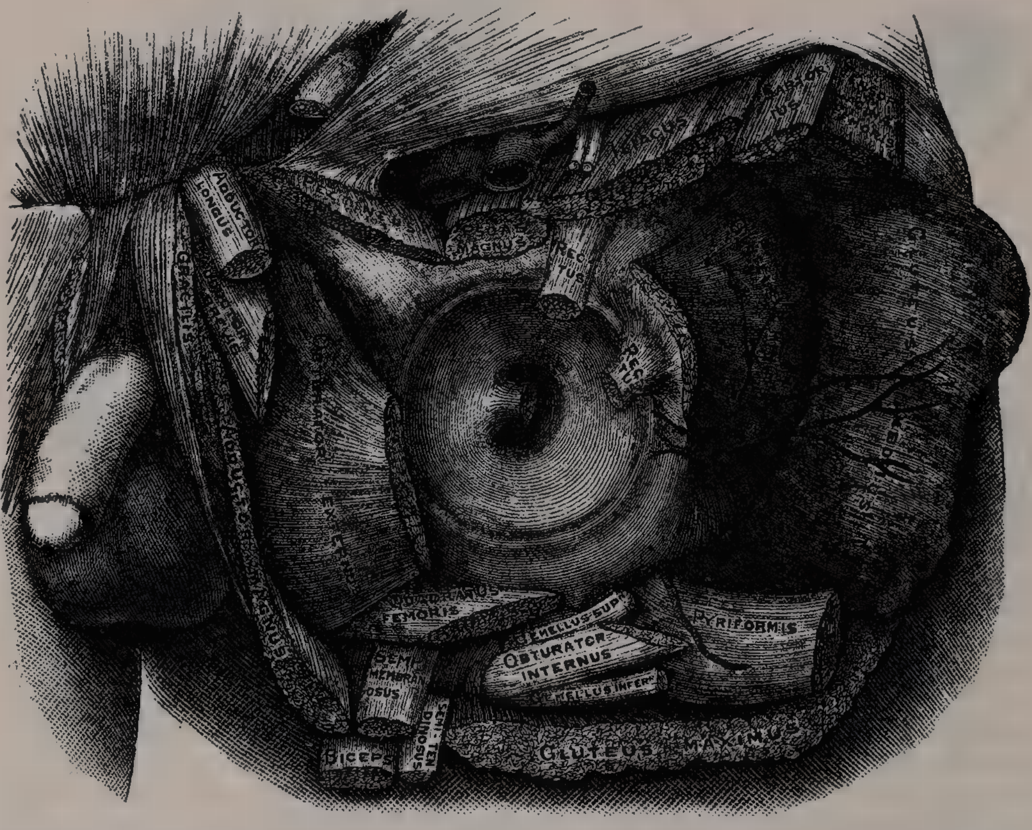
The arteries supplying the joint are derived from the obturator, sciatic, internal circumflex, and gluteal.

The nerves are articular branches from the sacral plexus, great sciatic, obturator, accessory obturator, and a filament from the branch of the anterior crural supplying the Rectus.

Actions.—The movements of the hip are very extensive, and consist of flexion, extension, adduction, abduction, circumduction, and rotation.

The hip-joint presents a very striking contrast to the shoulder-joint in the much more complete mechanical arrangements for its security and for the limitation of its movements. In the shoulder, as has been seen, the head of the humerus is not adapted at all in size to the glenoid cavity, and is hardly

FIG. 376.—Relation of muscles to the capsule of the hip-joint. From a drawing by F. A. Barton.



restrained in any of its ordinary movements by the capsular ligament. In the hip-joint, on the contrary, the head of the femur is closely fitted to the acetabulum for a distance extending over nearly half a sphere, and at the margin of the bony cup it is still more closely embraced by the cotyloid ligament, so that the head of the femur is held in its place by that ligament even when the fibres of the capsule have been quite divided (Humphry). The ilio-femoral ligament is the strongest of all the ligaments in the body, and is put on the stretch by any attempt to extend the femur beyond a straight line with the trunk. That is to say, this ligament is the chief agent in maintaining the erect position without muscular fatigue; for a vertical line passing through the centre of gravity of the trunk falls behind the centres of rotation in the hip-joints, and therefore the pelvis tends to fall backwards, but is prevented by the tension of the ilio-femoral and capsular ligaments. The security of the joint may be also provided for by the two bones being directly united through the ligamentum teres; but it is doubtful whether this so-called ligament can have much influence upon the mechanism of the joint. Flexion of the hip-joint is arrested by the soft parts of the thigh and abdomen being brought

into contact, when the leg is flexed on the thigh; and by the action of the hamstring muscles when the leg is extended;* extension by the tension of the ilio-femoral ligament; adduction by the thighs coming into contact; adduction with flexion by the outer band of the ilio-femoral ligament, the outer part of the capsular ligament; abduction by the inner band of the ilio-femoral ligament and the pubo-femoral band; rotation outwards by the outer band of the ilio-femoral ligament; and rotation inwards by the ischio-capsular ligament and the hinder part of the capsule. The muscles which *flex* the femur on the pelvis are, the Psoas, Iliacus, Rectus, Sartorius, Pectineus, Adductor longus and brevis, and the anterior fibres of the Gluteus medius and minimus. *Extension* is mainly performed by the Gluteus maximus, assisted by the hamstring muscles. The thigh is *adducted* by the Adductor magnus, longus and brevis, the Pectineus, the Gracilis, and lower part of the Gluteus maximus, and *abducted* by the Gluteus medius and minimus, and upper part of the Gluteus maximus. The muscles which *rotate* the thigh *inwards* are the anterior fibres of the Gluteus medius, the Gluteus minimus, and the Tensor fasciæ femoris; while those which rotate it *outwards* are the posterior fibres of the Gluteus medius, the Pyriformis, Obturator externus and internus, Gemellus superior and inferior, Quadratus femoris, Iliacus, Gluteus maximus, the three Adductors, the Pectineus, and the Sartorius.

Surface Form.—A line drawn from the anterior superior spinous process of the ilium to the most prominent part of the tuberosity of the ischium (Nélaton's line) runs through the centre of the acetabulum, and would, therefore, indicate the level of the hip-joint; or, in other words, the upper border of the great trochanter, which lies on Nélaton's line, is on a level with the centre of the hip-joint.

Surgical Anatomy.—In dislocation of the hip, 'the head of the thigh-bone may rest at any point around its socket' (Bryant); but whatever position the head ultimately assumes, the primary displacement is generally downwards and inwards, the capsule giving way at its weakest—that is, its lower and inner—part. The situation that the head of the bone subsequently assumes is determined by the degree of flexion or extension, and of outward or inward rotation of the thigh at the moment of luxation, influenced, no doubt, by the ilio-femoral ligament, which is not easily ruptured. When, for instance, the head is forced backwards, this ligament forms a fixed axis, round which the head of the bone rotates, and is thus driven on to the dorsum of the ilium. The ilio-femoral ligament also influences the position of the thigh in the various dislocations: in the dislocations backwards it is tense, and produces inversion of the limb; in the dislocation on to the pubes, it is relaxed, and therefore allows the external rotators to evert the thigh; while in the thyroid dislocation it is tense, and produces flexion. The muscles inserted into the upper part of the femur, with the exception of the Obturator internus, have very little direct influence in determining the position of the bone. But Bigelow has endeavoured to show that the Obturator internus is the principal agent in deciding whether, in the backward dislocations, the head of the bone shall be ultimately lodged on the dorsum of the ilium, or in or near the sciatic notch. In both dislocations the head passes, in the first instance, in the same direction; but, as Bigelow asserts, in the displacement on to the dorsum, the head of the bone travels up behind the acetabulum, in front of the muscle; while in the dislocation into the sciatic notch the head passes behind the muscle, and is prevented from reaching the dorsum, in consequence of the tendon of the muscle arching over the neck of the bone, and it therefore remains in the neighbourhood of the sciatic notch. Bigelow distinguishes these two forms of dislocation by describing them as dislocations backwards, 'above and below' the Obturator internus.

The ilio-femoral ligament is rarely torn in dislocations of the hip, and this fact is taken advantage of by the surgeon in reducing these dislocations by manipulation. It is made to act as the fulcrum to a lever, of which the long arm is the shaft of the femur, and the short arm the neck of the bone.

The hip-joint is rarely the seat of acute synovitis from injury, on account of its deep position and its thick covering of soft parts. Acute inflammation may, and does, frequently occur as the result of constitutional conditions, as rheumatism, pyæmia, &c. When, in these cases, effusion takes place, and the joint becomes distended with fluid, the swelling is not very easy to detect on account of the thickness of the capsule and the depth of the articulation. It is principally to be found on the front of the joint, just internal to the ilio-femoral ligament; or behind, at the lower and back part. In these two places the capsule is thinner than elsewhere. Disease of the hip-joint is much oftener of a chronic character, and is usually of tuberculous origin. It begins either in the bones or in

* The hip-joint cannot be completely flexed, in most persons, without at the same time flexing the knee, on account of the shortness of the hamstring muscles.—Cleland, *Journ. of Anat. and Phys.* No. I. Old Series, p. 87.

the synovial membrane; usually in the former, and probably, in most cases, in the growing, highly vascular tissue in the neighbourhood of the epiphysial cartilage. In this respect it differs very materially from tuberculous arthritis of the knee, where the disease usually commences in the synovial membrane. The reasons why the disease so commonly begins in this situation are twofold: first, this part being the centre of rapid growth, its nutrition is unstable and apt to pass into inflammatory action; and, secondly, great strain is thrown upon it, from the frequency of falls and blows upon the hip, which causes crushing of the epiphysial cartilage or the cancellous tissue in its neighbourhood, with the results likely to follow such an injury. In addition to these, the depth of the joint protects it from the causes of synovitis.

In chronic hip-disease the affected limb assumes an altered position, the cause of which it is important to understand. In the early stage of a typical case, the limb is flexed, abducted, and rotated outwards. In this position all the ligaments of the joint are relaxed: the front of the capsule by flexion; the outer band of the ilio-femoral ligament by abduction; and the inner band of this ligament and the back of the capsule by rotation outwards. It is, therefore, the position of greatest ease. The condition is not quite obvious at first, upon examining a patient. If the patient is laid in the supine position, the affected limb will be found to be extended and parallel with the other. But it will be seen that the pelvis is tilted downwards on the diseased side and the limb apparently longer than its fellow, and that the lumbar spine is arched forwards (lordosis). If now the thigh is abducted and flexed, the tilting downwards and the arching forwards of the pelvis disappear. The condition is thus explained. A limb which is flexed and abducted is obviously useless for progression, and, in order to overcome the difficulty, the patient depresses the affected side of his pelvis in order to produce parallelism of his limbs, and at the same time rotates his pelvis on its transverse horizontal axis, so as to direct the limb downwards, instead of forwards. In the later stages of the disease the limb becomes flexed and adducted and inverted. This position probably depends upon muscular action, at all events as regards the adduction. The Adductor muscles are supplied by the obturator nerve, which also largely supplies the joint. These muscles are therefore thrown into reflex action by the irritation of the peripheral terminations of this nerve in the inflamed articulation.

Osteo-arthritis is not uncommon in the hip-joint, and is said to be more common in the male than in the female, in whom the knee-joint is more frequently affected. It is a disease of middle age or advanced life.

Congenital dislocation is more commonly met with in the hip-joint than in any other articulation. The displacement usually takes place on to the dorsum ilii. It gives rise to extreme lordosis, and a waddling gait is noticed as soon as the child commences to walk.

Excision of the hip may be required for disease or for injury, especially gunshot. It may be performed either by an anterior incision or a posterior one. The former entails less interference with important structures, especially muscles, than the posterior one, but permits of less efficient drainage. In these days, however, when the surgeon aims at securing healing of the wound without suppuration, this second desideratum is not of so much importance. In the operation from the front, an incision is made three to four inches in length, starting immediately below and external to the anterior superior spinous process of the ilium, downwards and inwards between the Sartorius and Tensor fasciæ femoris, to the neck of the bone, dividing the capsule at its upper part. A narrow-bladed saw now divides the neck of the femur, and the head of the bone is extracted with sequestrum forceps. All diseased tissue is carefully removed with a sharp spoon or scissors, and the cavity thoroughly flushed out with a hot antiseptic fluid.

The posterior method consists in making an incision three or four inches long, commencing midway between the top of the great trochanter and the anterior superior spine, and ending over the shaft, just below the trochanter. The muscles are detached from the great trochanter, and the capsule opened freely. The head and neck are freed from the soft parts and the bone sawn through just below the top of the trochanter with a narrow saw. The head of the bone is then levered out of the acetabulum. In both operations, if the acetabulum is eroded, it must be freely gouged.

II. KNEE-JOINT

The knee-joint was formerly described as a ginglymus or hinge-joint, but is really of a much more complicated character. It must be regarded as consisting of three articulations in one: one between each condyle of the femur and the corresponding semilunar cartilage and tuberosity of the tibia, which are condyloid joints, and one between the patella and the femur, which is partly arthrodial, but not completely so, since the articular surfaces are not mutually adapted to each other, so that the movement is not a simple gliding one. This view of the construction of the knee-joint receives confirmation from the study of the articulation in some of the lower mammals, where three synovial membranes are sometimes found, corresponding to these three subdivisions, either entirely

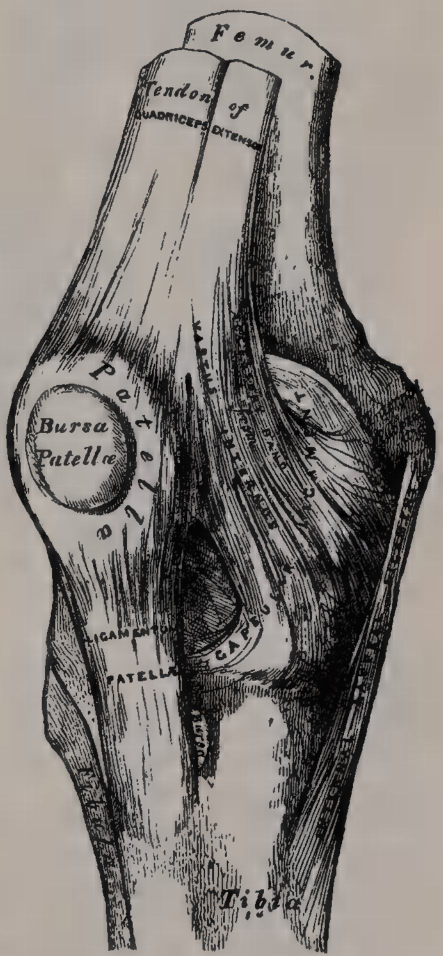
distinct or only connected together by small communications. This view is further rendered probable by the existence of the two crucial ligaments within the joint, which must be regarded as the external and internal lateral ligaments of the inner and outer joints respectively. The existence of the ligamentum mucosum would further indicate a tendency to separation of the synovial cavity into two minor sacs, one corresponding to each joint.

The bones entering into the formation of the knee-joint are the condyles of the femur above, the head of the tibia below, and the patella in front. They are connected together by ligaments, some of which are placed on the exterior of the joint, while others occupy its interior.

External Ligaments	*Interior Ligaments*
Capsular.	Anterior, or External Crucial.
Anterior, or Ligamentum Patellæ.	Posterior, or Internal Crucial.
Posterior, or Ligamentum Posticum Winslowii.	Two Semilunar Fibro-cartilages.
Internal Lateral.	Transverse.
Two External Lateral.	Coronary.
	Ligamentum mucosum } Processes of Synovial membrane.
	Ligamenta alaria } Processes of Synovial membrane.

The **Capsular Ligament** consists of an exceedingly thin, but strong fibrous membrane which fills in the intervals left between the specially named bands, which are constituents of the capsule and inseparably connected with it. Unlike other diarthrodial joints, the capsular ligament does not form a complete investment for the joint, for it is deficient in front and above, beneath the tendon of the Quadriceps extensor. It is largely made up of expansions from the fascia lata and from the tendons surrounding the joint. In front, expansions from the Vasti muscles and fascia lata fill in the interval between the anterior and lateral ligaments, constituting the *lateral patellar ligaments*, and form the anterior part of the capsular ligament. Behind, it consists of vertical fibres which arise from the condyles and intercondyloid notch of the femur, and are augmented by fibres derived from the tendon of the Semimembranosus muscle. Here it forms part of the posterior ligament. On the outer side of the joint, a prolongation from the ilio-tibial band fills in the interval between the posterior and the external lateral ligaments, and partly covers the latter. On the inner side, expansions from the Sartorius and Semimembranosus pass upwards to the internal lateral ligament and strengthen the capsule on the inner side of the joint.

Fig. 377.—Right knee-joint. Anterior view.



The **Anterior Ligament**, or **Ligamentum Patellæ** (fig. 377), is the central portion of the common tendon of the Extensor muscles of the thigh, which is continued from the patella to the tubercle of the tibia, supplying the place of an anterior ligament. It is a strong, flat, ligamentous band, about three inches in length, attached, above, to the apex and adjoining margins of the patella and the rough depression on its posterior surface; below, to the tubercle of the tibia; its superficial fibres being continuous over the front of the patella with those of the tendon of the Quadriceps extensor. The lateral portions of the tendon of the Extensor muscles pass down on either side of the patella, attached to the borders of this

bone and its ligament, to be inserted into the upper extremity of the tibia on each side of the tubercle; externally, these portions merge into the capsular ligament, as stated above, forming the lateral patellar ligaments. The posterior surface of the ligamentum patellæ is separated from the synovial membrane of the joint by a large pad (*infrapatellar*) of fat, and from the tibia by a synovial bursa.

The **Posterior Ligament (Ligamentum Posticum Winslowii)** (fig. 378) is a broad, flat, fibrous band, formed of fasciculi separated from one another by apertures for the passage of vessels and nerves. It is attached above to the upper margin of the intercondyloid notch and posterior surface of the femur close to the articular margins of the condyles, and below to the posterior margin of the head of the tibia. Superficial to the main part of the ligament is a strong fasciculus derived from the tendon of the Semimembranosus, and passing from the back part of the inner tuberosity of the tibia obliquely upwards and

FIG. 378.—Right knee-joint. Posterior view.

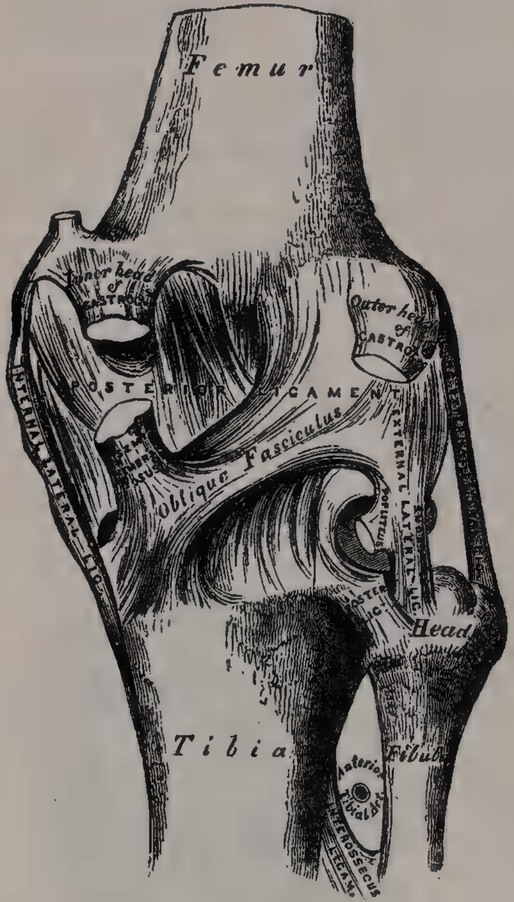


FIG. 379.—Right knee-joint. Showing internal ligaments.

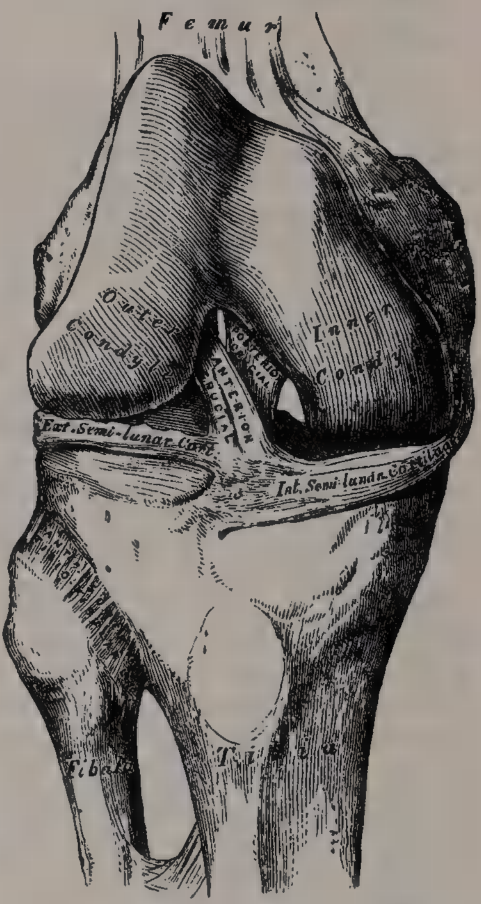


outwards to the back part of the outer condyle of the femur, where it becomes lost in the general ligament.* The posterior ligament forms part of the floor of the popliteal space, and the popliteal artery rests upon it.

The **Internal Lateral Ligament** is a broad, flat, membranous band, situated nearer to the back than the front of the joint. It is attached, above, to the inner tuberosity of the femur immediately below the Adductor tubercle; below, to the inner tuberosity and inner surface of the shaft of the tibia. The fibres of the posterior part of the ligament are short, and are inserted into the inner part of the tuberosity of the tibia above the groove for the Semimembranosus muscle. They incline backwards as they descend. The anterior part of the ligament is a flattened band, about four inches in length, which inclines forwards as it descends. It is inserted into the inner surface of the shaft of the tibia about

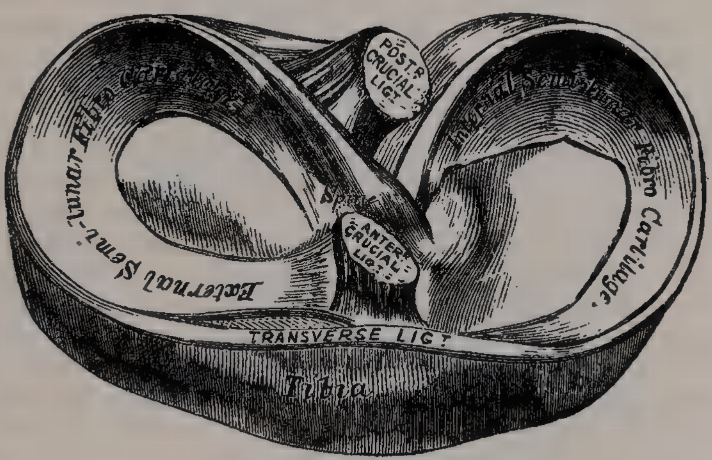
* This oblique band is by some anatomists termed the Ligamentum Posticum Winslowii, in contradistinction to the Posterior ligament, which is regarded as part of the capsular ligament.

an inch and a half below the level of the tuberosity. It is crossed, at its lower part, by the tendons of the Sartorius, Gracilis, and Semitendinosus muscles, a synovial bursa being interposed. Its *deep surface* covers the anterior portion of the tendon of the Semimembranosus, with which it is connected by a few fibres, the synovial membrane of the joint, and the inferior internal articular vessels and nerve; it is intimately adherent to the internal semilunar fibro-cartilage.

The **Long External Lateral Ligament** is a strong, rounded fibrous cord, situated nearer to the back than the front of the joint. It is attached, above, to the back part of the outer tuberosity of the femur, immediately above the groove for the Popliteus muscle; below, to the outer side of the head of the fibula, in front of the styloid process. Its *outer surface* is covered by the tendon of the Biceps, which divides at its insertion into two parts, separated by the ligament. Passing beneath the ligament are the tendon of the Popliteus muscle, and the inferior external articular vessels and nerve. It has no attachment to the external semilunar fibro-cartilage.

The **Short External Lateral Ligament** is an accessory bundle of fibres placed behind and parallel with the preceding, attached, above, to the lower and back part of the outer tuberosity of the femur; below, to the summit of the styloid process of the fibula. This ligament is intimately connected with the capsular

FIG. 380.—Head of tibia, with semilunar fibro-cartilages. Seen from above. Right side.



ligament, while passing beneath it are the tendon of the Popliteus muscle, and the inferior external articular vessels and nerve.

The **Crucial** are two interosseous ligaments of considerable strength, situated in the interior of the joint, nearer its posterior than its anterior part. They are called *crucial* because they cross each other somewhat like the lines of the letter X; and have received the names *anterior* and *posterior*, from the position of their attachment to the tibia.

The **Anterior** or **External Crucial Ligament** (fig. 379) is attached to the depression in front of the spine of the tibia, being blended with the anterior extremity of the external semilunar fibro-cartilage, and passing obliquely upwards, backwards, and outwards, is inserted into the inner and back part of the outer condyle of the femur.

The **Posterior** or **Internal Crucial Ligament** is stronger, but shorter and less oblique in its direction, than the anterior. It is attached to the back part of the depression behind the spine of the tibia, to the popliteal notch, and to the posterior extremity of the external semilunar fibro-cartilage; and passes upwards, forwards, and inwards, to be inserted into the outer and fore part of the inner condyle of the femur. It is in relation, in front, with the anterior crucial ligament; behind, with the capsular ligament.

The **Semilunar Fibro-cartilages** (fig. 380) are two crescentic lamellæ, which serve to deepen the surfaces of the head of the tibia, for articulation with the condyles of the femur. The circumferential border of each cartilage is thick, convex, and attached to the inside of the capsule of the knee; the border which

is directed towards the centre of the joint is thin, concave, and free. Their upper surfaces are concave, and in relation with the condyles of the femur; their lower surfaces are flat, and rest upon the head of the tibia. Each cartilage covers nearly the peripheral two-thirds of the corresponding articular surface of the tibia; both surfaces of the cartilages are smooth, and invested by synovial membrane.

The **Internal Semilunar Fibro-cartilage** is nearly semicircular in form, a little elongated from before backwards, and broader behind than in front; its anterior extremity, thin and pointed, is attached to a depression on the anterior margin of the head of the tibia, in front of the anterior crucial ligament; its posterior extremity is attached to the depression behind the spine, between the attachments of the external semilunar fibro-cartilage and the posterior crucial ligaments.

The **External Semilunar Fibro-cartilage** forms nearly an entire circle, covering a larger portion of the articular surface than the internal one. It is grooved on its outer side for the tendon of the Popliteus muscle, which separates it from the external lateral ligament. Its extremities, at their insertion, are interposed between the two extremities of the internal semilunar fibro-cartilage; the anterior extremity being attached in front of the spine of the tibia to the outer side of, and behind, the anterior crucial ligament, with which it blends; the posterior extremity being attached behind the spine of the tibia and in front of the posterior extremity of the internal semilunar fibro-cartilage. Just before its insertion posteriorly it gives off a strong fasciculus, the *ligament of Wrisberg*, which passes obliquely upwards and inwards, to be inserted into the inner condyle of the femur, close to and behind the attachment of the posterior crucial ligament. Occasionally a small fasciculus is given off, which passes forwards to be inserted into the back part of the anterior crucial ligament. The external semilunar fibro-cartilage gives off from its anterior convex margin a fasciculus, which forms the transverse ligament.

The **Transverse Ligament** is a band of fibres which passes transversely from the anterior convex margin of the external semilunar fibro-cartilage to the anterior convex margin of the internal semilunar fibro-cartilage; its thickness varies considerably in different subjects, and it is sometimes absent altogether.

The **Coronary Ligaments** are merely portions of the capsular ligament, which connect the circumference of each of the semilunar fibro-cartilages with the margin of the head of the tibia.

The **Synovial Membrane** of the knee-joint is the largest and most extensive in the body. Commencing at the upper border of the patella, it forms a short *cul-de-sac* beneath the Quadriceps extensor tendon of the thigh, on the lower part of the front of the shaft of the femur: this very frequently communicates with a synovial bursa interposed between the tendon and the front of the femur, by an orifice of variable size. On each side of the patella, the synovial membrane extends beneath the aponeurosis of the Vasti muscles, and more especially beneath that of the Vastus internus. Below the patella it is separated from the anterior ligament by a considerable quantity of adipose tissue, known as the *infrapatellar pad*. In this situation it sends off a triangular prolongation, which extends from the anterior part of the joint below the patella, to the front of the intercondyloid notch. This fold has been termed the **ligamentum mucosum**. It also sends off two fringe-like folds, called the **ligamenta alaria**, which extend from the sides of the ligamentum mucosum, upwards and laterally between the patella and femur. On either side of the joint, it passes downwards from the femur, lining the capsule to its point of attachment to the semilunar cartilages; it may then be traced over the upper surfaces of these cartilages to their free borders, and thence along their under surfaces to the tibia. At the back part of the external one it forms a *cul-de-sac* between the groove on its surface and the tendon of the Popliteus; it surrounds the crucial ligaments, and lines the inner surface of the ligaments which enclose the joint. The pouch of synovial membrane between the Extensor tendon and front of the femur is supported, during the movements of the knee, by a small muscle, the Subcrureus, which is inserted into it.

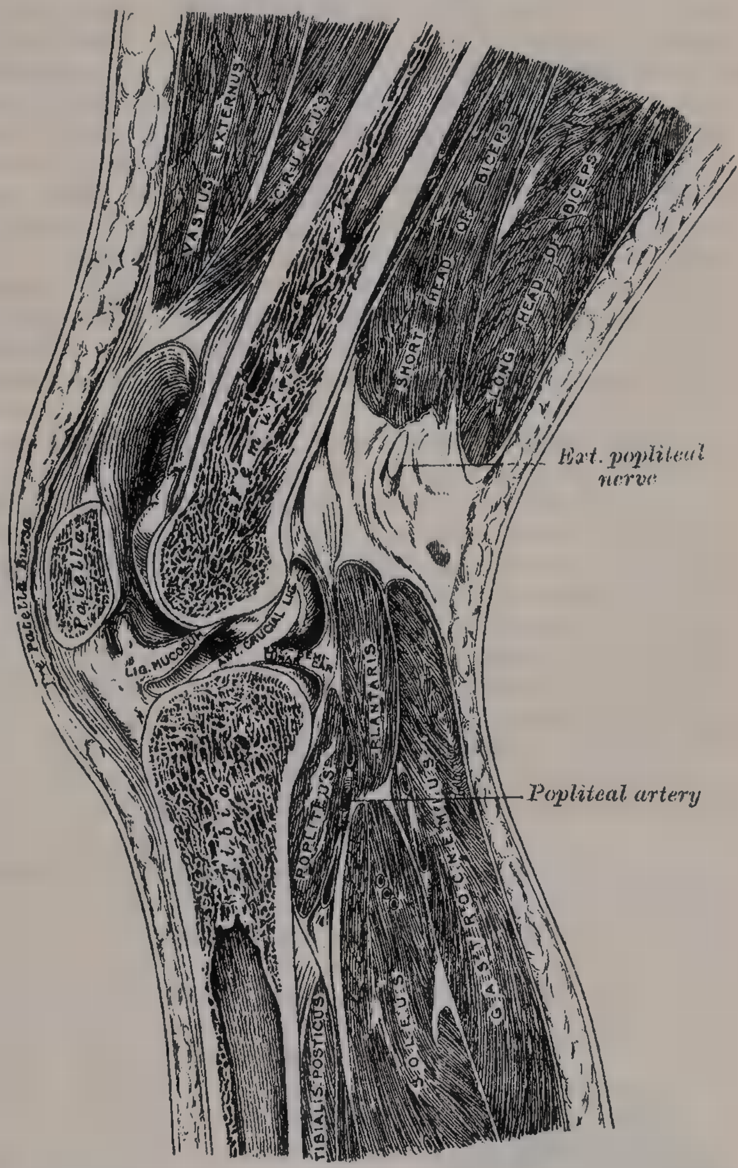
The folds of synovial membrane and the fatty processes contained in them act, as it seems, mainly as padding to fill up interspaces and obviate concussion. Sometimes the bursa beneath the Quadriceps extensor is completely shut off from the rest of the synovial cavity, thus forming a closed sac between the Quadriceps

and the lower part of the front of the femur; or it may communicate with the synovial cavity by a minute aperture.

The bursæ about the knee-joint are the following:

In front there are four bursæ: one is interposed between the patella and the skin; another of small size between the upper part of the tibia and the ligamentum patellæ; a third between the lower part of the tuberosity of the tibia and the skin; and a fourth between the anterior surface of the lower end of the femur and the under surface of the Quadriceps extensor cruris, which usually communicates with the synovial membrane of the knee-joint. On the outer side there are four bursæ: (1) one beneath the outer head of the Gastrocnemius (which sometimes communicates with the joint); (2) one above the external lateral ligament, between it and the tendon of the Biceps; (3) one beneath the external lateral ligament, between it and the tendon of the Popliteus (this is sometimes only an expansion from the next bursa); (4) one beneath the tendon of the Popliteus, between it and the condyle of the femur, which is almost always an extension from the synovial membrane. On the inner side there are five bursæ: (1) one beneath the inner head of the Gastrocnemius, which sends a prolongation between the tendons of the Gastrocnemius and Semimembranosus. This bursa often communicates with the joint; (2) one above the internal lateral ligament between it and the tendons of the Sartorius, Gracilis, and Semitendinosus; (3) one beneath the internal lateral ligament between it and the tendon of the Semimembranosus (this is sometimes only an expansion from the next bursa); (4) one beneath the tendon of the Semimembranosus, between it and the head of the tibia; (5) occasionally there is a bursa between the tendons of the Semimembranosus and Semitendinosus.

Fig. 381.—Longitudinal section through the middle of the right knee-joint. (After Braune.)



Structures around the Joint.—In front, and at the sides, the Quadriceps extensor; on the outer side, the tendons of the Biceps and the Popliteus and the external popliteal nerve; on the inner side, the Sartorius, Gracilis, Semitendinosus and Semimembranosus; behind, an expansion from the tendon of the Semimembranosus, the popliteal vessels, and the internal popliteal nerve, Popliteus, Plantaris, and inner and outer heads of the Gastrocnemius, some lymphatic glands, and fat.

The *Arteries* supplying the joint are the anastomotica magna, a branch of

the femoral, the articular branches of the popliteal, the anterior and posterior recurrent branches of the anterior tibial, and the descending branch from the external circumflex of the profunda.

The *Nerves* are derived from the obturator, anterior crural, and external and internal popliteal.

Actions.—The knee-joint permits of movements of flexion and extension, and, in certain positions, of slight rotation inwards and outwards. The movement of flexion and extension does not, however, take place in a simple hinge-like manner, as in other joints, but is a complicated movement, consisting of a certain amount of gliding and rotation; so that the same part of one articular surface is not always applied to the same part of the other articular surface, and the axis of motion is not a fixed one. If the joint is examined while in a condition of extreme flexion, the posterior part of the articular surfaces of the tibia will be found to be in contact with the posterior rounded extremities of the condyles of the femur; and if a simple hinge-like movement were to take place, the axis, round which the revolving movement of the tibia occurs, would be in the back part of the condyle. If the leg be now brought forwards into a position of semi-flexion, the upper surface of the tibia will be seen to glide over the condyles of the femur, so that the middle part of the articular facets are in contact, and the axis of rotation must therefore have shifted forwards to nearer the centre of the condyles. If the leg be now fully extended, a still further gliding takes place, and a further shifting forwards of the axis of rotation. This is not, however, a simple movement, but is accompanied by a certain amount of rotation outwards round a vertical axis drawn through the centre of the head of the tibia. This rotation is due to the greater length of the internal condyle and to the fact that the anterior portion of its articular surface is inclined obliquely outwards. In consequence of this, it will be seen that towards the close of the movement of extension—that is to say, just before complete extension is effected—the tibia glides upwards and outwards over this oblique surface on the inner condyle, and the leg is therefore necessarily rotated outwards. In flexion of the joint the converse of these movements takes place: the tibia glides backwards round the end of the femur, and at the commencement of the movement the tibia is directed downwards and inwards along the oblique curve of the inner condyle, thus causing an inward rotation to the leg.

During flexion and extension, the patella moves on the lower end of the femur, but this movement is not a simple gliding one; for if the articular surface of this bone is examined, it will be found to present on each side of the central vertical ridge two less marked transverse ridges, which divide the surface, except a small portion along the inner border, which is cut off by a slight vertical ridge, into six facets (see fig. 382), and therefore does not present a uniform curved surface, as would be the case if a simple gliding movement took place. These six facets—three on each side of the median vertical ridge—correspond to and denote the parts of the bone respectively in contact with the condyles of the femur during flexion, semiflexion, and extension. In flexion, only the upper facets on the patella are in contact with the condyles of the femur; the lower two-thirds of the bone rests upon the mass of fat which occupies the space between the femur and tibia. In the semiflexed position of the joint, the middle facets on the patella rest upon the most prominent portion of the condyles, and thus afford greater leverage to the Quadriceps by increasing its distance from the centre of motion. In complete extension the patella is drawn up so that only the lower facets are in contact with the articular surfaces of the condyles. The narrow strip along the inner border is in contact with the outer aspect of the internal condyle when the leg is fully flexed at the knee-joint. As in the elbow, so it is in the knee—the axis of rotation in flexion and extension is not precisely at right angles to the axis of the bone, but during flexion there is a certain amount of alteration of plane; so that, whereas in flexion the femur and tibia are in the same plane, in extension the one bone

Fig. 382.—View of the posterior surface of the right patella. Showing diagrammatically the areas of contact with the femur in different positions of the knee.

forms an angle with the other. There is, however, this difference between the two extremities—that in the upper, during extension, the humeri are parallel, and the bones of the forearm diverge; in the lower, the femora converge below, and the tibiæ are parallel.

In addition to the slight rotation during flexion and extension, the tibia enjoys an independent rotation on the condyles of the femur, in certain positions of the joint. The movement takes place between the interarticular fibro-cartilages and the tibia, whereas the movement of flexion and extension takes place between the interarticular fibro-cartilages and the femur. So that the knee may be said to consist of two joints, separated by the fibro-cartilages: an upper (menisco-femoral), in which flexion and extension take place; and a lower (menisco-tibial), allowing of a certain amount of rotation. The latter movement can only take place in the semiflexed position of the limb, when all the ligaments are relaxed.

During *flexion* the ligamentum patellæ is put upon the stretch, as is also the posterior crucial ligament in extreme flexion. The other ligaments are all relaxed by flexion of the joint, though the relaxation of the anterior crucial ligament is very trifling. Flexion is only checked during life by the contact of the leg with the thigh. In the act of extending the leg upon the thigh the ligamentum patellæ is tightened by the Quadriceps extensor; but when the leg is fully extended, as in the erect posture, the ligament becomes relaxed, so as to allow free lateral movement to the patella, which then rests on the front of the lower end of the femur. The other ligaments, with the exception of the posterior crucial, which is partly relaxed, are all on the stretch. When the limb has been brought into a straight line, extension is checked mainly by the tension of all the ligaments except the posterior crucial and ligamentum patellæ. The movements of *rotation*, of which the knee is capable, are permitted in the semiflexed condition by the partial relaxation of both crucial ligaments, as well as the lateral ligaments. Rotation inwards appears to be limited by the tension of the anterior crucial ligament, and by the interlocking of the two ligaments; but rotation outwards does not appear to be checked by either crucial ligament, since they uncross during the execution of this movement, but by the lateral ligaments, especially the internal. The main function of the crucial ligaments is to act as a direct bond of union between the tibia and femur, preventing the former bone from being carried too far backwards or forwards. Thus the anterior crucial ligament prevents the tibia from being carried too far forwards by the Extensor tendons, and the posterior crucial checks too great movement backwards by the Flexors. They also assist the lateral ligaments in resisting any lateral bending of the joint. The interarticular cartilages are intended, as it seems, to adapt the surface of the tibia to the shape of the femur to a certain extent, so as to fill up the intervals which would otherwise be left in the varying positions of the joint, and to interrupt the jars which would be so frequently transmitted up the limb in jumping or falls on the feet; also to permit of the two varieties of motion, flexion and extension, and rotation, as explained above. The patella is a great defence to the knee-joint from any injury inflicted in front, and it distributes upon a large and tolerably even surface, during kneeling, the pressure which would otherwise fall upon the prominent ridges of the condyles; it also affords leverage to the Quadriceps extensor muscle to act upon the tibia, and Ward has pointed out* how this leverage varies in the various positions of the joint, so that the action of the muscle produces velocity at the expense of force in the commencement of extension, and, on the contrary, at the close of extension tends to diminish velocity, and therefore the shock to the ligaments at the moment tension of these structures takes place.

Extension of the leg on the thigh is performed by the Quadriceps extensor. *Flexion* by the hamstring muscles, assisted by the Gracilis and Sartorius, and, indirectly, by the Gastrocnemius, Popliteus, and Plantaris. *Rotation outwards* by the Biceps, and *rotation inwards* by the Popliteus, Semitendinosus, and, to a slight extent, the Semimembranosus, the Sartorius, and the Gracilis.

Surface Form.—The interval between the two bones entering into the formation of the knee-joint can always easily be felt. If the limb is extended, it is situated on a slightly higher level than the apex of the patella; but if the limb is slightly flexed, a knife carried

* *Human Osteology*, p. 405.

horizontally backwards immediately below the apex of the patella would pass directly into the joint. When the knee is semiflexed, the internal border of the inner condyle of the femur, the upper border of the inner tuberosity of the tibia, and the inner margin of the patella form a triangular depressed area, which coincides with the level of the joint and with the internal semilunar fibro-cartilage. If this cartilage is displaced inwards, a gap will be felt in this situation. When the knee-joint is distended with fluid, the outline of the synovial membrane at the front of the knee may be fairly well mapped out.

Surgical Anatomy.—From a consideration of the construction of the knee-joint, it would at first sight appear to be one of the least secure of any of the joints in the body. It is formed between the two longest bones, and therefore the amount of leverage which can be brought to bear upon it is considerable; the articular surfaces are but ill adapted to each other, and the range and variety of motion which it enjoys are great. All these circumstances tend to render the articulation insecure; but, nevertheless, on account of the powerful ligaments which bind the bones together, the joint is one of the strongest in the body, and dislocation from traumatism is a rare occurrence. When, on the other hand, the ligaments have been softened or destroyed by disease, partial displacement is liable to occur, and is frequently brought about by the mere action of the muscles displacing the articular surfaces from each other. The tibia may be dislocated in any direction from the femur—forwards, backwards, inwards, or outwards; or a combination of two of these dislocations may occur—that is, the tibia may be dislocated forwards and laterally, or backwards and laterally; and any of these dislocations may be complete or incomplete. As a rule, however, the antero-posterior dislocations are complete, the lateral ones incomplete.

One or other of the semilunar cartilages may become displaced and nipped between the femur and tibia. The accident is produced by a twist of the leg when the knee is flexed, and is accompanied by a sudden pain and fixation of the knee in a flexed position. The cartilage may be displaced either inwards or outwards: that is to say, either inwards towards the tibial spine, so that the cartilage becomes lodged in the intercondyloid notch; or outwards, so that the cartilage projects beyond the margin of the two articular surfaces.

Acute synovitis, the result of traumatism or exposure to cold, is very common in the knee, on account of its superficial position. When distended with fluid, the swelling shows itself above and at the sides of the patella, reaching about an inch, occasionally two inches or more, above the trochlear surface of the femur, and extending a little higher under the Vastus internus than the Vastus externus. The swelling extends lower at the inner side of the patella than it does on its outer side. The lower level of the synovial membrane is just above the level of the upper part of the head of the fibula. In the middle line it covers the upper third of the ligamentum patellæ, being separated from it, however, by the infrapatellar of pad fat. Chronic synovitis principally shows itself in the form of pulpy degeneration of the synovial membrane, leading to tuberculous arthritis. The reasons why tuberculous disease of the knee usually commences in the synovial membrane appear to be the complex and extensive nature of this sac; the extensive vascular supply to it; and the fact that injuries are generally diffused and applied to the front of the joint rather than to the ends of the bones. Syphilitic disease not infrequently attacks the knee-joint. In the hereditary form of the disease it is usually symmetrical, attacking both joints, which become filled with synovial effusion, and is very intractable and difficult of cure. In the tertiary form of the disease, gummatous infiltration of the synovial membrane may take place. The knee is one of the joints most commonly affected with osteo-arthritis, and is said to be more frequently the seat of this disease in women than in men. The occurrence of the so-called loose cartilages is almost confined to the knee, though they are occasionally met with in the elbow, and, rarely, in some other joints. Many of them occur in cases of osteo-arthritis, in which calcareous or cartilaginous material is formed in one of the synovial fringes and constitutes the foreign body, and may or may not become detached, in the former case only meriting the usual term, 'loose' cartilage. In other cases they have their origin in the exudation of inflammatory lymph, and possibly, in some rare instances, a portion of the articular cartilage or one of the semilunar cartilages becomes detached and constitutes the foreign body.

In inflammatory affections of the knee-joint, the position of greatest ease, and therefore the one which is always assumed, is that of slight flexion. In this position there is the most complete relaxation of ligamentous structures, and therefore the greatest diminution in the tension caused by the effusion. If this flexed position is maintained for any length of time, it becomes permanent from fibrous adhesions taking place, and the utility of the limb is materially impaired. Attention should therefore be paid by the surgeon to the position of the limb; and by carefully applied splints, with the leg in an extended position, this untoward result should be prevented. In cases of septic synovitis, incisions to evacuate the pus should be made vertically on either side of the patella, between it and the condyles of the femur: a drainage tube can then be passed across the joint from one side to the other.

Genu valgum, or knock knee, is a common deformity of childhood, in which, owing to

changes in and about the joint, the angle between the outer border of the tibia and femur is diminished, so that as the patient stands the two internal condyles of the femora are in contact, but the two internal malleoli of the tibiæ are more or less widely separated from each other. When, however, the knees are flexed to a right angle, the two legs are practically parallel with each other. At the commencement of the disease there is a yielding of the internal lateral ligament and other fibrous structures on the inner side of the joint; as a result of this there is a constant undue pressure of the outer tuberosity of the tibia against the outer condyle of the femur. This extra pressure causes arrest of growth and, possibly, wasting of the outer condyle, and a consequent tendency for the tibia to become separated from the internal condyle. To prevent this the internal condyle becomes depressed; probably, as was first pointed out by Mickulicz, by an increased growth of the lower end of the diaphysis on its inner side, so that the line of the epiphysis becomes oblique instead of transverse to the axis of the bone, with a direction downwards and inwards.

Genu varum is a deformity in which the knees are widely separated, the femur and tibia being curved outwards. In early life, the disease is due to rickets; in advanced life, it may be due to osteitis deformans.

Excision of the knee-joint is most frequently required for tuberculous disease of this articulation, but is also practised in cases of disorganisation of the knee after rheumatic fever, pyæmia, &c., in osteo-arthritis, and in old neglected infantile paralysis, when there is a flail-like, distorted limb. It is also occasionally called for in cases of injury, gunshot or otherwise. The operation is best performed either by a horse-shoe incision, starting from one condyle, descending as low as the tubercle of the tibia, where it crosses the front of the leg, and then carried upward to the other condyle; or by a transverse incision across the patella. In this latter incision the patella is either removed or sawn across, and the halves subsequently sutured together. The bone having been cleared, and in those cases where the operation is performed for tuberculous disease, all pulpy tissue having been carefully removed, the section of the femur is first made. This should never include, in children, more than, at the most, two-thirds of the articular surface, otherwise the epiphysial cartilage will be involved, with disastrous results as regards the growth of the limb. Afterwards a thin slice should be removed from the upper end of the tibia, not more than half an inch. If any diseased tissue still appears to be left in the bones, it should be removed with the gouge, rather than that a further section of the bones should be made.

The bursæ about the knee-joint are sometimes the seat of enlargement. The prepatellar bursa—i.e. the bursa between the front of the patella and the skin—is frequently affected in individuals who are in the habit of constantly kneeling, and it is then known as 'housemaid's knee.' The bursa beneath the Semimembranosus tendon also constantly becomes enlarged, and forms a fluctuating swelling at the back of the knee. During extension, the swelling is firm and tense; but during flexion it becomes soft, and, as the bursa often communicates with the synovial membrane, the fluid it contains, when enlarged, can be made to disappear by pressure when the knee is flexed.

III. ARTICULATIONS BETWEEN THE TIBIA AND FIBULA

The articulations between the tibia and fibula are affected by ligaments which connect both extremities, as well as the shafts of the bones. They may, consequently, be subdivided into three sets: 1. The Superior Tibio-fibular articulation. 2. The Middle Tibio-fibular ligament or interosseous membrane. 3. The Inferior Tibio-fibular articulation.

1. Superior Tibio-fibular Articulation

This articulation is an arthrodial joint. The contiguous surfaces of the bones present two flat, oval facets covered with cartilage, and connected together by the following ligaments:

Capsular.

Anterior Superior Tibio-fibular. Posterior Superior Tibio-fibular.

The **Capsular Ligament** surrounds the articulation, being attached round the margins of the articular facets on the tibia and fibula, and is much thicker in front than behind.

The **Anterior Superior Ligament** (fig. 379) consists of two or three broad and flat bands, which pass obliquely upwards and inwards from the front of the head of the fibula to the front of the outer tuberosity of the tibia.

The **Posterior Superior Ligament** (fig. 378) is a single thick and broad band, which passes upwards and inwards from the back part of the head of the

fibula to the back part of the outer tuberosity of the tibia. It is covered by the tendon of the Popliteus muscle.

A **Synovial Membrane** lines this articulation, which at its upper and back part is occasionally continuous with that of the knee-joint.

2. Middle Tibio-fibular Ligament or Interosseous Membrane

An interosseous membrane extends between the contiguous margins of the tibia and fibula, and separates the muscles on the front from those on the back of the leg. It consists of a thin, aponeurotic lamina composed of oblique fibres, which for the most part pass downwards and outwards between the interosseous ridges on the two bones; some few fibres, however, pass in the opposite direction, downwards and inwards. It is broader above than below. Its upper margin does not quite reach the superior tibio-fibular joint, but presents a free concave border, above which is a large, oval aperture for the passage of the anterior tibial vessels forwards to the anterior aspect of the leg. At its lower part is an opening for the passage of the anterior peroneal vessels. It is continuous below with the inferior interosseous ligament; and is perforated in numerous parts for the passage of small vessels. It is in relation, in front, with the Tibialis anticus, Extensor longus digitorum, Extensor proprius hallucis, Peroneus tertius, and the anterior tibial vessels and nerve; behind, with the Tibialis posticus and Flexor longus hallucis.

3. Inferior Tibio-fibular Articulation

This articulation is formed by the rough, convex surface of the inner side of the lower end of the fibula, connected with a concave rough surface on the outer side of the tibia. Below, to the extent of about two lines, these surfaces are smooth, and covered with cartilage, which is continuous with that of the ankle-joint. The ligaments of this joint are—

Anterior Inferior Tibio-fibular.	Transverse or Inferior.
Posterior Inferior Tibio-fibular.	Inferior Interosseous.

The **Anterior Inferior Ligament** (fig. 384) is a flat, triangular band of fibres, broader below than above, which extends obliquely downwards and outwards between the adjacent margins of the tibia and fibula, on the front aspect of the articulation. It is in relation, in front, with the Peroneus tertius, the aponeurosis of the leg, and the integument; behind, with the inferior interosseous ligament; and lies in contact with the cartilage covering the astragalus.

The **Posterior Inferior Ligament,** smaller than the preceding, is disposed in a similar manner on the posterior surface of the articulation.

The **Transverse** or **Inferior Ligament** lies under cover of the posterior ligament, and is a strong, thick band of yellowish fibres which passes transversely across the back of the joint, from the external malleolus to the posterior border of the articular surface of the tibia, almost as far as its malleolar process. This ligament projects below the margin of the bones, and forms part of the articulating surface for the astragalus.

The **Inferior Interosseous Ligament** consists of numerous short, strong, fibrous bands, which pass between the contiguous rough surfaces of the tibia and fibula, and constitute the chief bond of union between the bones. This ligament is continuous, above, with the interosseous membrane.

The **Synovial Membrane** lining the articular surface is derived from that of the ankle-joint.

Actions.—The movement permitted in these articulations is limited to a very slight gliding of the articular surfaces one upon another.

IV. ANKLE-JOINT

The **Ankle** is a ginglymus, or hinge-joint. The bones entering into its formation are the lower extremity of the tibia and its malleolus, and the external malleolus of the fibula, which form a mortise to receive the upper convex surface of the astragalus and its two lateral facets. The bony surfaces are covered with

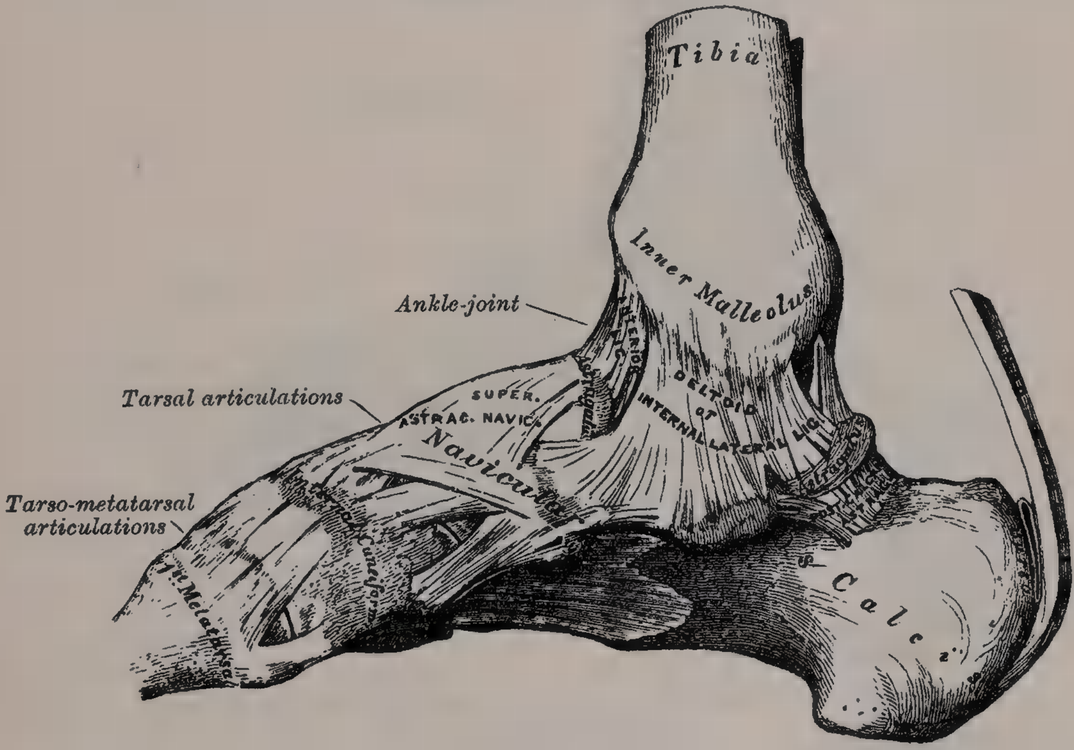
cartilage, and connected by a capsule, which in places forms thickened bands constituting the following ligaments :

	Capsular.	
Anterior.		Internal Lateral.
Posterior.		External Lateral.

The **Capsular Ligament** is an imperfect ligamentous structure which surrounds the joint, and is attached, above, to the borders of the articular surface of the tibia ; and below, to the astragalus around its upper articular surface. The parts of which it is composed vary considerably in strength, and are described under separate names as distinct ligaments. These are :

The **Anterior Ligament** (fig. 383), which is a broad, thin, membranous layer, attached, above, to the anterior margin of the lower extremity of the tibia ; below, to the margin of the astragalus, in front of its articular surface. It is in relation, in front, with the Extensor tendons of the toes, with the tendons of the Tibialis anticus and Peroneus tertius, and the anterior tibial vessels and nerve ; behind, it lies in contact with the synovial membrane.

Fig. 383.—Ankle-joint : tarsal and tarso-metatarsal articulations. Internal view. Right side.



The **Posterior Ligament** is very thin, and consists principally of transverse fibres. It is attached, above, to the margin of the articular surface of the tibia, blending with the transverse tibio-fibular ligament ; below, to the astragalus behind its superior articular facet. Externally, where a somewhat thickened band of transverse fibres is attached to the hollow on the inner surface of the external malleolus, it is thicker than internally.

The **Internal Lateral** or **Deltoid Ligament** is a strong, flat, triangular band, attached, above, to the apex and anterior and posterior borders of the inner malleolus. The most anterior fibres pass forwards to be inserted into the navicular bone and the inner margin of the inferior calcaneo-navicular ligament ; the middle descend almost perpendicularly to be inserted into the sustentaculum tali of the os calcis ; and the posterior fibres pass backwards and outwards to be attached to the inner side of the astragalus. This ligament is sometimes described as consisting of five parts, viz. : *anterior astragalo-tibial*, *posterior astragalo-tibial*, *tibio-navicular*, *calcaneo-tibial*, and *deep astragalo-tibial*. They are only, however, differentiated bands of the one ligament made

in the process of dissection. This ligament is covered by the tendons of the Tibialis posticus and Flexor longus digitorum muscles.

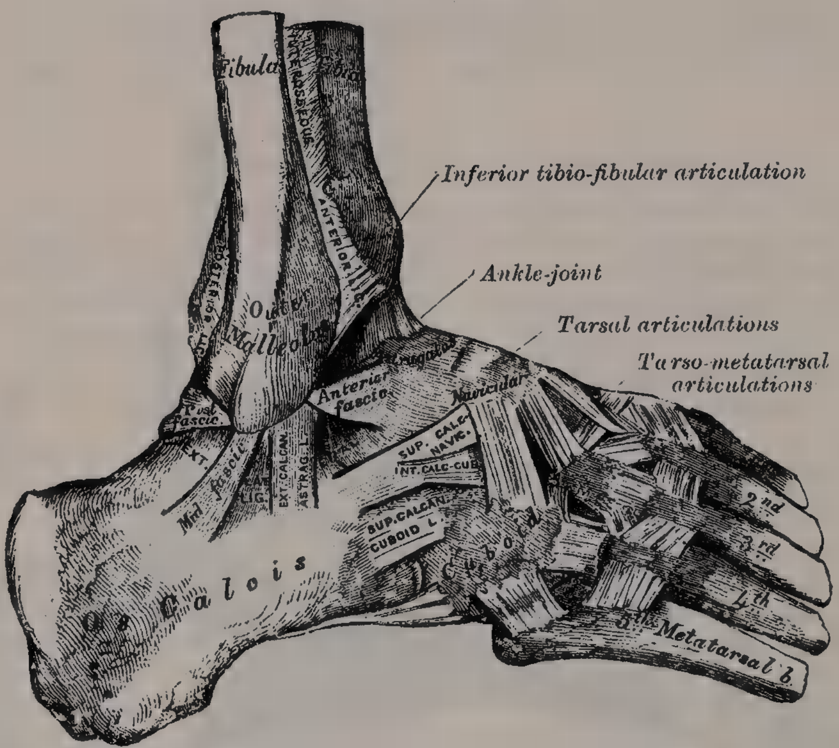
The **External Lateral Ligament** (fig. 384) consists of three distinctly specialised fasciculi of the capsule, taking different directions, and separated by distinct intervals, for which reason it is described by some anatomists as three distinct ligaments.*

The *anterior fasciculus* (anterior astragalo-fibular), the shortest of the three, passes from the anterior margin of the external malleolus, forwards and inwards, to the astragalus, in front of its external articular facet.

The *posterior fasciculus* (posterior astragalo-fibular), the strongest and most deeply seated, passes inwards from the depression at the inner and back part of the external malleolus to a prominent tubercle on the posterior surface of the astragalus. Its fibres are almost horizontal in direction.

The *middle fasciculus* (calcaneo-fibular), the longest of the three, is a narrow, rounded cord, passing from the apex of the external malleolus downwards and

FIG. 384.—Ankle-joint: tarsal and tarso-metatarsal articulations. External view. Right side.



slightly backwards to a tubercle on the outer surface of the os calcis. It is covered by the tendons of the Peroneus longus and brevis.

The **Synovial Membrane** invests the inner surface of the ligaments, and sends a duplicature upwards between the lower extremities of the tibia and fibula for a short distance.

Relations.—The tendons, vessels, and nerves in connection with the joint are, in front, from within outwards, the Tibialis anticus, Extensor proprius hallucis, anterior tibial vessels, anterior tibial nerve, Extensor longus digitorum, and Peroneus tertius; behind, from within outwards, the Tibialis posticus, Flexor longus digitorum, posterior tibial vessels, posterior tibial nerve, Flexor longus hallucis; and, in the groove behind the external malleolus, the tendons of the Peroneus longus and brevis.

The *Arteries* supplying the joint are derived from the malleolar branches of the anterior tibial and the peroneal.

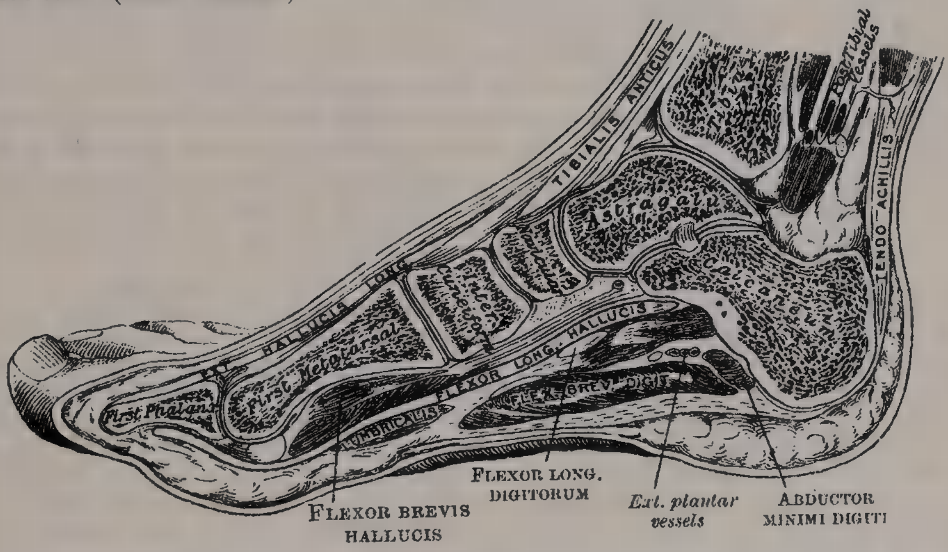
The *Nerves* are derived from the anterior and posterior tibial.

Actions.—It must be borne in mind that when the body is in the erect position, the foot is at right angles to the leg, and therefore the normal position of the ankle-joint is one of flexion. The movements of the joint are those of

* Humphry *On the Skeleton*, p. 559.

dorsiflexion and extension. Dorsiflexion consists in the approximation of the dorsum of the foot to the front of the leg, while in extension the heel is drawn up and the toes pointed downwards. The malleoli tightly embrace the astragalus in all positions of the joint, so that any slight degree of lateral movement which may exist is simply due to stretching of the inferior tibio-fibular ligaments, and slight bending of the shaft of the fibula. Of the ligaments, the internal, or deltoid, is of very great power—so much so, that it usually resists a force which fractures the process of bone to which it is attached. Its middle portion, together with the middle fasciculus of the external lateral ligament, binds the bones of the leg firmly to the foot, and resists displacement in every direction. Its anterior and posterior fibres limit extension and flexion of the foot respectively, and the anterior fibres also limit abduction. The posterior portion of the external lateral ligament assists the middle portion in resisting the displacement of the foot backwards, and deepens the cavity for the reception of the astragalus. The anterior fasciculus is a security against the displacement of the foot forwards, and limits extension of the joint. The movements of inversion and eversion of the foot, together with the minute changes in form by which it is applied to the ground or takes hold of an object in climbing, &c., are mainly

Fig. 385.—Section of the right foot near its inner border, dividing the tibia, astragalus, navicular, internal cuneiform, and first metatarsal bone, and the first phalanx of the great toe. (After Braune.)



effected in the tarsal joints; the one which enjoys the greatest amount of motion being that between the astragalus and os calcis behind, and the navicular and cuboid in front. This is often called the *transverse* or *medio-tarsal joint*, and it can, with the subordinate joints of the tarsus, replace the ankle-joint in a great measure when the latter has become ankylosed.

Extension of the foot upon the tibia and fibula is produced by the Gastrocnemius, Soleus, Plantaris, Tibialis posticus, Peroneus longus and brevis, Flexor longus digitorum, and Flexor longus hallucis. *Dorsiflexion*, by the Tibialis anticus, Peroneus tertius, Extensor longus digitorum, and Extensor proprius hallucis.* *Inversion*, in the extended position, is produced by the Tibialis anticus and posticus; and *eversion* by the Peronei.

Surface Form.—The line of the ankle-joint may be indicated by a transverse line drawn across the front of the lower part of the leg, about half an inch above the level of the tip of the internal malleolus. It can be felt on either side of the Extensor tendons; and during extension of the foot, the superior saddle-shaped facet of the astragalus can be plainly perceived below the anterior border of the lower end of the tibia.

Surgical Anatomy.—As the ankle-joint is a very strong and powerful articulation, displacement of the trochlear surface of the astragalus from the tibio-fibular mortise is not of

* The student must bear in mind that the Extensor longus digitorum and Extensor proprius hallucis are *extensors* of the toes, but *flexors* of the ankle; and that the Flexor longus digitorum and Flexor longus hallucis are *flexors* of the toes, but *extensors* of the ankle.

common occurrence, and great force is required to produce it. Nevertheless, dislocation does occasionally occur, both in an antero-posterior and a lateral direction. In the latter, which is the more common, fracture is a necessary accompaniment of the injury. The dislocation in these cases is somewhat peculiar, and is not a displacement in a horizontally lateral direction, such as usually occurs in lateral dislocations of ginglymoid joints, but the astragalus undergoes a partial rotation round an antero-posterior axis drawn through its own centre, so that the superior surface, instead of being directed upwards, is inclined more or less inwards or outwards according to the variety of the displacement.

The ankle-joint is more frequently sprained than any joint in the body, and this may lead to acute synovitis. In these cases, when the synovial sac is distended with fluid, the bulging appears principally in the front of the joint, beneath the anterior tendons, and on either side, between the Tibialis anticus and the internal lateral ligament on the inner side, and between the Peroneus tertius and the external lateral ligament on the outer side. In addition to this, bulging often occurs posteriorly, and a fluctuating swelling may be detected on either side of the tendo Achillis.

Chronic synovitis may result from constant sprains, and when once this joint has been sprained it is more liable to a recurrence of the injury than it was before; or the synovitis may be tuberculous in its origin, the disease usually commencing in the astragalus and extending to the joint, though it may commence as a synovitis the result probably of some slight strain in a tuberculous subject.

Excision of the ankle-joint is not often performed, for two reasons. In the first place, disease of the articulation for which this operation is indicated is frequently associated with disease of the tarsal bones, which prevents its performance; and, secondly, the foot after excision is often of very little use; far less, in fact, than after a Symes's amputation, which is, therefore, a preferable operation in these cases. Excision, may, however, be attempted in cases of tuberculous arthritis, in a young and otherwise healthy subject, where the disease is limited to the bones forming the joint. It may also be required after injury, where the vessels and nerves have not been damaged and the patient is young and free from visceral disease. The excision is best performed by two lateral incisions. One commencing two and a half inches above the external malleolus, carried down the posterior border of the fibula, round the end of this bone, and then forwards and downwards as far as the calcaneo-cuboid joint, midway between the tip of the external malleolus and the tuberosity on the fifth metatarsal bone. Through this incision the fibula is cleared, the external lateral ligament is divided, and the bone sawn through about half an inch above the level of the ankle-joint and removed. A similar curved incision is now made on the inner side of the foot, commencing two and a half inches above the lower end of the tibia, carried down the posterior border of the bone, round the internal malleolus and forwards and downwards to the tuberosity of the navicular bone. Through this incision the tibia is cleared in front and behind, the internal lateral, the anterior and posterior ligaments divided, and the end of the tibia protruded through the wound by displacing the foot outwards, and sawn off sufficiently high to secure a healthy section of bone. The articular surface of the astragalus is now to be sawn off or the whole bone removed. In cases where the operation is performed for tuberculous arthritis, the latter course is probably preferable, as the injury done by the saw is frequently the starting point of fresh caries; and after removal of the whole bone the shortening is not appreciably increased, and the result as regards union appears to be as good as when two sawn surfaces of bone are brought into apposition.

V. ARTICULATIONS OF THE TARSUS

1. Articulations of the Os Calcis and Astragalus

The articulations between the os calcis and astragalus are two in number—anterior and posterior. Of these, the anterior forms part of the joint between the os calcis, astragalus, and navicular bone, and will be described hereafter as the astragalo-calcaneo-navicular articulation. The posterior or astragalo-calcanean articulation is formed between the posterior and larger facet on the inferior surface of the astragalus, and the external facet on the superior surface of the os calcis. It is an arthrodial joint, and the two bones are connected together by the following ligaments:

Capsular.
External Calcaneo-astragaloid.
Internal Calcaneo-astragaloid.
Posterior Calcaneo-astragaloid.
Anterior Calcaneo-astragaloid.
Interosseous.

The **Capsular Ligament** surrounds the two articular surfaces, and consists for the most part of short fibres, which are split up into distinct slips, which form the specially named ligaments of the articulation; between them there is only a weak fibrous investment.

The **External Calcaneo-astragaloid Ligament** (fig. 384) is a short, strong fasciculus, passing from the outer surface of the astragalus, immediately beneath its external malleolar facet, to the outer surface of the os calcis. It is placed in front of the middle fasciculus of the external lateral ligament of the ankle-joint, with the fibres of which it is parallel.

The **Internal Calcaneo-astragaloid Ligament** is a band of fibres connecting the internal tubercle of the back of the astragalus with the back of the sustentaculum tali. Its fibres blend with those of the inferior calcaneo-navicular ligament.

The **Posterior Calcaneo-astragaloid Ligament** (fig. 383) connects the external tubercle of the astragalus with the upper and inner part of the os calcis; it is a short band, the fibres of which radiate from their narrow attachment to the astragalus.

The **Anterior Calcaneo-astragaloid Ligament** extends from the front and outer surface of the neck of the astragalus to the superior surface of the os calcis. It forms the posterior boundary of the anterior calcaneo-astragaloid joint, and is sometimes described as the *anterior interosseous ligament.*

The **Interosseous Ligament** forms the chief bond of union between the bones. It is, in fact, the united capsular ligaments of the two joints mentioned above, the astragalo-calcaneo-navicular and the astragalo-calcanean, and consists of two partially united layers of fibres, one belonging to the anterior and the other to the posterior joint. It is attached by one extremity to the groove between the articulating facets on the under surface of the astragalus; by the other, to a corresponding depression on the upper surface of the os calcis. It is very thick and strong, being at least an inch in breadth from side to side, and serves to unite the os calcis and astragalus solidly together.

The **Synovial Membrane** (fig. 387) lines the capsule of the joint, and is distinct from the other synovial membranes of the tarsus.

Actions.—The movements permitted between the astragalus and os calcis are limited to a gliding of the one bone on the other in a direction from before backwards, and from side to side.

2. Articulation of the Astragalus with the Os Calcis and Navicular Bone

The articulation between the astragalus and navicular is an arthrodial joint: the rounded head of the astragalus being received into the concavity formed by the posterior surface of the navicular, the anterior articulating surface of the calcaneum, and the upper surface of the inferior calcaneo-navicular ligament, which are all directly continuous with each other. There are two ligaments in this joint:

Capsular. Superior Astragalo-navicular.

The **Capsular Ligament** consists of an imperfectly developed layer of fibres, except posteriorly, where they become greatly increased, and form, with a part of the capsule of the astragalo-calcanean joint, the strong interosseous ligament which fills in the canal formed by the opposing grooves on the os calcis and astragalus, as above mentioned.

The **Superior Astragalo-navicular Ligament** is a broad band, which passes obliquely forwards from the neck of the astragalus to the superior surface of the navicular bone. It is thin, and weak in texture, and covered by the Extensor tendons. The inferior calcaneo-navicular supplies the place of an inferior ligament.

The **Synovial Membrane** lines all parts of the capsule of the joint.

Actions.—This articulation permits of considerable mobility; but its feebleness is such as to allow occasionally of dislocation of the other bones of the tarsus from the astragalus.

3. Articulations of the Os Calcis with the Cuboid

The ligaments connecting the os calcis with the cuboid are five in number:

Capsular

Dorsal { Superior Calcaneo-cuboid.
Internal Calcaneo-cuboid (Interosseous).

Plantar { Long Calcaneo-cuboid.
Short Calcaneo-cuboid.

The **Capsular Ligament** is an imperfectly developed layer, in which are certain strengthened bands, which form the other named ligaments of the joint.

The **Superior** or **Dorsal Calcaneo-cuboid Ligament** (fig. 384) is a thin but broad fasciculus, which passes between the contiguous surfaces of the os calcis and cuboid, on the dorsal surface of the joint.

The **Internal Calcaneo-cuboid (Interosseous) Ligament** (fig. 384) is a short, but thick and strong, band of fibres, arising from the os calcis, in the deep hollow which intervenes between it and the astragalus, and closely blended, at its origin, with the superior calcaneo-navicular ligament, so as to form with it a V-shaped structure. It is inserted into the inner side of the cuboid bone. This ligament forms one of the chief bonds of union between the first and second rows of the tarsus.

The **Long Calcaneo-cuboid (Long Plantar) Ligament** (fig. 386), the more superficial of the two plantar ligaments, is the longest of all the ligaments of the tarsus: it is attached to the under surface of the os calcis, from near the tuberosities to the anterior tubercle; its fibres pass forwards to be attached to the ridge on the under surface of the cuboid bone, the more superficial fibres being continued onwards to the bases of the second, third, and fourth metatarsal bones. This ligament crosses the groove on the under surface of the cuboid bone, converting it into a canal for the passage of the tendon of the Peroneus longus.

Fig. 386.—Ligaments of plantar surface of the foot.

The **Short Calcaneo-cuboid (Short Plantar) Ligament** lies nearer to the bones than the preceding, from which it is separated by a little areolar tissue. It is exceedingly broad, about an inch in length, and extends from the tubercle, and the depression in front of it, on the fore part of the under surface of the os calcis, to the inferior surface of the cuboid bone behind the peroneal groove.

Synovial Membrane.—The synovial membrane in this joint is distinct. It lines the inner surface of the ligaments.

Actions.—The movements permitted between the os calcis and cuboid are limited to a slight gliding upon each other.

The *transverse tarsal* or *medio-tarsal joint* is formed by the articulation of the os calcis with the cuboid, and by the articulation of the astragalus with the navicular. The movement which takes place in this joint is more extensive than that in the other tarsal joints, and consists of a sort of rotation by means of which the sole of the foot may be slightly flexed and extended or carried inwards (inverted) and outwards (everted).

4. The Ligaments connecting the Os Calcis and Navicular

Though these two bones do not directly articulate, they are connected by two ligaments:

Superior or External Calcaneo-navicular.
Inferior or Internal Calcaneo-navicular.

The **Superior** or **External Calcaneo-navicular** (fig. 384) arises, as already mentioned, with the internal calcaneo-cuboid in the deep hollow between the

astragalus and os calcis; it passes forwards from the upper surface of the anterior extremity of the os calcis to the outer side of the navicular bone. These two ligaments resemble the letter Y, being blended together behind, but separated in front.

The **Inferior** or **Internal Calcaneo-navicular** (fig. 386) is by far the larger and stronger of the two ligaments between these bones; it is a broad and thick band of fibres, which passes forwards and inwards from the anterior margin of the sustentaculum tali of the os calcis to the under surface of the navicular bone. This ligament not only serves to connect the os calcis and navicular, but supports the head of the astragalus, forming part of the articular cavity in which it is received. The *upper surface* presents a fibro-cartilaginous facet, lined by the synovial membrane continued from the anterior calcaneo-astragaloid articulation, upon which a portion of the head of the astragalus rests. Its *under surface* is in contact with the tendon of the Tibialis posticus muscle; * its inner border is blended with the fore part of the Deltoid ligament, thus completing the socket for the head of the astragalus.

Surgical Anatomy.—The inferior calcaneo-navicular ligament, by supporting the head of the astragalus, is principally concerned in maintaining the arch of the foot, and, when it yields, the head of the astragalus is pressed downwards, inwards, and forwards by the weight of the body, and the foot becomes flattened, expanded, and turned outwards, constituting the disease known as *flat-foot.* This ligament contains a considerable amount of elastic fibres, so as to give elasticity to the arch and spring to the foot; hence it is sometimes called the 'spring' ligament. It is supported, on its under surface, by the tendon of the Tibialis posticus, which spreads out at its insertion into a number of fasciculi, which are attached to most of the tarsal and metatarsal bones; this prevents undue stretching of the ligament, and is a protection against the occurrence of flat-foot.

5. The Articulation of the Navicular with the Cuneiform Bones

The navicular is connected to the three cuneiform bones by

Dorsal and Plantar ligaments.

The **Dorsal Ligaments** are small, longitudinal bands, arranged as three bundles, one to each of the cuneiform bones. That bundle of fibres which connects the navicular with the internal cuneiform is continuous round the inner side of the articulation with the plantar ligament which connects these two bones.

The **Plantar Ligaments** have a similar arrangement to those on the dorsum. They are strengthened by processes given off by the tendon of the Tibialis posticus.

The **Synovial Membrane** of these joints is part of the great tarsal synovial membrane.

Actions.—The movements permitted between the navicular and cuneiform bones are limited to a slight gliding upon each other.

6. The Articulation of the Navicular with the Cuboid

The navicular bone is connected with the cuboid by

Dorsal, Plantar, and Interosseous ligaments.

The **Dorsal Ligament** passes obliquely forwards and outwards from the navicular to the cuboid bone.

The **Plantar Ligament** passes nearly transversely between these two bones.

The **Interosseous Ligament** consists of strong transverse fibres which pass between the rough non-articular portions of the lateral surfaces of these two bones.

The **Synovial Membrane** of this joint is part of the great tarsal synovial membrane.

Actions.—The movements permitted between the navicular and cuboid bones are limited to a slight gliding upon each other.

* Hancock describes an extension of this ligament upwards on the inner side of the foot, which completes the socket of the joint in that direction. *Lancet,* 1866, vol. i. p. 618.

7. The Articulation of the Cuneiform Bones with each other

These bones are connected together by

Dorsal, Plantar, and Interosseous ligaments.

The **Dorsal Ligaments** consist of two bands which pass transversely: one connecting the internal with the middle cuneiform, and the other connecting the middle with the external cuneiform.

The **Plantar Ligaments** have a similar arrangement to those on the dorsum. They are strengthened by the processes given off from the tendon of the Tibialis posticus.

The **Interosseous Ligaments** consist of strong transverse fibres which pass between the rough non-articular portions of the lateral surfaces of the adjacent cuneiform bones.

The **Synovial Membrane** of these joints is part of the great tarsal synovial membrane.

Actions.—The movements permitted between the cuneiform bones are limited to a slight gliding upon each other.

8. The Articulation of the External Cuneiform Bone with the Cuboid

These bones are connected together by

Dorsal, Plantar, and Interosseous ligaments.

The **Dorsal Ligament** passes transversely between these two bones.

The **Plantar Ligament** has a similar arrangement. It is strengthened by a process given off from the tendon of the Tibialis posticus.

The **Interosseous Ligament** consists of strong transverse fibres which pass between the rough non-articular portions of the lateral surfaces of the adjacent sides of these two bones.

The **Synovial Membrane** of this joint is part of the great tarsal synovial membrane.

Actions.—The movements permitted between the external cuneiform and cuboid are limited to a slight gliding upon each other.

Nerve-supply.—All the joints of the tarsus are supplied by the anterior tibial nerve.

Surgical Anatomy.—In spite of the great strength of the ligaments which connect the tarsal bones together, dislocation at some of the tarsal joints does occasionally occur; though, on account of the spongy character of the bones, they are more frequently broken than dislocated, as the result of violence. When dislocation does take place, it is most commonly in connection with the astragalus; for not only may this bone be dislocated from the tibia and fibula at the ankle-joint, but the other bones may be dislocated from it, the trochlear surface of the bone remaining *in situ* in the tibio-fibular mortise. This constitutes what is known as the *sub-astragaloid* dislocation. Or, again, the astragalus may be dislocated from all its connections—from the tibia and fibula above, the os calcis below, and the navicular in front—and may even undergo a rotation, on either a vertical or a horizontal axis. In the former case the long axis of the bone becoming directed across the joint, so that the head faces the articular surface on one or other malleolus; or, in the latter, the lateral surfaces becoming directed upwards and downwards, so that the trochlear surface faces to one or the other side. Finally, dislocation may occur at the medio-tarsal joint, the anterior tarsal bones being luxated from the astragalus and calcaneum. The other tarsal bones are also, occasionally, though rarely, dislocated from their connections.

VI. TARSO-METATARSAL ARTICULATIONS

These are arthrodial joints. The bones entering into their formation are four tarsal bones, viz. the internal, middle and external cuneiform, and the cuboid, which articulate with the bases of the metatarsal bones of the five toes. The metatarsal bone of the great toe articulates with the internal cuneiform; that of the second is deeply wedged in between the internal and external cuneiform, resting against the middle cuneiform, and being the most strongly articulated of all the metatarsal bones; the third metatarsal articulates with the

extremity of the external cuneiform; the fourth, with the cuboid and external cuneiform; and the fifth, with the cuboid. The articular surfaces are covered with cartilage and connected together by the following ligaments:

Dorsal. Plantar. Interosseous.

The **Dorsal Ligaments** consist of strong, flat bands, which connect the tarsal with the metatarsal bones. The first metatarsal is connected to the internal cuneiform by a single broad, thin band; the second has three dorsal ligaments, one from each cuneiform bone; the third has one from the external cuneiform; the fourth has two, one from the external cuneiform and one from the cuboid; and the fifth, one from the cuboid.

The **Plantar Ligaments** consist of longitudinal and oblique bands connecting the tarsal and metatarsal bones, but disposed with less regularity than on the dorsal surface. Those for the first and second metatarsal are the most strongly marked; the second and third metatarsal receive strong bands, which pass obliquely across from the internal cuneiform; the plantar ligaments of the fourth and fifth metatarsal consist of a few scanty fibres derived from the cuboid.

The **Interosseous Ligaments** are three in number: internal, middle, and external. The *internal* one is the strongest of the three, and passes from the outer surface of the internal cuneiform to the adjacent angle of the second metatarsal. The *middle* one, less strong than the preceding, connects the external cuneiform with the adjacent angle of the second metatarsal. The *external* interosseous ligament connects the outer angle of the external cuneiform with the adjacent side of the third metatarsal.

The **Synovial Membrane** between the internal cuneiform bone and the first metatarsal bone is a distinct sac. The synovial membrane between the middle and external cuneiform behind, and the second and third metatarsal bones in front, is part of the great tarsal synovial membrane. Two prolongations are sent forwards from it, one between the adjacent sides of the second and third metatarsal bones, and one between the third and fourth metatarsal bones. The synovial membrane between the cuboid and the fourth and fifth metatarsal bones is a distinct sac. From it a prolongation is sent forwards between the fourth and fifth metatarsal bones.

Actions.—The movements permitted between the tarsal and metatarsal bones are limited to a slight gliding upon each other.

VII. ARTICULATIONS OF THE METATARSAL BONES WITH EACH OTHER

The base of the first metatarsal bone is not connected with the second metatarsal bone by any ligaments; in this respect it resembles the thumb.

The bases of the four outer metatarsal bones are connected by dorsal, plantar, and interosseous ligaments.

The **Dorsal Ligaments** pass transversely between the adjacent metatarsal bones.

The **Plantar Ligaments** have a similar arrangement to those on the dorsum.

The **Interosseous Ligaments** consist of strong transverse fibres which pass between the rough non-articular portions of the lateral surfaces.

The **Synovial Membrane** between the second and third, and the third and fourth, metatarsal bones is part of the great tarsal synovial membrane.

The synovial membrane between the fourth and fifth metatarsal bones is a prolongation of the synovial membrane of the cubo-metatarsal joint.

Actions.—The movement permitted in the tarsal ends of the metatarsal bones is limited to a slight gliding of the articular surfaces upon one another.

The Synovial Membranes in the Tarsal and Metatarsal Joints

The **Synovial Membranes** (fig. 387) found in the articulations of the tarsus and metatarsus are six in number: one for the posterior calcaneo-astragaloid articulation; a second for the anterior calcaneo-astragaloid and astragalo-navicular articulations; a third for the calcaneo-cuboid articulation; and a fourth for the articulations of the navicular with the three cuneiforms, the three cuneiforms with each other, the external cuneiform with the cuboid, and the middle and external

cuneiforms with the bases of the second and third metatarsal bones, and the lateral surfaces of the second, third, and fourth metatarsal bones with each other; a fifth for the internal cuneiform with the metatarsal bone of the great toe; and

FIG. 387.—Oblique section of the articulations of the tarsus and metatarsus. Showing the six synovial membranes.

a sixth for the articulation of the cuboid with the fourth and fifth metatarsal bones. A small synovial membrane is sometimes found between the contiguous surfaces of the navicular and cuboid bones.

Nerve-supply.—The nerves supplying the tarso-metatarsal joints are derived from the anterior tibial.

The *digital extremities* of all the metatarsal bones are connected together by the *transverse metatarsal ligament.*

The **Transverse Metatarsal Ligament** is a narrow band which passes transversely across the anterior extremities of all the metatarsal bones, connecting them together. It is blended anteriorly with the plantar (glenoid) ligament of the metatarso-phalangeal articulations. To its posterior border is connected the fascia covering the Interossei muscles. Its inferior surface is concave where the Flexor tendons pass over it. Above it the tendons of the Interossei muscles pass to their insertion. It differs from the transverse metacarpal ligament in that it connects the metatarsal bone of the great toe with the rest of the metatarsal bones.

VIII. METATARSO-PHALANGEAL ARTICULATIONS

The metatarso-phalangeal articulations are of the condyloid kind, formed by the reception of the rounded head of the metatarsal bone into a superficial cavity in the extremity of the first phalanx.

The ligaments are—

Plantar. Two Lateral.

The **Plantar Ligaments** (Glenoid ligaments of Cruveilhier) are thick, dense, fibrous structures. Each is placed on the plantar surface of the joint in the interval between the lateral ligaments, to which they are connected; they are loosely united to the metatarsal bones, but very firmly to the bases of the first phalanges. Their plantar surface is intimately blended with the transverse metatarsal ligament, and presents a groove for the passage of the Flexor tendons, the sheath surrounding which is connected to each side of the groove. By their deep surface, they form part of the articular surface for the head of the metatarsal bone, and are lined by a synovial membrane.

The **Lateral Ligaments** are strong, rounded cords, placed one on each side of the joint, and attached, by one extremity, to the posterior tubercle on the side of the head of the metatarsal bone; and, by the other, to the contiguous extremity of the phalanx.

The **Posterior Ligament** is supplied by the Extensor tendon placed over the back of the joint.

Actions.—The movements permitted in the metatarso-phalangeal articulations are flexion, extension, abduction, and adduction.

IX. ARTICULATIONS OF THE PHALANGES

The articulations of the phalanges are ginglymoid joints.

The ligaments are—

Plantar. Two Lateral.

The arrangement of these ligaments is similar to those in the metatarso-phalangeal articulations: the Extensor tendon supplies the place of a posterior ligament.

Actions.—The only movements permitted in the phalangeal joints are flexion and extension; these movements are more extensive between the first and second phalanges than between the second and third. The movement of flexion is very considerable, but extension is limited by the plantar and lateral ligaments.

Surface Form.—The principal joints which it is necessary to distinguish, with regard to the surgery of the foot, are the medio-tarsal and the tarso-metatarsal joints. The joint between the astragalus and the navicular is best found by means of the tubercle of the navicular bone, for the line of the joint is immediately behind this process. If the foot is grasped and forcibly extended, a rounded prominence, the head of the astragalus, will appear on the inner side of the dorsum in front of the ankle-joint, and if a knife is carried downwards, just in front of this prominence and behind the line of the navicular tubercle, it will enter the astragalo-navicular joint. The calcaneo-cuboid joint is situated midway between the external malleolus and the prominent end of the fifth metatarsal bone. The plane of the joint is in the same line as that of the astragalo-navicular. The position of the joint between the fifth metatarsal bone and the cuboid is easily found by the projection of the fifth metatarsal bone, which is the guide to it. The direction of the line of the joint is very oblique, so that, if continued inwards, it would pass through the inner side of the head of the first metatarsal bone. The joints between the third and fourth metatarsal bones and the cuboid and external cuneiform are the direct continuation inwards of the previous joint, but their planes are less oblique. The tarso-metatarsal articulation of the great toe corresponds to a groove which can be felt by making firm pressure on the inner side of the foot one inch in front of the tubercle on the navicular bone; and the joint between the second metatarsal bone and the middle cuneiform is to be found on the dorsum of the foot, half an inch behind the level of the tarso-metatarsal joint of the great toe. The line of the joints between the metatarsal bones and the first phalanges is about an inch behind the webs of the corresponding toes.

THE MUSCLES AND FASCIÆ *

THE Muscles are connected with the bones, cartilages, ligaments, and skin, either directly or through the intervention of fibrous structures, called tendons or aponeuroses. Where a muscle is attached to bone or cartilage, the fibres terminate in blunt extremities upon the periosteum or perichondrium, and do not come into direct relation with the osseous or cartilaginous tissue. Where muscles are connected with the skin, they either lie as a flattened layer beneath it, or are connected with its areolar tissue by larger or smaller bundles of fibres, as in the muscles of the face.

The muscles vary extremely in their form. In the limbs, they are of considerable length, especially the more superficial ones; they surround the bones, and constitute an important protection to the various joints. In the trunk, they are broad, flattened, and expanded, forming the parietes of the cavities which they enclose; hence the reason of the terms, *long*, *broad*, *short*, &c., used in the description of a muscle.

There is a considerable variation in the arrangement of the fibres of certain muscles with reference to the tendons to which they are attached. In some, the fibres are parallel and run directly from their origin to their insertion; these are quadrilateral muscles, such as the Thyro-hyoid. A modification of these is found in the fusiform muscles, in which the fibres are not quite parallel, but slightly curved, so that the muscle tapers at each end; in their action, however, they resemble the quadrilateral muscles. Secondly, in other muscles the fibres are convergent; arising by a broad origin, they converge to a narrow or pointed insertion. This arrangement of fibres is found in the triangular muscles—e.g. the Temporal. In some muscles, which otherwise would belong to the quadrilateral or triangular type, the origin and insertion are not in the same plane, but the plane of the line of origin intersects that of their insertion: such is the case in the Pectineus muscle. Thirdly, in some muscles the fibres are oblique and converge, like the plumes of a quill-pen, to one side of a tendon which runs the entire length of the muscle. Such a muscle is rhomboidal or penniform, as the Peronei. A modification of these rhomboidal muscles is found in those cases where oblique fibres converge to both sides of a central tendon which runs down the middle of the muscle; these are called bipenniform, and an example is afforded in the Rectus femoris. Finally, we have muscles in which the fibres are arranged in curved bundles in one or more planes, as in the Sphincter muscles. The arrangement of the muscular fibres is of considerable importance in respect to their relative strength and range of movement. Those muscles where the fibres are long and few in number have great range, but diminished strength; where, on the other hand, the fibres are short and more numerous, there is great power, but lessened range.

Muscles differ much in size: the Gastrocnemius forms the chief bulk of the back of the leg, and the fibres of the Sartorius are nearly two feet in length,

* The Muscles and Fasciæ are described conjointly, in order that the student may consider the arrangement of the latter in his dissection of the former. It is rare for the student of anatomy in this country to have the opportunity of dissecting the fasciæ separately; and it is for this reason, as well as from the close connection that exists between the muscles and their investing sheaths, that they are considered together. Some general observations are first made on the anatomy of the muscles and fasciæ, the special description being given in connection with the different regions.

while the Stapedius, a small muscle of the internal ear, weighs about a grain, and its fibres are not more than two lines in length.

The names applied to the various muscles have been derived: 1, from their situation, as the Tibialis, Radialis, Ulnaris, Peroneus; 2, from their direction, as the Rectus abdominis, Obliqui capitis, Transversalis; 3, from their uses, as Flexors, Extensors, Abductors, &c.; 4, from their shape, as the Deltoid, Trapezius, Rhomboideus; 5, from the number of their divisions, as the Biceps, the Triceps; 6, from their points of attachment, as the Sterno-cleido-mastoid, Sterno-hyoid, Sterno-thyroid.

In the description of a muscle, the term *origin* is meant to imply its more fixed or central attachment; and the term *insertion* the movable point to which the force of the muscle is directed; but the origin is absolutely fixed in only a very small number of muscles, such as those of the face, which are attached by one extremity to the bone, and by the other to the movable integument; in the greater number, the muscle can be made to act from either extremity.

In the dissection of the muscles, the student should pay especial attention to the exact *origin, insertion,* and *actions* of each, and its more important *relations* with surrounding parts. An accurate knowledge of the points of attachment of the muscles is of great importance in the determination of their action. By a consideration of the action of the muscles, the surgeon is able to explain the causes of displacement in various forms of fracture, and the causes which produce distortion in various deformities, and, consequently, to adopt appropriate treatment in each case. The relations, also, of some of the muscles, especially those in immediate apposition with the larger blood-vessels, and the surface-markings they produce, should be carefully remembered, as they form useful guides in the application of ligatures to those vessels.

Tendons are white, glistening, fibrous cords, varying in length and thickness, sometimes round, sometimes flattened, of considerable strength, and devoid of elasticity. They consist almost entirely of white fibrous tissue, the fibrils of which have an undulating course parallel with each other, and are firmly united together. They are very sparingly supplied with blood-vessels, the smaller tendons presenting in their interior no trace of them. Nerves supplying tendons have a special modification of their terminal fibres, named organ of Golgi (see page 48). The tendons consist principally of a substance which yields gelatin.

Aponeuroses are flattened or ribbon-shaped tendons, of a pearly-white colour, iridescent, glistening, and similar in structure to the tendons. They are only sparingly supplied with blood-vessels.

The tendons and aponeuroses are connected, on the one hand, with the muscles; and, on the other hand, with the movable structures, as the bones, cartilages, ligaments, and fibrous membranes (for instance, the sclerotic). Where the muscular fibres are in a direct line with those of the tendon or aponeurosis, the two are directly continuous, the muscular fibre being distinguishable from that of the tendon only by its striation. But where the muscular fibre joins the tendon or aponeurosis at an oblique angle, the former terminates, according to Kölliker, in rounded extremities, which are received into corresponding depressions on the surface of the latter, the connective tissue between the fibres being continuous with that of the tendon. The latter mode of attachment occurs in all the penniform and bipenniform muscles, and in those muscles the tendons of which commence in a membranous form, as the Gastrocnemius and Soleus.

The fasciæ (fascia, *a bandage*) are fibro-areolar or aponeurotic laminæ, of variable thickness and strength, found in all regions of the body, investing the softer and more delicate organs. The fasciæ have been subdivided, from the situation in which they are found, into two groups, superficial and deep.

The *superficial fascia* is found immediately beneath the integument over almost the entire surface of the body. It connects the skin with the deep or aponeurotic fascia, and consists of fibro-areolar tissue, containing in its meshes pellicles of fat in varying quantity. In the eyelids and scrotum, where fat is rarely deposited, this tissue is very liable to serous infiltration. The superficial fascia varies in thickness in different parts of the body: in the groin it is so thick as to be capable of being subdivided into several laminæ. Beneath the fatty layer of the superficial fascia, which is immediately subcutaneous, there is generally another layer of the same structure, comparatively devoid of adipose tissue, in which the trunks of the subcutaneous vessels and nerves are found, as

the superficial epigastric vessels in the abdominal region, the radial and ulnar veins in the forearm, the saphenous veins in the leg and thigh, and the superficial lymphatic glands; certain cutaneous muscles also are situated in the superficial fascia, as the Platysma myoides in the neck, and the Orbicularis palpebrarum around the eyelids. This fascia is most distinct at the lower part of the abdomen, the scrotum, perinæum, and extremities; is very thin in those regions where muscular fibres are inserted into the integument, as on the side of the neck, the face, and around the margin of the anus. It is very dense in the scalp, in the palms of the hands, and soles of the feet, forming a fibro-fatty layer, which binds the integument firmly to the subjacent structure.

The superficial fascia connects the skin to the subjacent parts, facilitates the movement of the skin, serves as a soft nidus for the passage of vessels and nerves to the integument, and retains the warmth of the body, since the fat contained in its areolæ is a bad conductor of heat.

The *deep fascia* is a dense, inelastic, unyielding fibrous membrane, forming sheaths for the muscles, and in some cases affording them broad surfaces for attachment. It consists of shining tendinous fibres, placed parallel with one another, and connected together by other fibres disposed in a rectilinear manner. It is usually exposed on the removal of the superficial fascia, forming a strong investment, which not only binds down collectively the muscles in each region, but gives a separate sheath to each, as well as to the vessels and nerves. The fasciæ are thick in unprotected situations, as on the outer side of a limb, and thinner on the inner side. The deep fasciæ assist the muscles in their action, by the degree of tension and pressure they make upon their surface: and, in certain situations, this is increased and regulated by muscular action, as, for instance, by the Tensor fasciæ femoris and Gluteus maximus in the thigh, by the Biceps in the upper and lower extremities, and Palmaris longus in the hand. In the limbs, the fasciæ not only invest the entire limb, but give off septa which separate the various muscles, and are attached beneath to the periosteum: these prolongations of fasciæ are usually spoken of as intermuscular septa.

The Muscles and Fasciæ may be arranged, according to the general division of the body, into those of the cranium, face, and neck; those of the trunk; those of the upper extremity; and those of the lower extremity.

MUSCLES AND FASCIÆ OF THE CRANIUM AND FACE

The Muscles of the Cranium and Face consist of ten groups, arranged according to the region in which they are situated.

I. Cranial Region.
II. Auricular Region.
III. Palpebral Region.
IV. Orbital Region.
V. Nasal Region.
VI. Maxillary Region.
VII. Mandibular Region.
VIII. Intermaxillary Region.
IX. Temporo-mandibular Region.
X. Pterygo-mandibular Region.

The muscles contained in each of these groups are the following:

I. Cranial Region.
Occipito-frontalis.

II. Auricular Region.
Attrahens auriculam.
Attollens auriculam.
Retrahens auriculam.

III. Palpebral Region.
Orbicularis palpebrarum.
Tensor tarsi.
Corrugator supercilii.

IV. Orbital Region.
Levator palpebræ.
Rectus superior.
Rectus inferior.
Rectus internus.
Rectus externus.
Obliquus superior.
Obliquus inferior.

V. Nasal Region.
Pyramidalis nasi.
Levator labii superioris alæque nasi.

Dilatator naris posterior.
Dilatator naris anterior.
Compressor naris.
Compressor narium minor.
Depressor alæ nasi.

VI. *Maxillary Region.*
Levator labii superioris.
Levator anguli oris.
Zygomaticus major.
Zygomaticus minor.

VII. *Mandibular Region.*
Levator labii inferioris.
Depressor labii inferioris.
Depressor anguli oris.

VIII. *Intermaxillary Region.*
Orbicularis oris.
Buccinator.
Risorius.

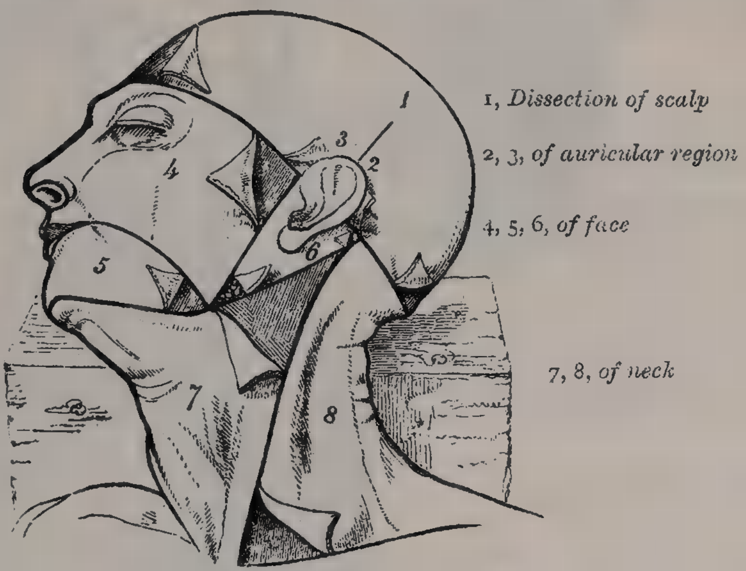
IX. *Temporo-mandibular Region.*
Masseter.
Temporal.

X. *Pterygo-mandibular Region.*
Pterygoideus externus.
Pterygoideus internus.

I. Cranial Region—Occipito-frontalis

Dissection (fig. 388).—The head being shaved, and a block placed beneath the back of the neck, make a vertical incision through the skin from before backwards, commencing at the root of the nose in front, and terminating behind at the occipital protuberance; make a second incision in a horizontal direction along the forehead and round the side of

Fig. 388.—Dissection of the head, face, and neck.



the head, from the anterior to the posterior extremity of the preceding. Raise the skin in front, from the subjacent muscle, from below upwards; this must be done with great care, in order to avoid cutting through the vessels and nerves which lie immediately beneath the skin.

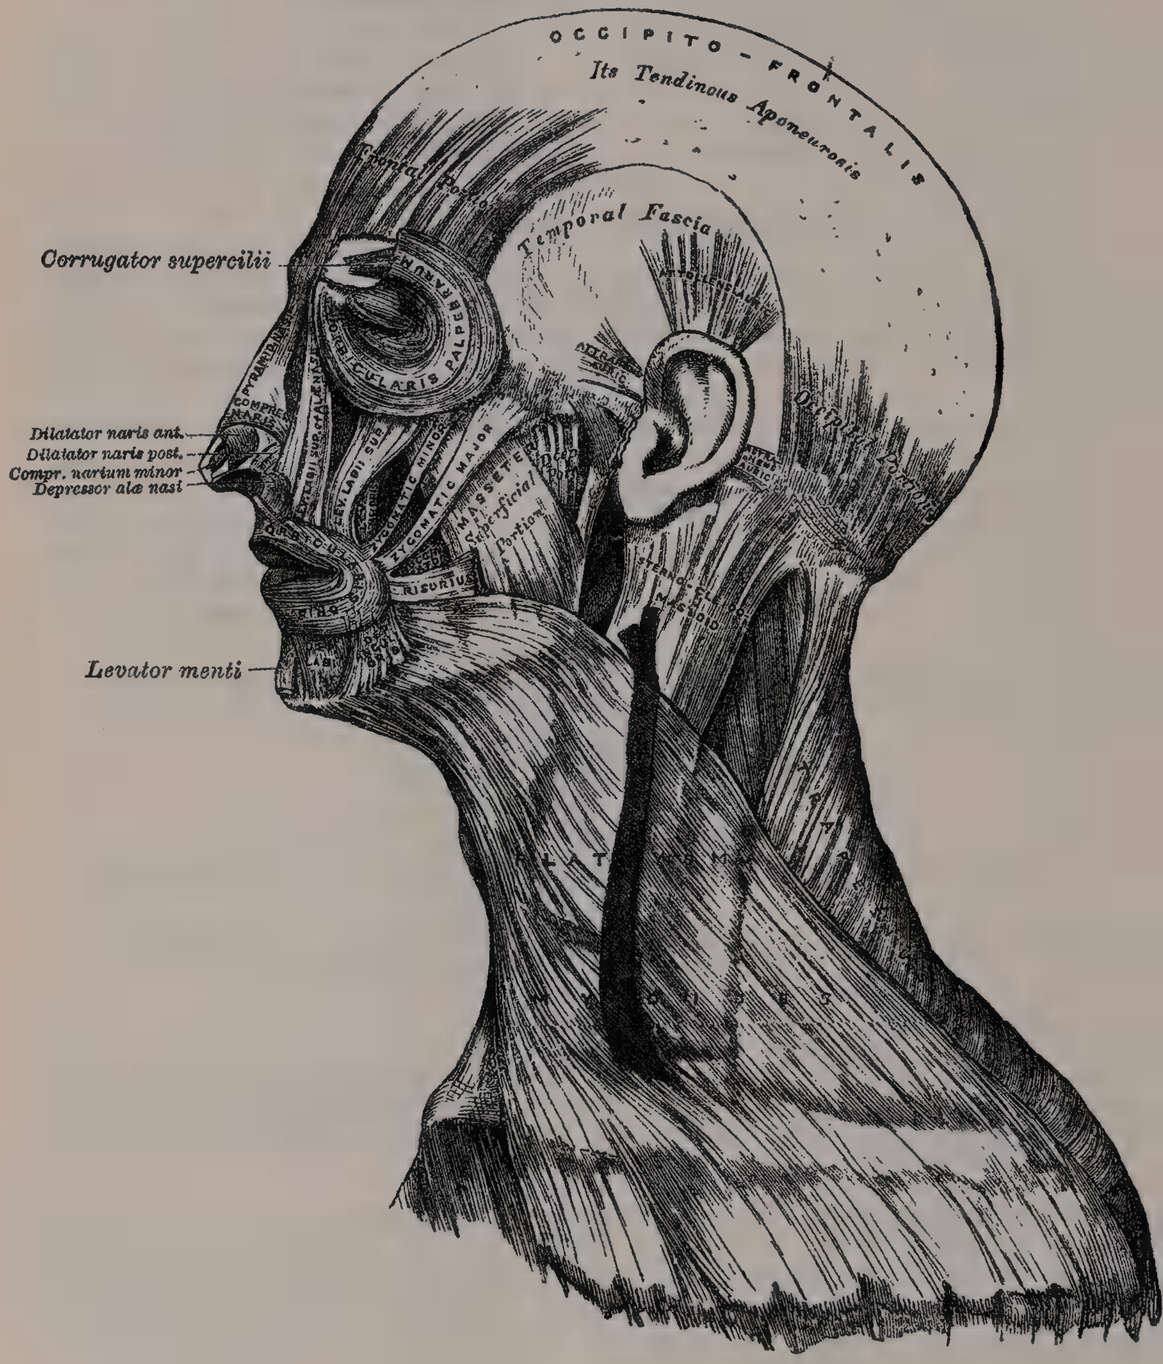
The Skin of the Scalp.—This is thicker than in any other part of the body, but its thickness varies in different situations: it is thickest in the occipital region, whereas in the temporal and mastoid regions it is moderately thin. It is intimately adherent to the superficial fascia. The hair-follicles are very closely set together, and extend throughout the whole thickness of the skin. It also contains a number of sebaceous glands.

The **superficial fascia** in the cranial region is a firm, dense, fibro-fatty layer, intimately adherent to the integument, and to the Occipito-frontalis and its tendinous aponeurosis; it is continuous, behind, with the superficial fascia at the back part of the neck; and, laterally, is continued over the temporal fascia. It contains between its layers the superficial vessels and nerves and much granular fat.

The **Occipito-frontalis** (fig. 389) is a broad musculo-fibrous layer, which covers the whole of one side of the vertex of the skull, from the occiput to the eyebrow.

It consists of two muscular slips, connected by an intervening tendinous aponeurosis. The *occipital portion* (sometimes called the *occipitalis* muscle) is thin, quadrilateral in form, and about an inch and a half in length; it arises from the outer two-thirds of the superior curved line of the occipital bone, and from the mastoid portion of the temporal. Its fibres of origin are tendinous, but they soon become muscular, and ascend in a parallel direction to terminate in the tendinous aponeurosis. The *frontal portion* (sometimes called the *frontalis*

FIG. 389.—Muscles of the head, face, and neck.



muscle) is thin, of a quadrilateral form, and intimately adherent to the superficial fascia. It is broader, its fibres are longer, and their structure paler than the occipital portion. It has no bony attachments. Its internal fibres are continuous with those of the Pyramidalis nasi. Its middle fibres become blended with the Corrugator supercilii and Orbicularis palpebrarum; and the outer fibres are also blended with the latter muscle over the external angular process. From these attachments, the fibres are directed upwards and join the aponeurosis below the coronal suture. The inner margins of the frontal portions of the two

muscles are joined together for some distance above the root of the nose; but between the occipital portions there is a considerable, though variable, interval, which is occupied by the aponeurosis.

The **aponeurosis** covers the upper part of the vertex of the skull, being continuous across the middle line with the aponeurosis of the opposite muscle. Behind, it is attached, in the interval between the occipital origins, to the occipital protuberance and highest curved lines of the occipital bone; in front, it forms a short and narrow prolongation between the frontal portions; and on each side it has connected with it the Attollens and Attrahens muscles of the pinna; in this situation it loses its aponeurotic character, and is continued over the temporal fascia to the zygoma as a layer of laminated areolar tissue. This aponeurosis is closely connected to the integument by the firm, dense, fibro-fatty layer which forms the superficial fascia: it is connected with the pericranium by loose cellular tissue, which allows of a considerable degree of movement of the integument.

Nerves.—The frontal portion of the Occipito-frontalis is supplied by the facial nerve; its occipital portion, by the posterior auricular branch of the same nerve.

Actions.—The frontal portion of the muscle raises the eyebrows and the skin over the root of the nose, and at the same time draws the scalp forwards, throwing the integument of the forehead into transverse wrinkles. The posterior portion draws the scalp backwards. By bringing alternately into action the frontal and occipital portions the entire scalp may be moved forwards and backwards. In the ordinary action of the muscles, the eyebrows are elevated, and at the same time the aponeurosis is fixed by the posterior portion, thus giving to the face the expression of surprise: if the action is more exaggerated, the eyebrows are still further raised, and the skin of the forehead thrown into transverse wrinkles, as in the expression of fright or horror.

Surgical Anatomy.—From an anatomical point of view, the scalp consists of five layers, viz. the skin, subcutaneous tissue, Occipito-frontalis muscle and its aponeurosis, subaponeurotic connective tissue, and pericranium. But from a surgical standpoint it is better to regard the first three of these structures as a single layer, since they are all intimately fused together, and when torn off in an accident, or turned down as a flap in a surgical operation, remain firmly connected to each other. In consequence of the dense character of the subcutaneous tissue, the amount of swelling which occurs as the result of inflammation is slight; and the edges of a wound which does not involve the Occipito-frontalis muscle or its aponeurosis do not gape. The blood-vessels, also, which lie in this tissue, when wounded, are unable to freely contract and retract; and therefore the hæmorrhage from scalp wounds is often very considerable, but can always be arrested by pressure—a matter of great importance, as it is often very difficult or impossible to pick up with forceps a wounded vessel in the scalp.

The skin of the scalp is abundantly supplied with sebaceous and sudoriparous glands. The former are sometimes the seat of cystic enlargement, constituting the so-called *atheromatous cysts* or *wens*.

The subaponeurotic connective tissue is, from a surgical point of view, of considerable importance. It is loose and lax, and is easily torn through; and hence, when a flap wound occurs in the scalp, this is the tissue which is torn when the flap is separated from the parts beneath. The vessels are therefore torn down with the flap, and there is little risk of sloughing, unless the vitality of the part has been actually destroyed by the injury. In consequence of its loose nature and feeble vitality, any septic inflammation is apt to assume a very diffuse form and spread all over the skull, and, unless relieved by timely incisions, lead to extensive destruction of the integument, from the tension to which it is subjected.

II. Auricular Region (fig. 389)

Attrahens auriculam. Attollens auriculam.
Retrahens auriculam.

These three small muscles are placed immediately beneath the skin around the pinna. In man, in whom the pinna is almost immovable, they are rudimentary. They are the analogues of large and important muscles in some of the mammalia.

Dissection.—This requires considerable care, and should be performed in the following manner: To expose the Attollens auriculam, draw the pinna or broad part of the ear downwards, when a tense band will be felt beneath the skin, passing from the side of the head

to the upper part of the concha; by dividing the skin over this band, in a direction from below upwards, and then reflecting it on each side, the muscle is exposed. To bring into view the Attrahens auriculam, draw the helix backwards by means of a hook, when the muscle will be made tense, and may be exposed in a similar manner to the preceding. To expose the Retrahens auriculam, draw the pinna forwards, when the muscle, being made tense, may be felt beneath the skin, at its insertion into the back part of the concha, and may be exposed in the same manner as the other muscles.

The **Attrahens auriculam** (*Auricularis anterior*), the smallest of the three, is thin, fan-shaped, and its fibres pale and indistinct; they arise from the lateral edge of the aponeurosis of the Occipito-frontalis, and converge to be inserted into a projection on the front of the helix.

Relations.—*Superficially*, with the skin; *deeply*, with the areolar tissue derived from the aponeurosis of the Occipito-frontalis, beneath which are the superficial temporal artery and vein and the temporal fascia.

The **Attollens auriculam** (*Auricularis superior*), the largest of the three, is thin and fan-shaped: its fibres arise from the aponeurosis of the Occipito-frontalis, and converge to be inserted by a thin, flattened tendon into the upper part of the cranial surface of the pinna.

Relations.—*Superficially*, with the integument; *deeply*, with the areolar tissue derived from the aponeurosis of the Occipito-frontalis, beneath which is the temporal fascia.

The **Retrahens auriculam** (*Auricularis posterior*) consists of two or three fleshy fasciculi, which arise from the mastoid portion of the temporal bone by short aponeurotic fibres. They are inserted into the lower part of the cranial surface of the concha.

Relations.—*Superficially*, with the integument; *deeply*, with the mastoid portion of the temporal bone and the posterior auricular artery and nerve.

Nerves.—The Attrahens and Attollens auriculam are supplied by the temporal branch of the facial nerve; the Retrahens auriculam is supplied by the posterior auricular branch of the same nerve.

Actions.—In man, these muscles possess very little action: the Attrahens auriculam draws the ear forwards and upwards; the Attollens auriculam slightly raises it; and the Retrahens auriculam draws it backwards.

III. Palpebral Region (fig. 389)

Orbicularis palpebrarum.	Corrugator supercilii.
Tensor tarsi.	Levator palpebræ.

Dissection (fig. 388).—In order to expose the muscles of the face, continue the longitudinal incision, made in the dissection of the Occipito-frontalis, down the median line of the face to the tip of the nose, and from this point onwards to the upper lip; and carry another incision along the margin of the lip to the angle of the mouth, and transversely across the face to the angle of the jaw. Then make an incision in front of the external ear, from the angle of the jaw upwards, to join the transverse incision made in exposing the Occipito-frontalis. These incisions include a square-shaped flap, which should be removed with care, in the direction marked in the figure, as the muscles at some points are intimately adherent to the integument.

The **Orbicularis palpebrarum** is a sphincter muscle, which surrounds the circumference of the orbit and eyelids. It arises from the internal angular process of the frontal bone, from the nasal process of the superior maxillary bone in front of the lachrymal groove for the nasal duct, and from the anterior surface and borders of a short tendon, the *tendo oculi*, or *internal tarsal ligament*, placed at the inner angle of the orbit. From this origin, the fibres are directed outwards, forming a broad, thin, and flat layer, which covers the eyelids, surrounds the circumference of the orbit, and spreads out over the temple, and downwards on the cheek. The palpebral portion (pars ciliaris) of the Orbicularis is thin and pale; it arises from the bifurcation of the tendo oculi, and forms a series of concentric curves, which are inserted on the outer side of the eyelids into the external tarsal ligament. The orbital portion (pars orbicularis) is thicker and of a reddish colour: its fibres are well developed, and form complete ellipses. The upper fibres of this portion blend with the Occipito-frontalis and Corrugator supercilii.

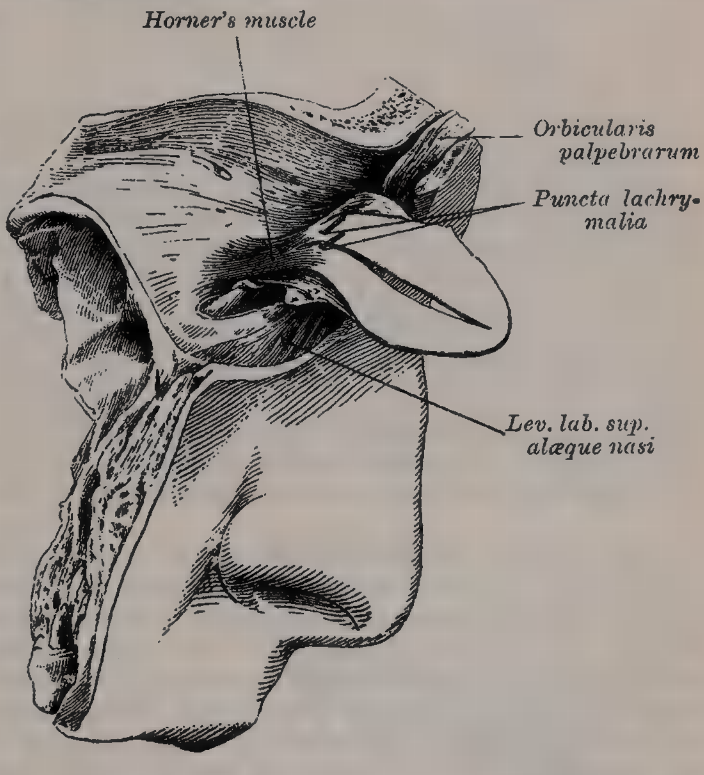
Relations.—By its *superficial surface*, with the integument. By its *deep surface*, above, with the Occipito-frontalis and Corrugator supercilii, with which it is intimately blended, and with the supra-orbital vessels and nerve; below, it covers the lachrymal sac, and the origin of the Levator labii superioris alæque nasi, the Levator labii superioris, and the Zygomaticus minor muscles. *Internally*, it is occasionally blended with the Pyramidalis nasi. *Externally*, it lies on the temporal fascia. On the eyelids, it is separated from the conjunctiva by the tarsal ligaments, the tarsal plates, and the Meibomian glands; and in the case of the upper lid, by the tendon of the Levator palpebræ muscle.

The *tendo oculi*, or *internal tarsal ligament*, is a short tendon, about two lines in length and one in breadth, attached to the nasal process of the superior maxillary bone in front of the lachrymal groove. Crossing the lachrymal sac, it divides into two parts, each division being attached to the inner extremity of the corresponding tarsal plate. As the tendon crosses the lachrymal sac, a strong aponeurotic lamina is given off from the posterior surface, which expands over the sac, and is attached to the ridge on the lachrymal bone. This is the reflected aponeurosis of the tendo oculi.

The *external tarsal ligament* is a much weaker structure than the tendo oculi. It is attached to the margin of the frontal process of the malar bone, and passes inwards to the outer commissure of the eyelid, where it divides into two slips, which are attached to the margins of the respective tarsal plates.

Use of Tendo oculi.—Besides giving attachment to part of the Orbicularis palpebrarum, and to the tarsal plates, it serves to suck the tears into the lachrymal sac, by its attachment to the sac. Thus, each time the eyelids are closed, the tendo oculi becomes tightened, through the action of the Orbicularis, and draws the wall of the lachrymal sac outwards and forwards, so that a vacuum is made in it, and the tears are sucked along the lachrymal canals into it.

Fig. 390.—Horner's muscle. (From a preparation in the Museum of the Royal College of Surgeons of England.)



The **Tensor tarsi** (Horner's muscle) is a small thin muscle, about three lines in breadth and six in length, situated at the inner side of the orbit, behind the tendo oculi and lachrymal sac (fig. 390). It arises from the crest and adjacent part of the orbital surface of the lachrymal bone, and, passing across the lachrymal sac, divides into two slips, which cover the lachrymal canals, and are inserted into the tarsal plates internal to the puncta lachrymalia. Its fibres appear to be continuous with those of the palpebral portion of the Orbicularis palpebrarum, from which they are usually considered to be derived; it is occasionally very indistinct.

The **Corrugator supercilii** is a small, narrow, pyramidal muscle, placed at the inner extremity of the eyebrow, beneath the Occipito-frontalis and Orbicularis palpebrarum muscles. It arises from the inner extremity of the superciliary ridge; whence its fibres pass upwards and outwards, between the palpebral and orbital portions of the Orbicularis palpebrarum, and are inserted into the deep surface of the skin, opposite the middle of the orbital arch.

Relations.—By its *anterior surface*, with the Occipito-frontalis and Orbicularis

palpebrarum muscles. By its *posterior surface*, with the frontal bone and supratrochlear nerve.

Nerves.—The Orbicularis palpebrarum, Corrugator supercilii, and Tensor tarsi are supplied by the facial nerve. Recent investigations tend to show that the Orbicularis palpebrarum, Corrugator supercilii, and frontal part of the Occipito-frontalis, are in reality supplied by fibres of the third nerve, which descend through the pons Varolii to join the facial nerve.

Actions.—The Orbicularis palpebrarum is the sphincter muscle of the eyelids. The palpebral portion acts involuntarily, closing the lids gently, as in sleep or in blinking; the orbicular portion is subject to the will. When the entire muscle is brought into action, the skin of the forehead, temple, and cheek is drawn inwards towards the inner angle of the orbit, and the eyelids are firmly closed, as in photophobia. When the skin of the forehead, temple, and cheek is thus drawn inwards by the action of the muscle it is thrown into folds, especially radiating from the outer angle of the eyelids, which give rise in old age to the so-called 'crow's feet.' The Levator palpebræ is the direct antagonist of this muscle; it raises the upper eyelid and exposes the globe of the eye. The Corrugator supercilii draws the eyebrow downwards and inwards, producing the vertical wrinkles of the forehead. It is the 'frowning' muscle, and may be regarded as the principal agent in the expression of suffering. The Tensor tarsi draws the eyelids and the extremities of the lachrymal canals inwards and compresses them against the surface of the globe of the eye; thus placing them in the most favourable situation for receiving the tears. It serves, also, to compress the lachrymal sac.

IV. Orbital Region (fig. 391)

Levator palpebræ superioris.	Rectus internus.
Rectus superior.	Rectus externus.
Rectus inferior.	Obliquus oculi superior.

Obliquus oculi inferior.

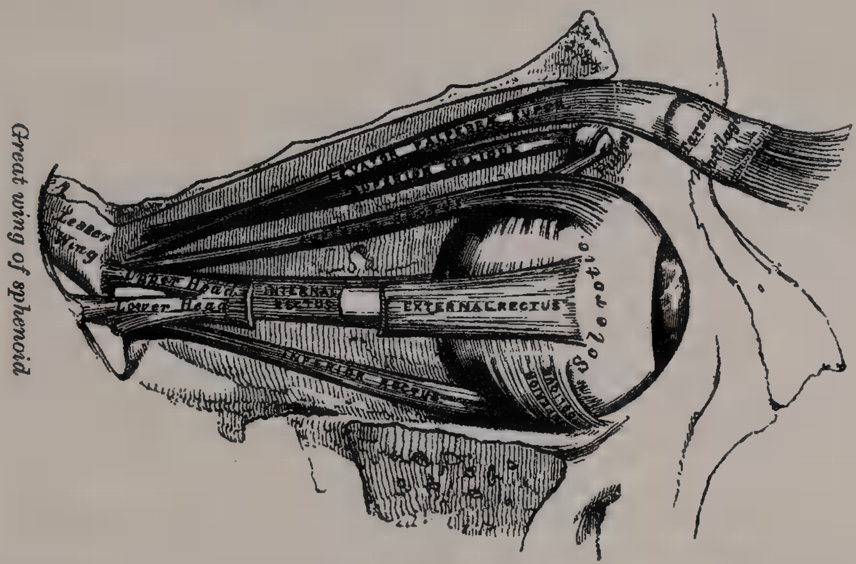
Dissection.—To open the cavity of the orbit, remove the skull-cap and brain; then saw through the frontal bone at the inner extremity of the supra-orbital ridge, and externally at its junction with the malar. Break in pieces the thin roof of the orbit by a few slight blows of the hammer, and take it away; drive forward the superciliary portion of the frontal bone by a smart stroke, but do not remove it, as that would destroy the pulley of the Obliquus superior. When the fragments are cleared away, the periosteum of the orbit will be exposed; this being removed, together with the fat which fills the cavity of the orbit, the several muscles of this region can be examined. The dissection will be facilitated by distending the globe of the eye. In order to effect this, puncture the optic nerve near the eyeball with a curved needle, and push the needle onwards into the globe; insert the point of a blowpipe through this aperture, and force a little air into the cavity of the eyeball; then apply a ligature round the nerve so as to prevent the air escaping. The globe being now drawn forwards, the muscles will be put upon the stretch.

The **Levator palpebræ superioris** is thin, flat, and triangular in shape. It arises from the under surface of the lesser wing of the sphenoid, above and in front of the optic foramen, from which it is separated by the origin of the Superior rectus. At its origin, it is narrow and tendinous, but soon becomes broad and fleshy, and finally terminates in a wide aponeurosis, which is inserted into the upper margin of the superior tarsal plate. From this aponeurosis a thin expansion is continued onwards, passing between the fibres of the Orbicularis to be inserted into the skin of the lid, and some deeper fibres blend with an expansion from the sheath of the Superior rectus muscle, and are with it prolonged into the conjunctiva. At each angle of the lid, the aponeurosis blends with the palpebral ligaments; and, at the inner angle, is also attached to the pulley of the Superior oblique muscle of the eye, which it serves to render tense.

Relations.—By its *upper surface*, with the frontal nerve, the supra-orbital artery, and the periosteum of the orbit and lachrymal gland; and, in the lid, with the inner surface of the tarsal ligament. By its *under surface*, with the Superior rectus; and, in the lid, with the conjunctiva. A small branch of the third nerve enters its under surface.

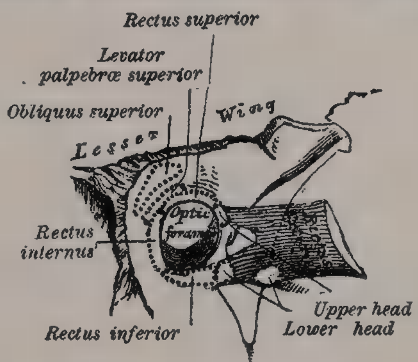
The **Four Recti muscles** arise from a fibrous ring which surrounds the optic foramen and encloses the optic nerve. From this ring a little tendinous bridge is prolonged over the lower and inner part of the sphenoidal fissure, to be inserted into a tubercle of bone on the margin of the greater wing of the sphenoid, bounding the sphenoidal fissure. Two specialised parts of this fibrous ring may be made out: a lower, the more distinct, the *ligament* or *tendon of Zinn*, which gives origin to the Inferior rectus, part of the Internal rectus, and the lower head of origin of the External rectus; and an upper, which gives origin to the Superior rectus, the rest of the Internal rectus, and the upper head of the

FIG. 391.—Muscles of the right orbit.



External rectus. This upper band is sometimes termed the *superior tendon of Lockwood*. Each muscle passes forward in the position implied by its name, to be inserted by a tendinous expansion into the sclerotic coat, about three or four lines from the margin of the cornea. Between the two heads of the External rectus is a narrow interval, through which pass the two divisions of the third nerve, the nasal branch of the ophthalmic division of the fifth nerve, the sixth nerve, and the ophthalmic vein. Although these muscles present a common origin and are inserted in a similar manner into the sclerotic coat, there are certain differences to be observed in them, as regards their length and breadth. The Internal rectus is the broadest; the External is the longest; and the Superior is the thinnest and narrowest.

FIG. 392.—The relative position and attachment of the muscles of the left eyeball.



The **Superior oblique** is a fusiform muscle, placed at the upper and inner side of the orbit, internal to the Levator palpebræ. It arises about a line above the inner margin of the optic foramen, above and internal to the origin of the Superior rectus, and, passing forwards to the inner angle of the orbit, terminates in a rounded tendon, which plays in a fibro-cartilaginous ring or pulley attached to a depression beneath the internal angular process of the frontal bone, the contiguous surfaces of the tendon and ring being lined by a delicate synovial membrane, and enclosed in a thin fibrous investment. The tendon is reflected backwards, outwards, and downwards beneath the Superior rectus to the outer part of the globe of the eye, and is inserted into the sclerotic coat, behind the equator of the eyeball, the insertion of the muscle lying between the Superior and External recti.

Relations.—By its *upper surface*, with the periosteum lining the roof of the

orbit, and the fourth nerve. The tendon, where it lies on the globe of the eye, is covered by the Superior rectus. By its *under surface*, with the nasal nerve, ethmoidal arteries, and the upper border of the Internal rectus.

The **Inferior oblique** is a thin, narrow muscle, placed near the anterior margin of the orbit. It arises from the orbital plate of the superior maxillary bone, external to the lachrymal groove. Passing outwards, backwards, and upwards, between the Inferior rectus and the floor of the orbit, and then between the eyeball and the External rectus, it is inserted into the outer part of the sclerotic coat between the Superior and External rectus, near to, but somewhat behind, the tendon of insertion of the Superior oblique.

Relations.—By its *ocular surface*, with the globe of the eye, and with the Inferior rectus. By its *orbital surface*, with the periosteum covering the floor of the orbit, and with the External rectus. Its borders look forwards and backwards; the posterior one receives a branch of the third nerve.

Nerves.—The Levator palpebræ, Inferior oblique, and all the Recti excepting the External, are supplied by the third nerve; the Superior oblique, by the fourth; the External rectus, by the sixth.

Actions.—The Levator palpebræ raises the upper eyelid, and is the direct antagonist of the Orbicularis palpebrarum. The four Recti muscles are attached in such a manner to the globe of the eye that, acting singly, they will turn it either upwards, downwards, inwards, or outwards, as expressed by their names. The movement produced by the Superior or Inferior rectus is not quite a simple one, for inasmuch as they pass obliquely outwards and forwards to the eyeball, the elevation or depression of the cornea is accompanied by a certain deviation inwards, with a slight amount of rotation, which, however, is corrected by the Oblique muscles; the Inferior oblique correcting the deviation inwards of the Superior rectus, and the Superior oblique that of the Inferior rectus. The contraction of the External and Internal recti, on the other hand, produces a purely horizontal movement. If any two contiguous Recti of one eye act together they carry the globe of the eye in the diagonal of these directions, viz. upwards and inwards, upwards and outwards, downwards and inwards, or downwards and outwards. A little consideration will show that sometimes the corresponding Recti of the two eyes act in unison, and at others the opposite Recti act together. Thus, in turning the eyes to the right, the External rectus of the right eye will act in unison with the Internal rectus of the left eye; but if both eyes are directed to an object in the middle line at a short distance, the two Internal recti will act in unison. The movement of circumduction, as in looking round a room, is performed by the alternate action of the four Recti. The oblique muscles rotate the eyeball on its antero-posterior axis, this kind of movement being required for the correct viewing of an object when the head is moved laterally, as from shoulder to shoulder, in order that the picture may fall in all respects on the same part of the retina of each eye.*

Fasciæ of the Orbit.—The connective tissue of the orbit is in various places condensed into thin membranous layers, which may be conveniently described as (1) the orbital fascia; (2) the sheath of the muscles; and (3) the covering of the eyeball.

(1) The *orbital fascia.* This forms the periosteum of the orbit. It is loosely connected to the bones, from which it can be readily separated. Behind, it is connected with the dura mater by processes which pass through the optic foramen and sphenoidal fissure, and with the sheath of the optic nerve. In front, it is connected with the periosteum at the margin of the orbit, and sends off a process which assists in forming the palpebral fascia. From its internal surface two processes are given off: one to enclose the lachrymal gland, the other to hold the pulley of the Superior oblique muscle in position. A layer of non-striped muscle, the *orbitalis muscle* of H. Müller, may be seen bridging across the spheno-maxillary fissure.

(2) The sheaths of the muscles give off expansions to the margins of the orbit which limit the action of the muscles.

* 'On the Oblique Muscles of the Eye in Man and Vertebrate Animals,' by John Struthers, M.D., in *Anatomical and Physiological Observations.* For a fuller account than our space allows of the various co-ordinated actions of the muscles of a single eye and of both eyes, the reader may be referred to M. Foster's *Text-book of Physiology.*

(3) The fascia covering the eyeball—Tenon's capsule—will be described with the anatomy of the eyeball.

Surgical Anatomy.—The position and exact point of insertion of the tendons of the Internal and External recti muscles into the globe should be carefully examined from the front of the eyeball, as the surgeon is often required to divide the one or the other muscle for the cure of strabismus. In convergent strabismus, which is the more common form of the disease, the eye is turned inwards, requiring the division of the Internal rectus. In the divergent form, which is more rare, the eye is turned outwards, the External rectus being especially implicated. The deformity produced in either case is to be remedied by division of one or the other muscle. The operation is thus performed: the lids are to be well separated; the eyeball is rotated outwards or inwards, and the conjunctiva raised by a pair of forceps, and incised immediately beneath the lower border of the tendon of the muscle to be divided, a little behind its insertion into the sclerotic; the submucous areolar tissue is then divided, and into the small aperture thus made, a blunt hook is passed upwards between the muscle and the globe, and the tendon of the muscle and conjunctiva covering it, divided by a pair of blunt-pointed scissors. Or the tendon may be divided by a subconjunctival incision, one blade of the scissors being passed upwards between the tendon and the conjunctiva, and the other between the tendon and the sclerotic. The student, when dissecting these muscles, should remove on one side of the subject the conjunctiva from the front of the eye, in order to see more accurately the position of the tendons, while on the opposite side the operation may be performed.

V. Nasal Region (fig. 389)

Pyramidalis nasi.
Levator labii superioris alæque nasi.
Dilatator naris posterior.
Dilatator naris anterior.
Compressor naris.
Compressor narium minor.
Depressor alæ nasi.

The **Pyramidalis nasi** is a small pyramidal slip placed over the nasal bone. Its origin is by tendinous fibres from the fascia covering the lower part of the nasal bone and upper part of the cartilage, where it blends with the Compressor naris, and it is inserted into the skin over the lower part of the forehead between the two eyebrows, its fibres decussating with those of the Occipito-frontalis.

Relations.—By its *upper surface*, with the skin. By its *under surface*, with the frontal and nasal bones.

The **Levator labii superioris alæque nasi** is a thin triangular muscle, placed by the side of the nose, and extending between the inner margin of the orbit and upper lip. It arises by a pointed extremity from the upper part of the nasal process of the superior maxillary bone, and, passing obliquely downwards and outwards, divides into two slips, one of which is inserted into the cartilage of the ala of the nose; the other is prolonged into the upper lip, becoming blended with the Orbicularis oris and Levator labii superioris proprius.

Relations.—In front, with the integument; and with a small part of the Orbicularis palpebrarum above.

The **Dilatator naris posterior** is a small muscle, which is placed partly beneath the elevator of the nose and lip. It arises from the margin of the nasal notch of the superior maxilla, and from the sesamoid cartilages, and is inserted into the skin near the margin of the nostril.

The **Dilatator naris anterior** is a thin delicate fasciculus, passing from the cartilage of the ala of the nose to the integument near its margin. This muscle is situated in front of the preceding.

The **Compressor naris** is a small, thin, triangular muscle, arising by its apex from the superior maxillary bone, above and a little external to the incisive fossa; its fibres proceed upwards and inwards, expanding into a thin aponeurosis which is continuous on the bridge of the nose with that of the muscle of the opposite side, and with the aponeurosis of the Pyramidalis nasi.

The **Compressor narium minor** is a small muscle, attached by one end to the alar cartilage, and by the other to the integument at the end of the nose.

The **Depressor alæ nasi** is a short, radiated muscle, arising from the incisive fossa of the superior maxilla; its fibres ascend to be inserted into the septum, and back part of the ala of the nose. This muscle lies between the mucous membrane and muscular structure of the lip.

Nerves.—All the muscles of this group are supplied by the facial nerve.

Actions.—The Pyramidalis nasi draws down the inner angle of the eyebrows and produces transverse wrinkles over the bridge of the nose. The Levator labii superioris alæque nasi draws upwards the upper lip and ala of the nose; its most important action is upon the nose, which it dilates to a considerable extent. The action of this muscle produces a marked influence over the countenance, and it is the principal agent in the expression of contempt and disdain. The two Dilatatores nasi enlarge the aperture of the nose. Their action in ordinary breathing is to resist the tendency of the nostrils to close from atmospheric pressure, but in difficult breathing they may be noticed to be in violent action, as well as in some emotions, as anger. The Depressor alæ nasi is a direct antagonist of the other muscles of the nose, drawing the ala of the nose downwards, and thereby constricting the aperture of the nares. The Compressor naris depresses the cartilaginous part of the nose and draws the alæ together.

VI. Superior Maxillary Region (fig. 389)

Levator labii superioris.	Zygomaticus major.
Levator anguli oris.	Zygomaticus minor.

The **Levator labii superioris (proprius)** is a thin muscle, of a quadrilateral form. It arises from the lower margin of the orbit immediately above the infra-orbital foramen, some of its fibres being attached to the superior maxilla, others to the malar bone; its fibres converge to be inserted into the muscular substance of the upper lip, between the attachment of the Levator labii superioris alæque nasi and the Levator anguli oris.

Relations.—By its *superficial surface* above, with the lower segment of the Orbicularis palpebrarum; below, it is subcutaneous. By its *deep surface*, it conceals the origin of the Compressor naris and Levator anguli oris muscles; also, the infra-orbital vessels and nerve, as they escape from the infra-orbital foramen.

The **Levator anguli oris** arises from the canine fossa, immediately below the infra-orbital foramen; its fibres incline downwards and a little outwards, to be inserted into the angle of the mouth, intermingling with those of the Zygomaticus major, the Depressor anguli oris, and the Orbicularis.

Relations.—By its *superficial surface*, with the Levator labii superioris and the infra-orbital vessels and nerves. By its *deep surface*, with the superior maxilla, the Buccinator, and the mucous membrane.

The **Zygomaticus major** is a slender fasciculus, which arises from the malar bone, in front of the zygomatic suture, and descending obliquely downwards and inwards, is inserted into the angle of the mouth, where it blends with the fibres of the Levator anguli oris, the Orbicularis oris, and the Depressor anguli oris.

Relations.—By its *superficial surface*, with the subcutaneous adipose tissue. By its *deep surface*, with the Masseter and Buccinator muscles and the facial artery and vein.

The **Zygomaticus minor** arises from the malar bone, immediately behind the maxillary suture, and passing downwards and inwards, is continuous with the Orbicularis oris at the outer margin of the Levator labii superioris. It lies in front of the preceding.

Relations.—By its *superficial surface*, with the integument and the Orbicularis palpebrarum above. By its *deep surface*, with the Masseter, Buccinator, and Levator anguli oris, and the facial artery and vein.

Nerves.—This group of muscles is supplied by the facial nerve.

Actions.—The Levator labii superioris is the proper elevator of the upper lip, carrying it at the same time a little forwards. It assists in forming the naso-labial ridge, which passes from the side of the nose to the upper lip and gives to the face an expression of sadness. The Levator anguli oris raises the angle of the mouth and assists the Levator labii superioris in producing the naso-labial ridge. The Zygomaticus major draws the angle of the mouth backwards and upwards, as in laughing; while the Zygomaticus minor, being inserted into the outer part of the upper lip and not into the angle of the mouth, draws it backwards, upwards, and outwards, and thus gives to the face an expression of sadness.

VII. Inferior Maxillary Region (fig. 389)

Levator labii inferioris (Levator menti).
Depressor labii inferioris (Quadratus menti).
Depressor anguli oris (Triangularis menti).

Dissection.—The two principal muscles in this region may be dissected by making a vertical incision through the integument from the margin of the lower lip to the chin; a second incision should then be carried along the margin of the lower jaw as far as the angle, and the integument carefully removed in the direction shown in fig. 388. The Levator labii inferioris is to be dissected by everting the lower lip and raising the mucous membrane.

The **Levator labii inferioris** (**Levator menti**) is a small conical fasciculus, placed on the side of the frænum of the lower lip. It arises from the incisive fossa, external to the symphysis of the lower jaw; its fibres descend to be inserted into the integument of the chin.

Relations.—On its *inner surface*, with the mucous membrane; in the *median line*, it is blended with the muscle of the opposite side; and on its *outer side*, with the Depressor labii inferioris.

The **Depressor labii inferioris** (**Quadratus menti**) is a small quadrilateral muscle. It arises from the external oblique line of the lower jaw, between the symphysis and mental foramen, and passes obliquely upwards and inwards, to be inserted into the integument of the lower lip, its fibres blending with the Orbicularis oris, and with those of its fellow of the opposite side. It is continuous with the fibres of the Platysma at its origin. This muscle contains much yellow fat intermingled with its fibres.

Relations.—By its *superficial surface*, with part of the Depressor anguli oris, and with the integument, to which it is closely connected. By its *deep surface*, with the mental vessels and nerves, the mucous membrane of the lower lip, the labial glands, and the Levator menti, with which it is intimately united.

The **Depressor anguli oris** (**Triangularis menti**) is triangular in shape, arising, by its broad base, from the external oblique line of the lower jaw, whence its fibres pass upwards, to be inserted, by a narrow fasciculus, into the angle of the mouth. It is continuous with the Platysma at its origin, and with the Orbicularis oris and Risorius at its insertion, and some of its fibres are directly continuous with those of the Levator anguli oris.

Relations.—By its *superficial surface*, with the integument. By its *deep surface*, with the Depressor labii inferioris and Buccinator.

Nerves.—This group of muscles is supplied by the facial nerve.

Actions.—The Levator labii inferioris raises the lower lip, and protrudes it forwards, and at the same time wrinkles the integument of the chin, expressing doubt or disdain. The Depressor labii inferioris draws the lower lip directly downwards and a little outwards, as in the expression of irony. The Depressor anguli oris depresses the angle of the mouth, being the antagonist of the Levator anguli oris and Zygomaticus major; acting with these muscles, it will draw the angle of the mouth directly backwards.

VIII. Intermaxillary Region

Orbicularis oris. Buccinator. Risorius.

Dissection.—The dissection of these muscles may be considerably facilitated by filling the cavity of the mouth with tow, so as to distend the cheeks and lips; the mouth should then be closed by a few stitches, and the integument carefully removed from the surface.

The **Orbicularis oris** (fig. 389) is not a sphincter muscle like the Orbicularis palpebrarum, but consists of numerous strata of muscular fibres, having different directions, which surround the orifice of the mouth. These fibres are partially derived from the other facial muscles which are inserted into the lips, and are partly fibres proper to the lips themselves. Of the former, a considerable number are derived from the Buccinator and form the deeper stratum of the Orbicularis. Some of them—namely, those near the middle of the Buccinator—decussate at the angle of the mouth, those arising from the upper jaw passing to the lower lip, and those from the lower jaw to the upper lip. Other fibres of the muscle,

situated at its upper and lower part, pass across the lips from side to side without decussation. Superficial to this stratum is a second, formed by the Levator and Depressor anguli oris, which cross each other at the angle of the mouth; those from the Depressor passing to the upper lip, and those from the Levator to the lower lip, along which they run to be inserted into the skin near the median line. In addition to these there are fibres from other muscles inserted into the lips, the Levator labii superioris, the Levator labii superioris alæque nasi, the Zygomatici, and the Depressor labii inferioris; these intermingle with the transverse fibres above described, and have principally an oblique direction. The proper fibres of the lips are oblique, and pass from the under surface of the skin to the mucous membrane, through the thickness of the lip. And in addition to these are fibres by which the muscle is connected directly with the maxillary bones and the septum of the nose. These consist, in the upper lip, of four bands, two of which (*Musculus incisivus superior*) arise from the alveolar border of the superior maxilla, opposite the lateral incisor tooth, and arching outwards on each side are continuous at the angles of the mouth with the other muscles inserted into this part. The two remaining muscular slips, called the *Naso-labialis*, connect the upper lip to the back of the septum of the nose: as they descend from the septum, an interval is left between them. It is this interval which forms the depression seen on the surface of the skin beneath the septum of the nose, which is called the *philtrum*. The additional fibres for the lower segment (*Musculus incisivus inferior*) arise from the inferior maxilla, externally to the Levator labii inferioris, and arch outwards to the angles of the mouth, to join the Buccinator and the other muscles attached to this part.

Relations.—By its *superficial surface*, with the integument, to which it is closely connected. By its *deep surface*, with the buccal mucous membrane, the labial glands, and coronary vessels. By its *outer circumference*, it is blended with the numerous muscles which converge to the mouth from various parts of the face. Its *inner circumference* is free, and covered by mucous membrane.

The **Buccinator** (fig. 401) is a broad, thin muscle, quadrilateral in form, which occupies the interval between the jaws at the side of the face. It arises from the outer surface of the alveolar processes of the upper and lower jaws, corresponding to the three molar teeth; and behind, from the anterior border of the pterygo-mandibular ligament, through which it is continuous with the Superior constrictor of the pharynx. The fibres converge towards the angle of the mouth, where the central fibres intersect each other, those from below being continuous with the upper segment of the Orbicularis oris, and those from above with the inferior segment; the highest and lowest fibres continue forward uninterruptedly into the corresponding segment of the lip without decussation.

Relations.—By its *superficial surface*, behind, with a large mass of fat, which separates it from the ramus of the lower jaw, the Masseter, and a small portion of the Temporal muscle, and which has been named the *suctorial pad*, because it is supposed to assist in the act of sucking. By its outer surface, the Buccinator muscle is in relation with the Zygomatici, Risorius, Levator anguli oris, Depressor anguli oris, and Stenson's duct, which pierces it opposite the second molar tooth of the upper jaw; the facial artery and vein cross it from below upwards; it is also crossed by the branches of the facial and buccal nerves. By its *internal surface*, with the buccal glands and mucous membrane of the mouth.

The *pterygo-mandibular ligament* separates the Buccinator muscle from the Superior constrictor of the pharynx. It is a tendinous band, derived from the deep cervical fascia, attached by one extremity to the apex of the internal pterygoid plate, and by the other to the posterior extremity of the internal oblique line of the lower jaw. Its *inner surface* corresponds to the cavity of the mouth, and is lined by mucous membrane. Its *outer surface* is separated from the ramus of the jaw by a quantity of adipose tissue. Its *posterior border* gives attachment to the Superior constrictor of the pharynx; its *anterior border*, to the fibres of the Buccinator (see fig. 401).

The **Risorius** (*Risorius Santorini*) consists of a narrow bundle of fibres, which arises in the fascia over the Masseter muscle and, passing horizontally forwards, is inserted into the skin at the angle of the mouth (fig. 389). It is

placed superficial to the Platysma, and is broadest at its outer extremity. This muscle varies much in its size and form.

Nerves.—The muscles in this group are all supplied by the facial nerve. The buccal branch of the inferior maxillary nerve pierces the Buccinator muscle, and by some anatomists is regarded as partly supplying this muscle. Probably it merely pierces it on its way to the mucous membrane of the cheek.

Actions.—The Orbicularis oris in its ordinary action produces the direct closure of the lips; by its deep fibres, assisted by the oblique ones, it closely applies the lips to the alveolar arch. The superficial part, consisting principally of the decussating fibres, brings the lips together and also protrudes them forwards. The Buccinators contract and compress the cheeks, so that, during the process of mastication, the food is kept under the immediate pressure of the teeth. When the cheeks have been previously distended with air, the Buccinator muscles expel it from between the lips, as in blowing a trumpet. Hence the name (*buccina*, a trumpet). The Risorius retracts the angles of the mouth, and produces the unpleasant expression which is sometimes seen in tetanus, and is known as 'risus sardonicus.'

IX. Temporo-mandibular Region

Masseter. Temporal.

Masseteric Fascia.—Covering the Masseter muscle, and firmly connected with it, is a strong layer of fascia, derived from the deep cervical fascia. Above, this fascia is attached to the lower border of the zygoma, and behind it covers the parotid gland, constituting the *parotid fascia.*

The **Masseter** is exposed by the removal of this fascia (fig. 389); it is a short, thick muscle, somewhat quadrilateral in form, consisting of two portions, superficial and deep. The *superficial portion*, the larger, arises by a thick, tendinous aponeurosis from the malar process of the superior maxilla, and from the anterior two-thirds of the lower border of the zygomatic arch: its fibres pass downwards and backwards, to be inserted into the angle and lower half of the outer surface of the ramus of the jaw. The *deep portion* is much smaller, and more muscular in texture; it arises from the posterior third of the lower border and the whole of the inner surface of the zygomatic arch; its fibres pass downwards and forwards, to be inserted into the upper half of the ramus and outer surface of the coronoid process of the jaw. The deep portion of the muscle is partly concealed, in front, by the superficial portion; behind, it is covered by the parotid gland. The fibres of the two portions are united at their insertion.

Relations.—By its *superficial surface*, with the Zygomatici, the parotid gland and socia parotidis, and Stenson's duct; the branches of the facial nerve and the transverse facial vessels, which cross it; the masseteric fascia; the Risorius, Platysma myoides, and the integument. By its *deep surface*, with the Temporal muscle at its insertion, the ramus of the jaw, the Buccinator and the long buccal nerve, from which it is separated by a mass of fat. The masseteric nerve and artery enter it on its deep surface. Its *posterior margin* is overlapped by the parotid gland. Its *anterior margin* projects over the Buccinator muscle; and the facial vein lies on it below.

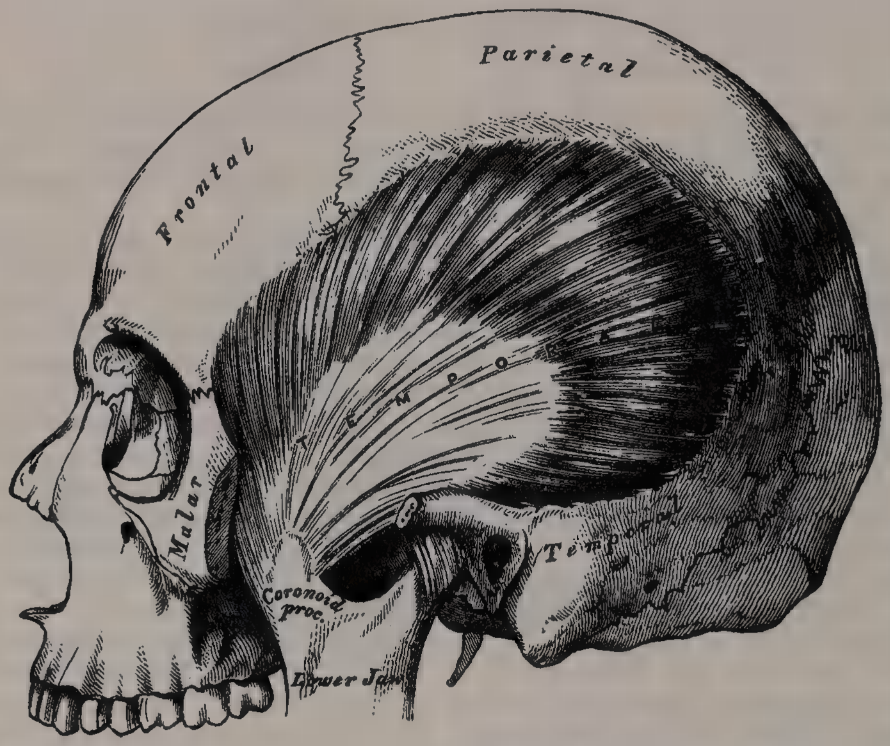
The **Temporal fascia** is seen, at this stage of the dissection, covering in the Temporal muscle. It is a strong, fibrous investment, covered, on its outer surface, by the Attrahens and Attollens auriculam muscles, the aponeurosis of the Occipito-frontalis, and by part of the Orbicularis palpebrarum. The temporal vessels and the auriculo-temporal nerve cross it from below upwards. Above, it is a single layer, attached to the entire extent of the upper temporal ridge; but below, where it is attached to the zygoma, it consists of two layers, one of which is inserted into the outer, and the other into the inner border of the zygomatic arch. A small quantity of fat, the orbital branch of the temporal artery, and a filament from the orbital, or temporo-malar, branch of the superior maxillary nerve, are contained between these two layers. It affords attachment by its inner surface to the superficial fibres of the Temporal muscle.

Dissection.—In order to expose the Temporal muscle, remove the temporal fascia, which may be effected by separating it at its attachment along the upper border of the zygoma, and dissecting it upwards from the surface of the muscle. The zygomatic arch

should then be divided, in front, at its junction with the malar bone; and, behind, near the external auditory meatus, and drawn downwards with the Masseter, which should be detached from its insertion into the ramus and angle of the jaw. The whole extent of the Temporal muscle is then exposed.

The **Temporal** (fig. 393) is a broad, radiating muscle, situated at the side of the head, and occupying the entire extent of the temporal fossa. It arises from the whole of the temporal fossa except that portion of it which is formed by the malar bone. Its attachment extends from the external angular process of the frontal in front, to the mastoid portion of the temporal behind; and from the curved line on the frontal and parietal bones above, to the pterygoid ridge on the great wing of the sphenoid below. It also arises from the inner surface of the temporal fascia. Its fibres converge as they descend, and terminate in an aponeurosis, the fibres of which, radiated at its commencement, converge into a thick and flat tendon, which is inserted into the inner surface, apex, and anterior border of the coronoid process of the jaw, nearly as far forwards as the last molar tooth.

FIG. 393.—The Temporal muscle; the zygoma and Masseter having been removed.



Relations.—By its *superficial surface*, with the integument, the temporal fascia, the Attrahens and Attollens auriculam muscles, the temporal vessels and nerves, the aponeurosis of the Occipito-frontalis, the temporal fascia, the zygoma, and Masseter. By its *deep surface*, with the temporal fossa, the External pterygoid and part of the Buccinator muscles, the internal maxillary artery, its deep temporal branches, the deep temporal nerves, and the buccal vessels and nerve. Behind the tendon are the masseteric vessels and nerve. Its anterior border is separated from the malar bone by a mass of fat.

Nerves.—Both muscles are supplied by the inferior maxillary nerve.

X. Pterygo-mandibular Region (fig. 394).

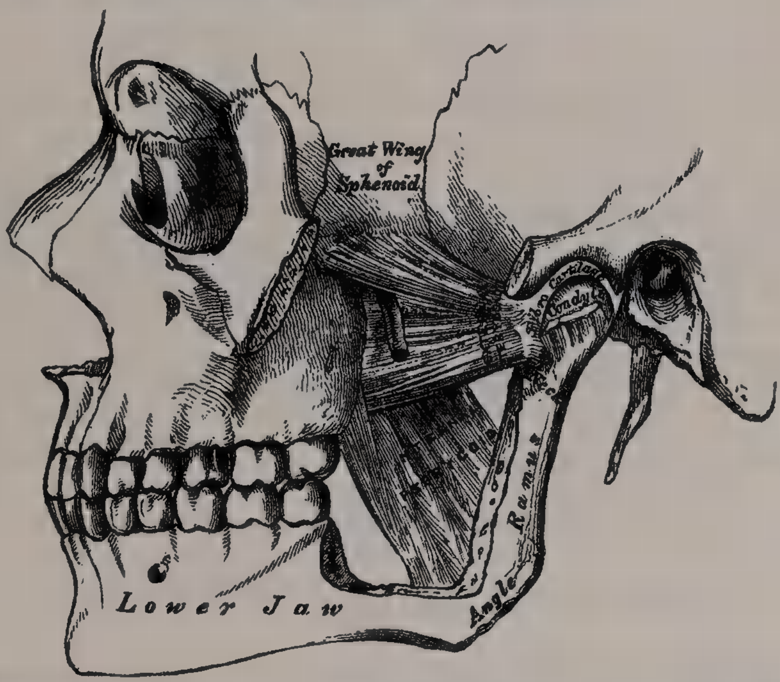
External pterygoid. Internal pterygoid.

Dissection.—The Temporal muscle having been examined, saw through the base of the coronoid process, and draw it upwards, together with the Temporal muscle, which should be detached from the surface of the temporal fossa. Divide the ramus of the jaw just below the condyle, and also, by a transverse incision extending across the middle, just above the dental foramen; remove the fragment of bone, and the Pterygoid muscles will be exposed.

The **External pterygoid** is a short, thick muscle, somewhat conical in form, which extends almost horizontally between the zygomatic fossa and the condyle of the jaw. It arises by two heads, separated by a slight interval: the *upper* arises from the inferior portion of the external surface of the greater wing of the sphenoid and from the pterygoid ridge, which separates the zygomatic from the temporal fossa; the *lower* from the outer surface of the external pterygoid plate. Its fibres pass horizontally backwards and outwards, to be inserted into a depression in front of the neck of the condyle of the lower jaw, and into the corresponding part of the interarticular fibro-cartilage of the temporo-mandibular articulation.

Relations.—By its *external surface*, with the ramus of the lower jaw, the internal maxillary artery, which crosses it,* the tendon of the Temporal muscle and the Masseter. By its *internal surface*, it rests against the upper part of the Internal pterygoid, the internal lateral ligament, the middle meningeal artery, and inferior maxillary nerve; by its *upper border* it is in relation with the temporal and masseteric branches of the inferior maxillary nerve; by its *lower border* it is in relation with the inferior dental and gustatory nerves.

Fig. 394.—The Pterygoid muscles; the zygomatic arch and a portion of the ramus of the jaw having been removed.



Through the interval between the two portions of the muscle, the buccal nerve emerges and the internal maxillary artery passes, when the trunk of this vessel lies on the lower part of the muscle (see fig. 394).

The **Internal pterygoid** is a thick quadrilateral muscle, and resembles the Masseter in form. It arises from the pterygoid fossa, being attached to the inner surface of the external pterygoid plate, and to the grooved surface of the tuberosity of the palate bone, and by a second slip from the outer surface of the tuberosities of the palate and superior maxillary bones; its fibres pass downwards, outwards, and backwards, to be inserted, by a strong tendinous lamina, into the lower and back part of the inner side of the ramus and angle of the lower jaw, as high as the dental foramen.

Relations.—By its *external surface*, with the ramus of the lower jaw, from which it is separated, at its upper part, by the External pterygoid, the internal lateral ligament, the internal maxillary artery, the dental vessels and nerves, the lingual nerve, and a process of the parotid gland. By its *internal surface*, with the Tensor palati, being separated from the Superior constrictor of the pharynx by a cellular interval.

Nerves.—These muscles are supplied by the inferior maxillary nerve.

* In many cases the artery will be found under cover of the muscle.

Actions.—The Temporal, Masseter, and Internal pterygoid raise the lower jaw against the upper with great force. The superficial portion of the Masseter assists the External pterygoid in drawing the lower jaw forwards upon the upper; the jaw being drawn back again by the deep fibres of the Masseter, and posterior fibres of the Temporal. The External pterygoid muscles are the direct agents in the trituration of the food, drawing the lower jaw directly forwards, so as to make the lower teeth project beyond the upper. If the muscle of one side acts, the corresponding side of the jaw is drawn forwards, and the other condyle remaining comparatively fixed, the symphysis deviates to the opposite side. The alternation of these movements on the two sides produces trituration.

Surface Form.—The outline of the muscles of the head and face cannot be traced on the surface of the body, except in the case of two of the masticatory muscles. Those of the head are thin, so that the outline of the bone is perceptible beneath them. Those of the face are small, covered by soft skin, and often by a considerable layer of fat, so that their outline is concealed; but they serve to round off and smooth prominent borders, and to fill up what would be otherwise unsightly angular depressions. Thus, the Orbicularis palpebrarum rounds off the prominent margin of the orbit, and the Pyramidalis nasi fills in the sharp depression beneath the glabella, and thus softens and tones down the abrupt depression which is seen on the unclothed bone. In like manner, the labial muscles, converging to the lips, and assisted by the superimposed fat, fill in the sunken hollow of the lower part of the face. Although the muscles of the face are usually described as arising from the bones, and inserted into the nose, lips, and corners of the mouth, they have fibres inserted into the skin of the face along their whole extent, so that almost every point of the skin of the face has its muscular fibre to move it; hence it is that when in action the facial muscles produce alterations in the skin-surface, giving rise to the formation of various folds or wrinkles, or otherwise altering the relative position of parts, so as to produce the varied expressions with which the face is endowed; these muscles are therefore termed the 'Muscles of expression.' The only two muscles in this region which greatly influence surface-form are the Masseter and the Temporal. The Masseter is a quadrilateral muscle, which imparts fulness to the hinder part of the cheek. When the muscle is firmly contracted, as when the teeth are clenched, its outline is plainly visible; the anterior border forms a prominent vertical ridge, behind which is a considerable fulness, especially marked at the lower part of the muscle; this fulness is entirely lost when the mouth is opened, and the muscle no longer in a state of contraction. The Temporal muscle is fan-shaped, and fills the Temporal fossa, substituting for it a somewhat convex form, the anterior part of which, on account of the absence of hair over the temple, is more marked than the posterior, and stands out in strong relief when the muscle is in a state of contraction.

MUSCLES AND FASCIÆ OF THE NECK

The Muscles of the Neck may be arranged into groups, corresponding with the region in which they are situated.

These groups are nine in number:

I. Superficial Region.
II. Infrahyoid Region.
III. Suprahyoid Region.
IV. Lingual Region.
V. Pharyngeal Region.
VI. Palatal Region.
VII. Anterior Vertebral Region.
VIII. Lateral Vertebral Region.
IX. Muscles of the Larynx.

The muscles contained in each of these groups are the following:

I. Superficial Region.

Platysma myoides.
Sterno-cleido-mastoid.

II. Infrahyoid Region.

Sterno-hyoid.
Sterno-thyroid.
Thyro-hyoid.
Omo-hyoid.

III. Suprahyoid Region.

Digastric.
Stylo-hyoid.
Mylo-hyoid.
Genio-hyoid.

IV. Lingual Region.

Extrinsic.
- Genio-hyo-glossus.
- Hyo-glossus.
- Chondro-glossus.
- Stylo-glossus.
- Palato-glossus.

Intrinsic.
- Superior lingualis.
- Inferior lingualis.
- Transverse lingualis.
- Vertical lingualis.

V. Pharyngeal Region.
- Inferior constrictor.
- Middle constrictor.
- Superior constrictor.
- Stylo-pharyngeus.
- Palato-pharyngeus.
- Salpingo-pharyngeus.

VI. Palatal Region.
- Levator palati.
- Tensor palati.
- Azygos uvulæ.
- Palato-glossus.
- Palato-pharyngeus.
- Salpingo-pharyngeus.

VII. Anterior Vertebral Region.
- Rectus capitis anticus major.
- Rectus capitis anticus minor.
- Rectus capitis lateralis.
- Longus colli.

VIII. Lateral Vertebral Region.
- Scalenus anticus.
- Scalenus medius.
- Scalenus posticus.

IX. Muscles of the Larynx.
Included in the description of the Larynx.

I. Superficial Cervical Region

Platysma myoides. Sterno-cleido-mastoid.

Dissection.—A block having been placed at the back of the neck, and the face turned to the side opposite that to be dissected, so as to place the parts upon the stretch, make two transverse incisions: one from the chin, along the margin of the lower jaw, to the mastoid process; and the other along the upper border of the clavicle. Connect these by an oblique incision made in the course of the Sterno-mastoid muscle, from the mastoid process to the sternum; the two flaps of integument having been removed in the direction shown in fig. 388, the superficial fascia will be exposed.

The **Superficial cervical fascia** is a thin aponeurotic lamina, which is hardly demonstrable as a separate membrane. Beneath it is found the Platysma myoides muscle.

The **Platysma myoides** (fig. 389) is a broad, thin plane of muscular fibres, placed immediately beneath the superficial fascia on each side of the neck. It arises by thin, fibrous bands from the fascia covering the upper part of the Pectoral and Deltoid muscles; its fibres pass over the clavicle, and proceed obliquely upwards and inwards along the side of the neck. The anterior fibres interlace, below and behind the symphysis menti, with the fibres of the muscle of the opposite side; the posterior fibres pass over the lower jaw, some of them being attached to the bone below the external oblique line, others passing on to be inserted into the skin and subcutaneous tissue of the lower part of the face, many of these fibres blending with the muscles about the angle and lower part of the mouth. Sometimes fibres can be traced to the Zygomatic muscles, or to the margin of the Orbicularis oris. Beneath the Platysma, the external jugular vein may be seen descending from the angle of the jaw to the clavicle.

Relations.—By its *external surface*, with the integument, to which it is united more closely below than above. By its *internal surface*, with the Pectoralis major and Deltoid, and with the clavicle. In the *neck*, with the external and anterior jugular veins, the deep cervical fascia, the superficial branches of the cervical plexus, the Sterno-mastoid, Sterno-hyoid, Omo-hyoid, and Digastric muscles. Behind the Sterno-mastoid muscle, it covers in the posterior triangle of the neck. On the *face*, it is in relation with the parotid gland, the facial artery and vein, and the Masseter and Buccinator muscles.

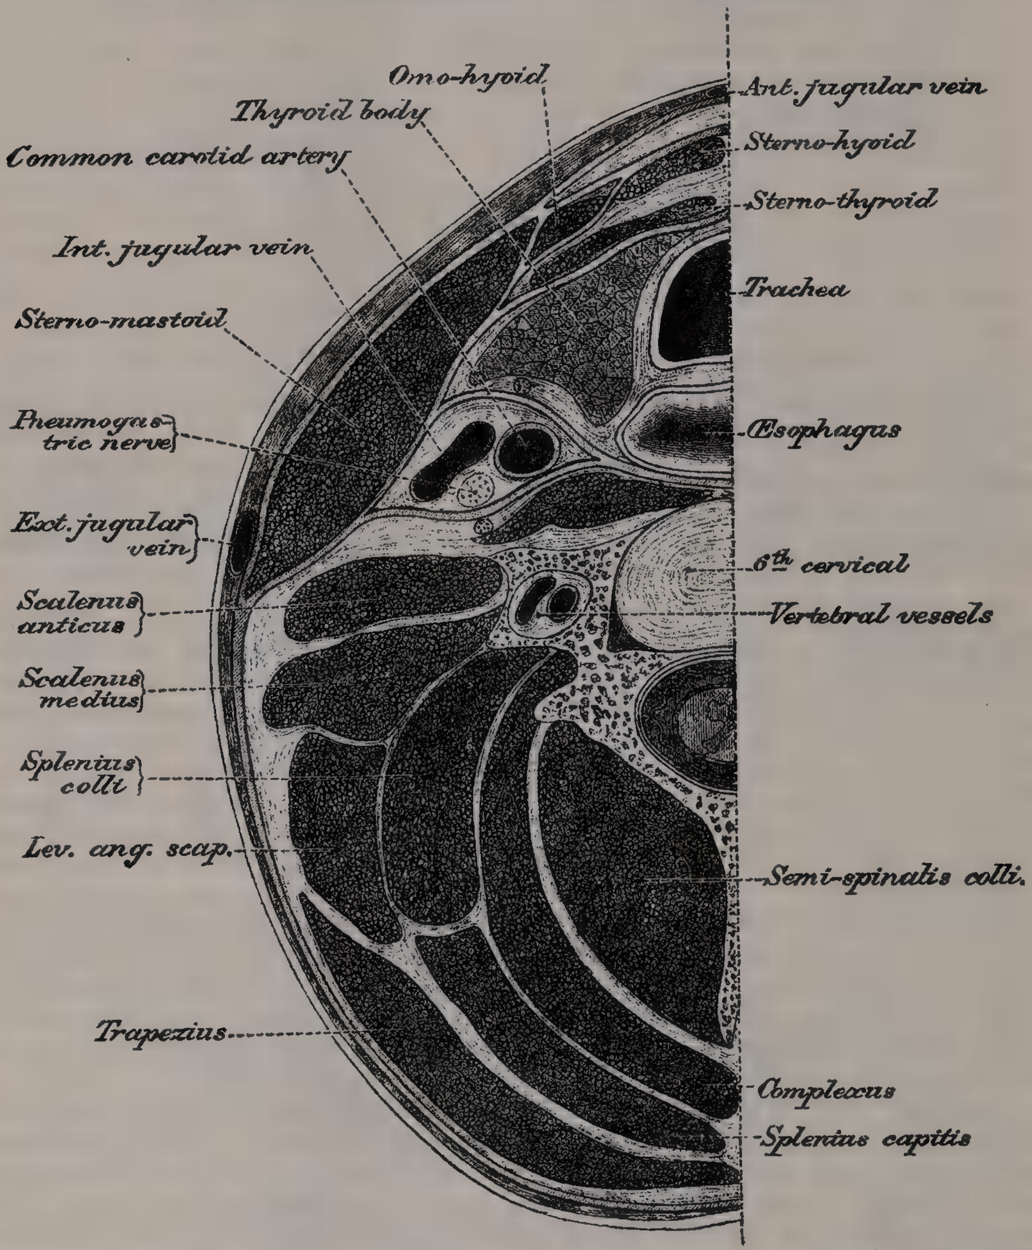
Actions.—The Platysma myoides produces a slight wrinkling of the surface of the skin of the neck, in an oblique direction, when the entire muscle is brought into action. Its anterior portion, the thickest part of the muscle, depresses the lower jaw; it also serves to draw down the lower lip and angle of the mouth on each side, being one of the chief agents in the expression of melancholy.

The **Deep cervical fascia** (fig. 395) lies under cover of the Platysma myoides muscle and constitutes a complete investment for the neck. It also forms a

sheath for the carotid vessels, and, in addition, is prolonged deeply in the shape of certain processes or lamellæ, which come into close relation with the structures situated in front of the vertebral column.

The investing portion of the fascia is attached behind to the ligamentum nuchæ and to the spine of the seventh cervical vertebra. It forms a thin investment to the Trapezius muscle, and at its anterior border is continued forwards as a rather loose areolar layer, covering the posterior triangle of the neck, to the posterior border of the Sterno-mastoid muscle, where it begins to assume the appearance of a true fascia. Along the hinder edge of this muscle it divides to

FIG. 395.—Section of the neck at about the level of the sixth cervical vertebra. Showing the arrangement of the deep cervical fascia.



enclose it, and at the anterior margin again forms a single lamella, which roofs in the anterior triangle of the neck, and, reaching forwards to the middle line, is continuous with the corresponding part from the opposite side of the neck. In the middle line of the neck it is attached to the symphysis menti and body of the hyoid bone.

Above, the fascia is attached to the superior curved line of the occiput, to the mastoid process of the temporal, and to the whole length of the body of the jaw. Opposite the angle of the jaw the fascia is very strong, and binds the anterior edge of the Sterno-mastoid firmly to that bone. Between the jaw and the

mastoid process it ensheathes the parotid gland—the layer which covers the gland extending upwards under the name of the *parotid fascia* to be fixed to the zygomatic arch. From the layer which passes under the parotid a strong band extends upwards to the styloid process, forming the *stylo-mandibular ligament.* From this three prolongations form: the *internal lateral ligament of the lower jaw*, the *pterygo-mandibular* and the *pterygo-spinous ligaments.* The latter of these three, the **pterygo-spinous ligament**, is a membranous band which stretches across from the upper half of the posterior free border of the external pterygoid plate to the spinous process of the sphenoid bone. It occasionally ossifies, and produces an adventitious foramen between its upper border and the base of the skull, through which pass the branches of the third division of the fifth nerve, which supply the muscles of mastication.

Below, the fascia is attached to the acromion process, the clavicle, and manubrium sterni. Some little distance above the last, however, it splits into two layers, superficial and deep. The former is attached to the anterior border of the manubrium, the latter to its posterior border and to the interclavicular ligament. Between these two layers is a slit-like interval, the *suprasternal space*, or *space of Burns.* It contains a small quantity of areolar tissue, and sometimes a lymphatic gland; the lower portions of the anterior jugular veins and their transverse connecting branch; and also the sternal heads of the Sterno-mastoid muscles.

The fascia which lines the deep aspect of the Sterno-mastoid gives off certain important processes, viz.: (1) A process to envelop the tendon of the Omo-hyoid, and bind it down to the sternum and first costal cartilage. (2) A strong sheath, the *carotid sheath*, which encloses the carotid artery, internal jugular vein, and the vagus nerve. (3) The *prevertebral fascia*, which extends inwards behind the carotid vessels, where it assists in forming their sheath, and passes in front of the prevertebral muscles. It thus forms the posterior limit of a fibrous compartment, which contains the larynx and trachea, the thyroid gland, and the pharynx and œsophagus. The prevertebral fascia is fixed above to the base of the skull, while below it is continued into the thorax in front of the Longus colli muscles. Parallel to the carotid vessels and along their inner aspect the prevertebral fascia gives off a thin lamina, the *bucco-pharyngeal fascia*, which closely invests the Constrictor muscles of the pharynx, and is continued forward from the Superior constrictor on to the Buccinator. It is attached to the prevertebral layer by loose connective tissue only, and thus an easily distended space, the *retro-pharyngeal space*, is found between them. This space is limited above by the base of the skull, while below it extends behind the œsophagus into the thorax, where it is continued into the posterior mediastinum. The prevertebral fascia is prolonged downwards and outwards behind the carotid vessels and in front of the Scaleni muscles, and forms a sheath for the brachial nerves and subclavian vessels in the posterior triangle of the neck, and, continued under the clavicle as the axillary sheath, is attached to the deep surface of the costo-coracoid membrane. Immediately above the clavicle an areolar space exists between the investing layer and the sheath of the subclavian vessels, and in it are found the lower part of the external jugular vein, the descending clavicular nerves, the suprascapular and transversalis colli vessels, and the posterior belly of the Omo-hyoid muscle. This space extends downwards behind the clavicle, and is limited below by the fusion of the costo-coracoid membrane with the anterior wall of the axillary sheath. (4) The *pretracheal fascia*, which extends inwards in front of the carotid vessels, and assists in forming the carotid sheath. It is further continued behind the depressor muscles of the hyoid bone, and, after enveloping the thyroid body, is prolonged in front of the trachea to meet the corresponding layer of the opposite side. Above, it is fixed to the hyoid bone, while below it is carried downwards in front of the trachea and large vessels at the root of the neck, and ultimately blends with the fibrous pericardium.

Surgical Anatomy.—The cervical fascia is of considerable importance from a surgical point of view. As will be seen from the foregoing description, it may be divided into three layers: (1) a superficial layer; (2) a layer passing in front of the trachea, and forming with the superficial layer a sheath for the depressors of the hyoid bone; (3) a prevertebral layer passing in front of the bodies of the cervical vertebræ, and forming with the second layer a space in which is contained the trachea, œsophagus, &c. The superficial layer forms a complete investment for the neck. It is attached behind to the ligamentum nuchæ and the spine of the seventh cervical vertebra: above, it is fixed

to the external occipital protuberance, to the superior curved line of the occiput, to the mastoid process, to the zygoma and the lower jaw; below, it is attached to the manubrium sterni, the clavicle, the acromion process, and the spine of the scapula; in front, it blends with the fascia of the opposite side. This layer would oppose the extension of abscesses or new growths towards the surface, and pus forming beneath it would have a tendency to extend laterally. If the pus is in the posterior triangle, it might extend backwards under the Trapezius, forwards under the Sterno-mastoid, or downwards under the clavicle for some distance, until stopped by the junction of the cervical fascia to the costo-coracoid membrane. If it is contained in the anterior triangle, it might find its way into the anterior mediastinum, being situated in front of the layer of fascia which passes down into the thorax to become continuous with the pericardium; but owing to the less density and thickness of the fascia in this situation it more frequently finds its way through it and points above the sternum. The second layer of fascia is connected above with the hyoid bone. It passes down beneath the depressors and in front of the thyroid body and trachea to become continuous with the fibrous layer of the pericardium. Laterally it invests the great vessels of the neck and is connected with the superficial layer beneath the Sterno-mastoid. Pus forming beneath this layer would in all probability find its way into the posterior mediastinum. The third layer (the prevertebral fascia) is connected above to the base of the skull. Pus forming beneath this layer, in cases, for instance, of caries of the bodies of the cervical vertebræ, might extend towards the posterior and lateral part of the neck and point in this situation, or might perforate this layer of fascia and the pharyngeal fascia and point into the pharynx (retro-pharyngeal abscess).

In cases of cut throat the cervical fascia is of considerable importance. When the wound involves only the superficial layer the injury is usually trivial, the special danger being injury to the external jugular vein, and the special complication diffuse cellulitis. But where the second of the two layers is opened up, important structures may be injured, and lead to serious results.

It may be worth while mentioning that in Burns's space is contained the sternal head of origin of the Sterno-mastoid muscle, so that this space is opened in division of this tendon. The anterior jugular vein is also contained in the same space.

The **Sterno-mastoid** or **Sterno-cleido-mastoid** (fig. 396) is a large, thick muscle, which passes obliquely across the side of the neck, being enclosed between the two laminæ of the investing layer of the deep cervical fascia. It is thick and narrow at its central part, but is broader and thinner at each extremity. It arises, by two heads, from the sternum and clavicle. The *sternal portion* is a rounded fasciculus, tendinous in front, fleshy behind, which arises from the upper and anterior part of the first piece of the sternum, and is directed upwards, outwards, and backwards. The *clavicular portion* arises from the inner third of the superior border and anterior surface of the clavicle, being composed of fleshy and aponeurotic fibres; it is directed almost vertically upwards. These two portions are separated from one another, at their origin, by a triangular interval, but become gradually blended, below the middle of the neck, into a thick, rounded muscle, which is inserted, by a strong tendon, into the outer surface of the mastoid process, from its apex to its superior border, and by a thin aponeurosis into the outer half of the superior curved line of the occipital bone. The Sterno-mastoid varies much in its extent of attachment to the clavicle: in one case the clavicular may be as narrow as the sternal portion; in another, as much as three inches in breadth. When the clavicular origin is broad, it is occasionally subdivided into numerous slips, separated by narrow intervals. More rarely, the corresponding margins of the Sterno-mastoid and Trapezius have been found in contact. In the application of a ligature to the third part of the subclavian artery, it will be necessary, where the muscles come close together, to divide a portion of one or of both.

This muscle divides the quadrilateral space at the side of the neck into two triangles, an anterior and a posterior. The boundaries of the *anterior triangle* are, in front, the median line of the neck; above, the lower border of the body of the jaw, and an imaginary line drawn from the angle of the jaw to the Sterno-mastoid; behind, the anterior border of the Sterno-mastoid muscle. The apex of the triangle is at the upper border of the sternum. The boundaries of the *posterior triangle* are, in front, the posterior border of the Sterno-mastoid; below, the middle third of the clavicle; behind, the anterior margin of the Trapezius.* The apex corresponds with the meeting of the Sterno-mastoid and Trapezius on the occipital bone.

* The anatomy of these triangles will be more exactly described with that of the vessels of the neck.

Relations.—By its *superficial surface*, with the integument and Platysma, from which it is separated by the external jugular vein, several of the superficial branches of the cervical plexus, and the anterior layer of the deep cervical fascia. By its *deep surface*, it is in relation with the Sterno-clavicular articulation ; a process of the deep cervical fascia ; the Sterno-hyoid, Sterno-thyroid, Omo-hyoid, posterior belly of the Digastric, Levator anguli scapulæ, Splenius and Scaleni muscles ; common carotid artery, internal and anterior jugular veins, commencement of the internal and external carotid arteries, the occipital, subclavian, transversalis colli, and suprascapular arteries and veins ; the phrenic, pneumogastric, hypoglossal, descendens and communicantes hypoglossi nerves ; the spinal accessory nerve, which pierces its upper third ; the cervical plexus, parts of the thyroid and parotid glands and deep lymphatic glands.

FIG. 396.—Muscles of the neck, and boundaries of the triangles.

Nerves.—The Platysma myoides is supplied by the facial nerve ; the Sterno-cleido-mastoid by the spinal accessory and branches from the anterior primary divisions of the second and third cervical nerves.

Actions.—When only one Sterno-mastoid muscle acts, it draws the head towards the shoulder of the same side, assisted by the Splenius and the Obliquus capitis inferior of the opposite side. At the same time it rotates the head so as to carry the face towards the opposite side. If the head is fixed, the two muscles assist in elevating the thorax in forced inspiration.

Surface Form.—The anterior edge of the muscle forms a very prominent ridge beneath the skin, which it is important to notice, as it constitutes a guide to the surgeon in making the necessary incisions for ligature of the common carotid artery, and for œsophagotomy.

Surgical Anatomy.—The surgical anatomy of the Sterno-mastoid muscle is of importance in connection with the deformity known as *wry-neck*, which is due to a paralytic or spastic condition of this muscle. The wry-neck may be temporary, as the result of direct irritation of the muscle or of the nerves which supply it, and may occur in acute glandular enlargement, cellulitis of the neck, myositis of the muscle, or cervical caries.

Or it may be permanent, and is then very often due to injury to the muscle during birth, especially in breech presentations; rupture of the muscle and subsequent cicatricial contraction taking place.

In these cases, division of the muscle is often necessary to effect a cure, and this may be done either subcutaneously or through an open wound. The subcutaneous method is thus performed: The external jugular and anterior jugular veins having been, if possible, defined, a tenotomy knife is introduced close to the margin of one tendon of origin of the muscle, about half an inch above the clavicle, and the tenotome passed flat behind the tendon and then turned forwards, and the tendon divided from behind forwards while the muscle is put well upon the stretch by an assistant. The other tendon is then divided in a similar manner. In dividing the clavicular origin, it is always desirable to introduce the tenotome along the posterior border, in order to avoid the external jugular vein. The open method is, however, much to be preferred, as being the more effectual and the less dangerous, if precautions are taken to keep the wound aseptic. The tendons of origin are freely exposed by a horizontal incision across the root of the neck and carefully divided; any tense bands of fascia which can be felt should also be divided. The wound is now sutured and dressed, and the head fixed in a perfectly straight position by a plaster-of-Paris bandage.

II. Infrahyoid Region (figs. 396, 397)

Sterno-hyoid.	Thyro-hyoid.
Sterno-thyroid.	Omo-hyoid.

Dissection.—The muscles in this region may be exposed by removing the deep fascia from the front of the neck. In order to see the entire extent of the Omo-hyoid, it is necessary to divide the Sterno-mastoid at its centre, and turn its ends aside, and to detach the Trapezius from the clavicle and scapula. This, however, should not be done until the Trapezius has been dissected.

The **Sterno-hyoid** is a thin, narrow, riband-like muscle, which arises from the inner extremity of the clavicle, the posterior sterno-clavicular ligament, and the upper and posterior part of the manubrium sterni; passing upwards and inwards, it is inserted, by short, tendinous fibres, into the lower border of the body of the os hyoides. This muscle is separated, below, from its fellow by a considerable interval; but the two muscles come into contact with one another in the middle of their course, and from this upwards, lie side by side. It sometimes presents, immediately above its origin, a transverse tendinous intersection, like those in the Rectus abdominis.

Relations.—By its *superficial surface*, below, with the sternum, the sternal end of the clavicle, and the Sterno-mastoid; and above, with the Platysma and deep cervical fascia. By its *deep surface*, with the Sterno-thyroid, Crico-thyroid, and Thyro-hyoid muscles, the thyroid gland, the superior thyroid vessels, the thyroid cartilage, the crico-thyroid and thyro-hyoid membranes. Usually two bursæ are found between the crico-thyroid membrane and the under surface of this muscle. Occasionally there is only one, and in some instances no bursa at all. They are called the Sterno-hyoid bursæ.

The **Sterno-thyroid** is shorter and wider than the preceding muscle, beneath which it is situated. It arises from the posterior surface of the manubrium sterni, below the origin of the Sterno-hyoid, and from the edge of the cartilage of the first rib, and sometimes of the second rib also; and is inserted into the oblique line on the side of the ala of the thyroid cartilage. This muscle is in close contact with its fellow at the lower part of the neck; and is occasionally traversed by a transverse or oblique tendinous intersection like those in the Rectus abdominis.

Relations.—By its *anterior surface*, with the Sterno-hyoid, Omo-hyoid, and Sterno-mastoid. By its *posterior surface*, from below upwards, with the trachea, vena innominata, common carotid (and on the right side the arteria innominata), the thyroid gland and its vessels, and the lower parts of the larynx and pharynx. The inferior thyroid vein lies along its inner border, a relation which it is important to remember in the operation of tracheotomy. On the left side the deep surface of the muscle is in relation to the œsophagus.

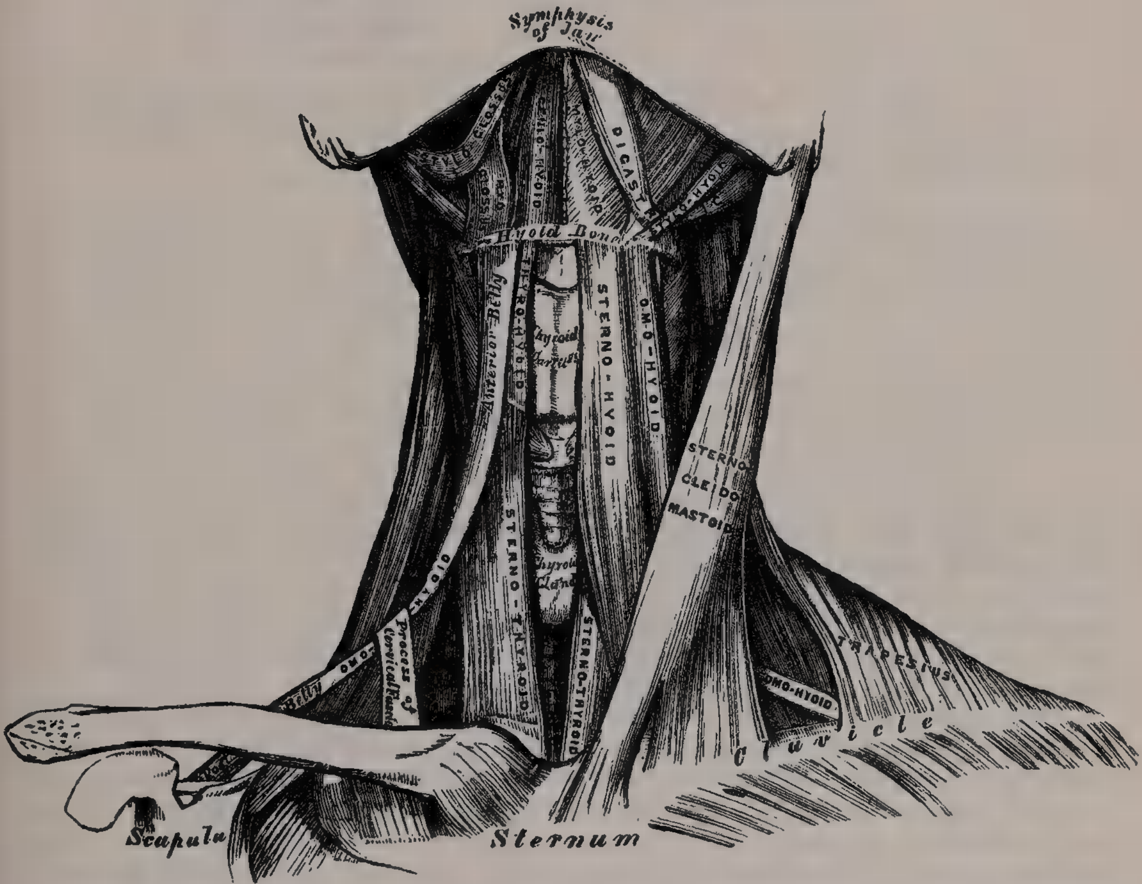
The **Thyro-hyoid** is a small, quadrilateral muscle appearing like a continuation of the Sterno-thyroid. It arises from the oblique line on the side of the thyroid

cartilage, and passes vertically upwards to be inserted into the lower border of the body and greater cornu of the hyoid bone.

Relations.—By its *external surface*, with the Sterno-hyoid and Omo-hyoid muscles. By its *internal surface*, with the thyroid cartilage, the thyro-hyoid membrane, and the superior laryngeal vessels and nerve.

The **Omo-hyoid** passes across the side of the neck, from the scapula to the hyoid bone. It consists of two fleshy bellies, united by a central tendon. It arises from the upper border of the scapula, and occasionally from the transverse ligament which crosses the suprascapular notch; its extent of attachment to the scapula varying from a few lines to an inch. From this origin, the posterior belly forms a flat, narrow fasciculus, which inclines forwards and slightly upwards across the lower part of the neck, being bound down to the clavicle by a fibrous expansion, and passing behind the Sterno-mastoid muscle, it becomes tendinous; it then changes its direction, forming an obtuse angle, and terminates in the anterior belly, which passes almost vertically upwards, close to the outer border

Fig. 397.—Muscles of the neck. Anterior view.



of the Sterno-hyoid, to be inserted into the lower border of the body of the os hyoides, just external to the insertion of the Sterno-hyoid. The central tendon of this muscle, which varies much in length and form, is held in position by a process of the deep cervical fascia, which sheathes it. This process is prolonged down, to be attached to the clavicle and first rib. It is by this means that the angular form of the muscle is maintained.

This muscle subdivides each of the two large triangles at the side of the neck into two smaller triangles; the two posterior ones being the *posterior superior* or *occipital*, and the *posterior inferior* or *subclavian triangles*; the two anterior, the *anterior superior* or *carotid*, and the *anterior inferior* or *muscular triangles*.

Relations.—By its *superficial surface*, with the Trapezius, the Sterno-mastoid, deep cervical fascia, Platysma, and integument. By its *deep surface*, with the Scaleni muscles, phrenic nerve, lower cervical nerves, which go to form the brachial plexus, the suprascapular vessels and nerve, sheath of the common carotid artery and internal jugular vein, the Sterno-thyroid and Thyro-hyoid muscles.

Nerves.—The Thyro-hyoid and anterior belly of the Omo-hyoid are supplied by the descendens hypoglossi; the Sterno-hyoid, Sterno-thyroid, and posterior belly of the Omo-hyoid, by branches from the loop of communication between the descendens and communicantes hypoglossi.

Actions.—These muscles depress the larynx and hyoid bone, after they have been drawn up with the pharynx in the act of deglutition. The Omo-hyoid muscles not only depress the hyoid bone, but carry it backwards, and to one or the other side. It is concerned especially in prolonged inspiratory efforts; for by tensing the lower part of the cervical fascia it lessens the inward suction of the soft parts, which would otherwise compress the great vessels and the apices of the lungs. The Thyro-hyoid may act as an elevator of the thyroid cartilage, when the hyoid bone ascends, drawing upwards the thyroid cartilage, behind the os hyoides. The Sterno-thyroid acts as a depressor of the thyroid cartilage.

III. Suprahyoid Region (figs. 396, 397)

Digastric.	Mylo-hyoid.
Stylo-hyoid.	Genio-hyoid.

Dissection.—To dissect these muscles, a block should be placed beneath the back of the neck, and the head drawn backwards, and retained in that position. On the removal of the deep fascia, the muscles are at once exposed.

The **Digastric** consists of two fleshy bellies united by an intermediate, rounded tendon. It is a small muscle, situated below the side of the body of the lower jaw, and extending, in a curved form, from the side of the head to the symphysis of the jaw. The *posterior belly*, longer than the anterior, arises from the digastric groove on the inner side of the mastoid process of the temporal bone, and passes downwards, forwards, and inwards. The *anterior belly* arises from a depression on the inner side of the lower border of the jaw, close to the symphysis, and passes downwards and backwards. The two bellies terminate in the central tendon which perforates the Stylo-hyoid muscle, and is held in connection with the side of the body and the greater cornu of the hyoid bone by a fibrous loop, lined by a synovial membrane. A broad aponeurotic layer is given off from the tendon of the Digastric on each side, which is attached to the body and great cornu of the hyoid bone; this is termed the *suprahyoid aponeurosis*. It forms a strong layer of fascia between the anterior portion of the two muscles, and a firm investment for the other muscles of the suprahyoid region which lie deeper.

The Digastric muscle divides the anterior superior triangle of the neck into two smaller triangles; the upper, or *submaxillary*, being bounded, above, by the lower border of the body of the jaw, and a line drawn from its angle to the mastoid process; below, by the posterior belly of the Digastric and the Stylo-hyoid muscles; in front, by the anterior belly of the Digastric: the lower or *carotid triangle* being bounded above by the posterior belly of the Digastric, behind by the Sterno-mastoid, below by the Omo-hyoid.

Relations.—By its *superficial surface*, with the Mastoid process, the Platysma, Sterno-mastoid, part of the Splenius, Trachelo-mastoid, and Stylo-hyoid muscles, and the parotid gland. By its *deep surface*, the anterior belly lies on the Mylo-hyoid; the posterior belly on the Stylo-glossus, Stylo-pharyngeus, and Hyo-glossus muscles, the external carotid artery and its occipital, lingual, facial, and ascending pharyngeal branches, the internal carotid artery, internal jugular vein, and hypoglossal nerve.

The **Stylo-hyoid** is a small, slender muscle, lying in front of, and above, the posterior belly of the Digastric. It arises from the back and outer surface of the styloid process, near the base; and, passing downwards and forwards, is inserted into the body of the hyoid bone, just at its junction with the greater cornu, and just above the Omo-hyoid. This muscle is perforated, near its insertion, by the tendon of the Digastric.

Relations.—By its *superficial surface*, above with the parotid gland and deep cervical fascia; below it is superficial, being situated immediately beneath the deep cervical fascia. By its *deep surface*, with the posterior belly of the Digastric,

the external carotid artery, with its lingual and facial branches, the Hyo-glossus muscle, and the hypoglossal nerve.

The Stylo-hyoid ligament.—In connection with the Stylo-hyoid muscle may be described a ligamentous band, the *Stylo-hyoid ligament.* It is a fibrous cord, often containing a little cartilage in its centre, which continues the styloid process down to the hyoid bone, being attached to the tip of the former and the small cornu of the latter. It is often more or less ossified, and in many animals forms a distinct bone, the *epihyal.*

The anterior belly of the Digastric should be removed, in order to expose the next muscle.

The **Mylo-hyoid** is a flat, triangular muscle, situated immediately beneath the anterior belly of the Digastric, and forming, with its fellow of the opposite side, a muscular floor for the cavity of the mouth. It arises from the whole length of the mylo-hyoid ridge of the lower jaw, extending from the symphysis in front to the last molar tooth behind. The posterior fibres pass inwards and slightly downwards, to be inserted into the body of the os hyoides. The middle and anterior fibres are inserted into a median fibrous raphé, extending from the symphysis of the lower jaw to the hyoid bone, where they join at an angle with the fibres of the opposite muscle. This median raphé is sometimes wanting; the muscular fibres of the two sides are then directly continuous with one another.

Relations.—By its *cutaneous* or *under surface,* with the Platysma, the anterior belly of the Digastric, the suprahyoid aponeurosis, the submaxillary gland, submental vessels, and mylo-hyoid vessels and nerve. By its *deep* or *superior surface,* with the Genio-hyoid, part of the Hyo-glossus, and Stylo-glossus muscles, the hypoglossal and lingual nerves, the submaxillary ganglion, the sublingual gland, the deep portion of the submaxillary gland and Wharton's duct; the sublingual and ranine vessels, and the buccal mucous membrane.

Dissection.—The Mylo-hyoid should now be removed, in order to expose the muscles which lie beneath; this is effected by reflecting it from its attachments to the hyoid bone and jaw, and separating it by a vertical incision from its fellow of the opposite side.

The **Genio-hyoid** is a narrow, slender muscle, situated immediately beneath* the inner border of the preceding. It arises from the inferior genial tubercle on the inner side of the symphysis of the jaw, and passes downwards and backwards, to be inserted into the anterior surface of the body of the os hyoides. This muscle lies in close contact with its fellow of the opposite side, and increases slightly in breadth as it descends.

Relations.—It is covered by the Mylo-hyoid, and lies along the lower border of the Genio-hyo-glossus.

Nerves.—The Mylo-hyoid and anterior belly of the Digastric are supplied by the mylo-hyoid branch of the inferior dental; the Stylo-hyoid and posterior belly of the Digastric, by the facial; the Genio-hyoid, by the hypoglossal.

Actions.—This group of muscles performs two very important actions. They raise the hyoid bone, and with it the base of the tongue, during the act of deglutition; or, when the hyoid bone is fixed by its depressors and those of the larynx, they depress the lower jaw. During the first act of deglutition, when the mass of food is being driven from the mouth into the pharynx, the hyoid bone, and with it the tongue, is carried upwards and forwards by the anterior belly of the Digastric, the Mylo-hyoid, and Genio-hyoid muscles. In the second act, when the mass is passing through the pharynx, the direct elevation of the hyoid bone takes place by the combined action of all the muscles; and after the food has passed, the hyoid bone is carried upwards and backwards by the posterior belly of the Digastric and Stylo-hyoid muscles, which assist in preventing its return into the mouth.

* This refers to the depth of the muscles from the skin in the order of dissection. In the erect position of the body each of these muscles lies above the preceding.

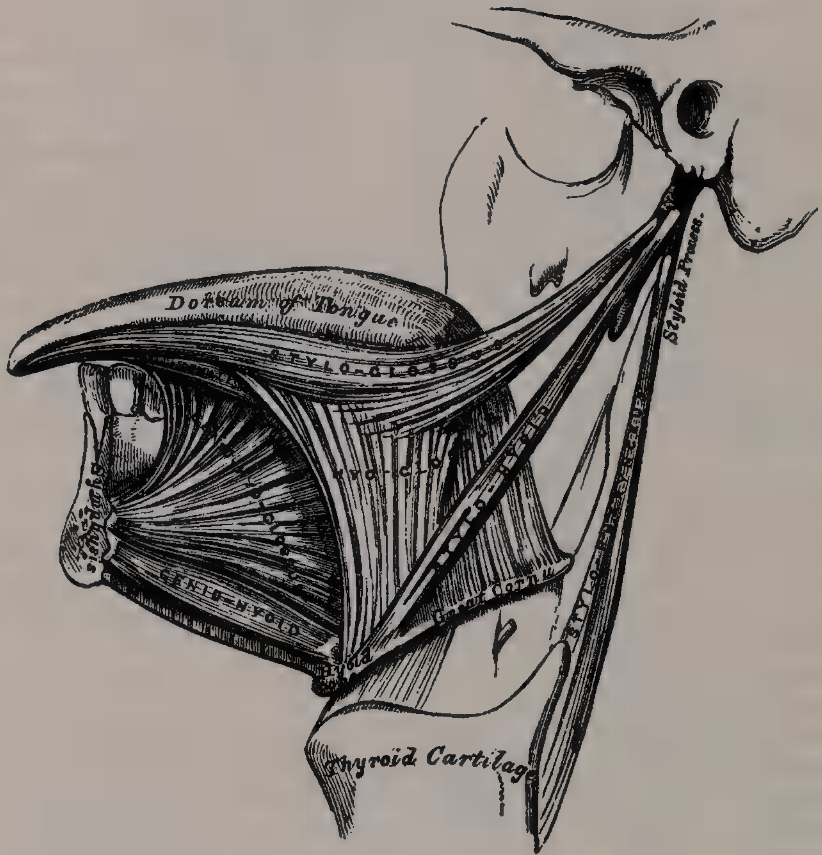
IV. Lingual Region

Genio-hyo-glossus. Chondro-glossus.
Hyo-glossus. Stylo-glossus.
Palato-glossus.

Dissection.—After completing the dissection of the preceding muscles, saw through the lower jaw just external to the symphysis. Then draw the tongue forwards, and attach it, by a stitch, to the nose; when its muscles, which are thus put on the stretch, may be examined.

The **Genio-hyo-glossus** has received its name from its triple attachment to the jaw, hyoid bone, and tongue, but its connection with the hyoid bone is very slight or altogether absent. It is a flat, triangular muscle, placed vertically close to the middle line, its apex corresponding with its point of origin from the lower jaw, its base with its insertion into the tongue and hyoid bone. It arises by a short tendon from the superior genial tubercle on the inner side of the symphysis

Fig. 398.—Muscles of the tongue. Left side.



of the jaw, immediately above the Genio-hyoid; from this point the muscle spreads out in a fan-like form, a few of the inferior fibres extending downwards, to be attached by a thin aponeurosis into the upper part of the body of the hyoid bone, a few fibres passing between the Hyo-glossus and Chondro-glossus to blend with the Constrictor muscles of the pharynx; the middle fibres passing backwards, and the superior ones upwards and forwards, to enter the whole length of the under surface of the tongue, from the base to the apex. The muscles lie one on either side of the median plane; behind, they are quite distinct from each other, and are separated at their insertion into the under surface of the tongue by a tendinous raphé, which extends through the middle of the organ; in front, the two muscles are more or less blended: distinct fasciculi are to be seen passing off from one muscle, crossing the middle line, and intersecting with bundles of fibres derived from the muscle on the other side.

Relations.—By its *internal surface* it is in contact with its fellow of the opposite side. By its *external surface*, with the Inferior lingualis, the Hyo-glossus, the lingual artery and hypoglossal nerve, the lingual nerve, and sublingual gland.

By its *upper border*, with the mucous membrane of the floor of the mouth (frænum linguæ). By its *lower border*, with the Genio-hyoid.

The **Hyo-glossus** is a thin, flat, quadrilateral muscle, which arises from the side of the body, and whole length of the greater cornu of the hyoid bone, and passes almost vertically upwards to enter the side of the tongue, between the Stylo-glossus and Inferior lingualis. Those fibres of this muscle which arise from the body of the hyoid bone are directed upwards and backwards, overlapping those arising from the greater cornu, which are directed upwards and forwards.

Relations.—By its *external surface*, with the Digastric, the Stylo-hyoid, Stylo-glossus, and Mylo-hyoid muscles, the submaxillary ganglion, the lingual and hypoglossal nerves, Wharton's duct, the ranine vein, the sublingual gland, and the deep portion of the submaxillary gland. By its *deep surface*, with the Stylo-hyoid ligament, the Genio-hyo-glossus, Inferior lingualis, and Middle constrictor, the lingual vessels, and the glosso-pharyngeal nerve.

The **Chondro-glossus** (fig. 399) is a distinct muscular slip, though it is sometimes described as a part of the Hyo-glossus, from which, however, it is separated by the fibres of the Genio-hyo-glossus, which pass to the side of the pharynx. It is about three-quarters to an inch in length, and arises from the inner side and base of the lesser cornu and contiguous portion of the body of the hyoid bone, and passes directly upwards to blend with the intrinsic muscular fibres of the tongue, between the Hyo-glossus and Genio-hyo-glossus. A small slip of muscular fibres is occasionally found, arising from the cartilago triticea in the thyro-hyoid ligament, and passing upwards and forwards, enters the tongue with the hindermost fibres of the Hyo-glossus.

Fig. 399.—Muscles of the tongue from below. (From a preparation in the Museum of the Royal College of Surgeons of England.)

The **Stylo-glossus**, the shortest and smallest of the three styloid muscles, arises from the anterior and outer side of the styloid process, near its apex, and from the stylo-mandibular ligament, to which its fibres, in most cases, are attached by a thin aponeurosis. Passing downwards and forwards between the internal and external carotid arteries, and becoming nearly horizontal in its direction, it divides upon the side of the tongue into two portions: one longitudinal, which enters the side of the tongue near its dorsal surface, blending with the fibres of the Inferior lingualis in front of the Hyo-glossus; the other oblique, which overlaps the Hyo-glossus muscle and decussates with its fibres.

Relations.—By its *external surface*, from above downwards, with the parotid gland, the Internal pterygoid muscle, the lingual nerve, and the mucous membrane of the mouth. By its *internal surface*, with the tonsil, the Superior constrictor, and the Hyo-glossus muscle.

The **Palato-glossus**, or **Constrictor isthmi faucium**, although it is one of the muscles of the tongue, serving to draw its base upwards during the act of deglutition, is more nearly associated with the soft palate, both in its situation and function; it will, consequently, be described with that group of muscles.

Nerves.—The Palato-glossus is probably innervated by the spinal accessory

nerve, through the pharyngeal plexus; the remaining muscles of this group by the hypoglossal.

Muscular substance of tongue.—The muscular fibres of the tongue run in various directions. These fibres are divided into two sets—Extrinsic and Intrinsic. The extrinsic muscles of the tongue are those which have their origin external to, and only their terminal fibres contained in, the substance of the organ. They are: the Stylo-glossus, the Hyo-glossus, the Palato-glossus, the Genio-hyo-glossus, and part of the Superior constrictor of the pharynx (Pharyngo-glossus). The intrinsic are those which are contained entirely within the tongue, and form the greater part of its muscular structure.

The tongue consists of symmetrical halves separated from each other in the middle line by a fibrous septum. Each half is composed of muscular fibres arranged in various directions, containing much interposed fat, and supplied by vessels and nerves.

To demonstrate the various fibres of the tongue, the organ should be subjected to prolonged boiling, in order to soften the connective tissue; the dissection may then be commenced from the dorsum. Immediately beneath the mucous membrane is a submucous, fibrous layer, into which the muscular fibres which terminate on the surface of the tongue are inserted. Upon removing this, with the mucous membrane, the first stratum of muscular fibres is exposed. This belongs to the group of intrinsic muscles, and has been named the *Superior lingualis*. It consists of a thin layer of oblique and longitudinal fibres, which arise from the submucous fibrous layer, close to the Epiglottis, and from the fibrous septum, and pass forwards and outwards to the edges of the tongue. Between its fibres pass some vertical fibres derived from the Genio-hyo-glossus and from the vertical intrinsic muscle, which will be described later on. Beneath this layer is the second stratum of muscular fibres, derived principally from the extrinsic muscles. In front, it is formed by the fibres derived from the Stylo-glossus, running along the side of the tongue, and sending one set of fibres over the dorsum which runs obliquely forwards and inwards to the middle line, and another set of fibres, seen at a later period of the dissection, on to the under surface of the sides of the anterior part of the tongue, which runs forwards and inwards, between the fibres of the Hyo-glossus, to the middle line. Behind this layer of fibres, derived from the Stylo-glossus, are fibres derived from the Hyo-glossus, together with some few fibres of the Palato-glossus. The Hyo-glossus, entering the side of the under surface of the tongue, between the Stylo-glossus and Inferior lingualis, passes round its margin and spreads out into a layer on the dorsum, which occupies the middle third of the organ, and runs almost transversely inwards to the septum. It is reinforced by some fibres from the Palato-glossus; other fibres of this muscle pass more deeply and intermingle with the next layer. The posterior part of the second layer of the muscular fibres of the tongue is derived from those fibres of the Hyo-glossus which arise from the lesser cornu of the hyoid bone, and are here described as a separate muscle—the Chondro-glossus. The fibres of this muscle are arranged in a fan-shaped manner, and spread out over the posterior third of the tongue. Beneath this layer is the great mass of the intrinsic muscles of the tongue, intersected at right angles by the terminal fibres of one of the extrinsic muscles—

the Genio-hyo-glossus. This portion of the tongue is paler in colour and softer in texture than that already described, and is sometimes designated the medullary portion in contradistiction to the firmer superficial part, which is termed the cortical portion. It consists largely of transverse fibres, the *Transverse lingualis*, and of vertical fibres, the *Vertical lingualis*. The Transverse lingualis forms the largest portion of the third layer of muscular fibres of the tongue. The fibres arise from the median septum, and pass outwards to be inserted into the submucous fibrous layer at the sides of the tongue. Intermingled with these transverse intrinsic fibres are transverse extrinsic fibres derived from the Palato-glossus and the Superior constrictor of the pharynx. These Transverse extrinsic fibres, however, run in the opposite direction, passing inwards towards the septum. Intersecting the transverse fibres are a large number of vertical fibres derived partly from the Genio-hyo-glossus and partly from intrinsic fibres, the *Vertical lingualis*. The fibres derived from the Genio-hyo-glossus enter the under surface of the tongue on each side of the median septum from base to apex. They ascend in a radiating manner to the dorsum, being inserted into the submucous fibrous layer covering the tongue on each side of the middle line. The Vertical lingualis is found only at the borders of the fore part of the tongue, external to the fibres of the Genio-hyo-glossus. Its fibres extend from the upper to the under surface of the organ, decussating with the fibres of the other muscles, and especially with the Transverse lingualis. The fourth layer of muscular fibres of the tongue consists partly of extrinsic fibres derived from the Stylo-glossus, and partly of intrinsic fibres, the *Inferior lingualis*. At the sides of the under surface of the organ are some fibres derived from the Stylo-glossus; as this muscle runs forwards at the side of the tongue, it gives off fibres which pass forwards and inwards between the fibres of the Hyo-glossus and form an inferior oblique stratum which joins in front with the anterior fibres of the Inferior lingualis. The Inferior lingualis is a longitudinal band, situated on the under surface of the tongue, and extending from the base to the apex of the organ. Behind, some of its fibres are connected with the body of the hyoid bone. It lies between the Hyo-glossus and the Genio-hyo-glossus; in front of the Hyo-glossus it comes into relation with the Stylo-glossus, with the fibres of which it blends. It is in relation by its under surface with the ranine artery.

Surgical Anatomy.—The fibrous septum which exists between the two halves of the tongue is very complete, so that the anastomosis between the two lingual arteries is not very free, a fact often illustrated by injecting one-half of the tongue with coloured size, while the other half is left uninjected, or is injected with size of a different colour.

This is a point of considerable importance in connection with removal of one-half of the tongue for cancer, an operation which is now frequently resorted to when the disease is strictly confined to one side of the tongue. If the mucous membrane is divided longitudinally exactly in the middle line, the tongue can be split into halves along the median raphé, without any appreciable hæmorrhage, and the diseased half can then be removed.

Actions.—The movements of the tongue, although numerous and complicated, may be understood by carefully considering the direction of the fibres of its muscles. The *Genio-hyo-glossi* muscles, by means of their posterior fibres, draw the base of the tongue forwards, so as to protrude the apex from the mouth. The anterior fibres draw the tongue back into the mouth. The whole length of these two muscles acting along the middle line of the tongue draw it downwards, so as to make it concave from side to side, forming a channel along which fluids may pass toward the pharynx, as in sucking. The *Hyo-glossi* muscles depress the tongue, and draw down its sides, so as to render it convex from side to side. The *Stylo-glossi* muscles draw the tongue upwards and backwards. The *Palato-glossi* muscles draw the base of the tongue upwards. The intrinsic muscles are mainly concerned in altering the shape of the tongue, whereby it becomes shortened, narrowed from side to side, or curved in different directions; thus, the Superior and Inferior linguales tend to shorten the tongue, but the former, in addition, turn the tip and sides upwards so as to render the dorsum concave, while the latter pull the tip downwards and cause the dorsum to become convex. The Transverse lingualis narrows and elongates the tongue, and the Vertical lingualis flattens and broadens it. The complex arrangement of the muscular

fibres of the tongue, and the various directions in which they run, give to this organ the power of assuming the various forms necessary for the enunciation of the different consonantal sounds; and Macalister states 'there is reason to believe that the musculature of the tongue varies in different races owing to the hereditary practice and habitual use of certain motions required for enunciating the several vernacular languages.'

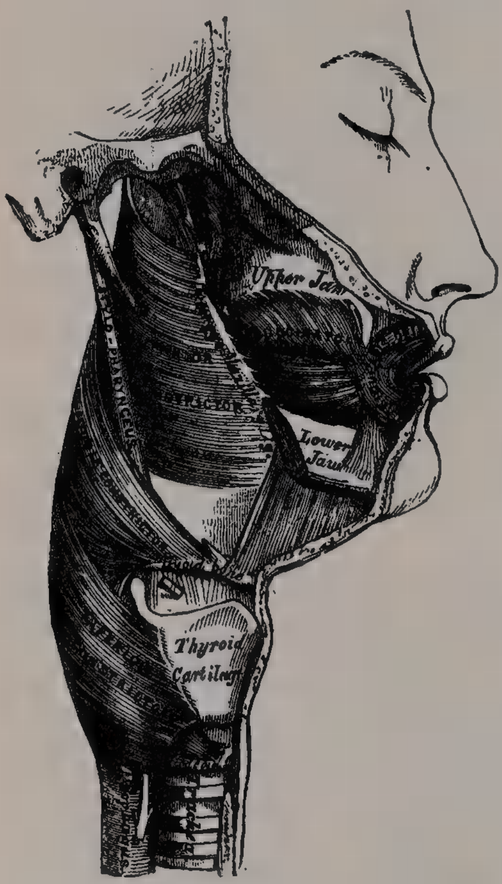
V. Pharyngeal Region

Inferior constrictor.	Superior constrictor.
Middle constrictor.	Stylo-pharyngeus.
Palato-pharyngeus. } Salpingo-pharyngeus. }	(See next section.)

Dissection (fig. 401).—In order to examine the muscles of the pharynx, cut through the trachea and œsophagus just above the sternum, and draw them upwards by dividing the loose areolar tissue connecting the pharynx with the front of the vertebral column. The parts being drawn well forwards, apply the edge of the saw immediately behind the styloid processes, and saw the base of the skull through from below upwards. The pharynx and mouth should then be stuffed with tow, in order to distend its cavity and render the muscles tense and easier of dissection.

The **Inferior constrictor**, the most superficial and thickest of the three constrictors, arises from the sides of the cricoid and thyroid cartilages. To the cricoid cartilage it is attached in the interval between the Crico-thyroid muscle in front, and the articular facet for the inferior cornu of the thyroid cartilage behind. To the thyroid cartilage it is attached to the oblique line on the side of the great ala, to the cartilaginous surface behind it, nearly as far as its posterior border, and to the inferior cornu. From these attachments the fibres spread backwards and inwards, to be inserted into the fibrous raphé in the posterior median line of the pharynx. The inferior fibres are horizontal, and continuous with the circular fibres of the œsophagus; the rest ascend, increasing in obliquity, and overlap the Middle constrictor.

Fig. 401.—Muscles of the pharynx. External view.



Relations.—The Inferior constrictor is covered by a thin membrane which surrounds the entire pharynx (bucco-pharyngeal fascia). *Behind*, it is in relation with the vertebral column and the prevertebral fascia and muscles; *laterally*, with the thyroid gland, the common carotid artery, and the Sterno-thyroid muscle; by its *internal surface*, with the Middle constrictor, the Stylo-pharyngeus, Palato-pharyngeus, the pharyngeal aponeurosis and mucous membrane of the pharynx. The internal laryngeal nerve and the laryngeal branch of the Superior thyroid artery pass near the upper border, and the inferior, or recurrent laryngeal nerve, and the laryngeal branch of the inferior thyroid artery, beneath the lower border of this muscle, previous to their entering the larynx.

The **Middle constrictor** is a flattened, fan-shaped muscle, smaller than the preceding. It arises from the whole length of the upper border of the greater cornu of the hyoid bone, from the lesser cornu, and from the stylo-hyoid ligament. The fibres diverge from their origin: the lower ones descending beneath

the Inferior constrictor, the middle fibres passing transversely, and the upper fibres ascending and overlapping the Superior constrictor. The muscle is inserted into the posterior median fibrous raphé, blending in the middle line with the one of the opposite side.

Relations.—This muscle is separated from the Superior constrictor by the glosso-pharyngeal nerve and the Stylo-pharyngeus muscle and Stylo-hyoid ligament; and from the Inferior constrictor by the internal laryngeal nerve and laryngeal branch of the superior thyroid artery. *Behind*, it lies on the prevertebral fascia, the Longus colli, and the Rectus capitis anticus major. *On each side* it is in relation with the carotid vessels, the pharyngeal plexus, and some lymphatic glands. Near its origin it is covered by the Hyo-glossus, from which it is separated by the lingual vessels. It lies upon the Superior constrictor, the Stylo-pharyngeus, the Palato-pharyngeus, the pharyngeal aponeurosis, and the mucous membrane of the pharynx.

The **Superior constrictor** is a quadrilateral muscle, thinner and paler than the other Constrictors, and situated at the upper part of the pharynx. It arises from the lower third of the posterior margin of the internal pterygoid plate and its hamular process, from the pterygo-mandibular ligament, from the alveolar process of the mandible above the posterior extremity of the mylo-hyoid ridge, and by a few fibres from the side of the tongue. From these points the fibres curve backwards, to be inserted into the median raphé, being also prolonged by means of a fibrous aponeurosis to the pharyngeal spine on the basilar process of the occipital bone. The superior fibres arch beneath the Levator palati and the Eustachian tube, the interval between the upper border of the muscle and the base of the skull being deficient in muscular fibres, and closed by the pharyngeal aponeurosis. This interval is known as the *sinus of Morgagni*.

Relations.—By its *outer surface*, with the prevertebral fascia and muscles, the vertebral column, the internal carotid and ascending pharyngeal arteries, the internal jugular vein and pharyngeal venous plexus, the glosso-pharyngeal, pneumogastric, spinal accessory, hypoglossal, lingual, and sympathetic nerves, the Middle constrictor and internal pterygoid muscles, the Styloid process, the Stylo-hyoid ligament, and the Stylo-pharyngeus. By its *internal surface*, with the Palato-pharyngeus, the tonsil, the pharyngeal aponeurosis and mucous membrane of the pharynx. Its *lower border* is separated from the Middle constrictor of the pharynx by the Stylo-pharyngeus muscle and the glosso-pharyngeal nerve.

The **Stylo-pharyngeus** is a long, slender muscle, round above, broad and thin below. It arises from the inner side of the base of the styloid process, passes downwards along the side of the pharynx between the Superior and Middle constrictors, and spreads out beneath the mucous membrane, where some of its fibres are lost in the Constrictor muscles; and others, joining with the Palato-pharyngeus, are inserted into the posterior border of the thyroid cartilage. The glosso-pharyngeal nerve runs on the outer side of this muscle, and crosses over it in passing forward to the tongue.

Relations.—*Externally*, with the Stylo-glossus muscle, the parotid gland, the external carotid artery, and the Middle constrictor. *Internally*, with the internal carotid, the internal jugular vein, the Superior constrictor, Palato-pharyngeus and mucous membrane.

Nerves.—The Constrictors are supplied by branches from the pharyngeal plexus, the Stylo-pharyngeus by the glosso-pharyngeal nerve, and the Inferior constrictor by additional branches from the external and recurrent laryngeal nerves.

Actions.—When deglutition is about to be performed, the pharynx is drawn upwards and dilated in different directions, to receive the food propelled into it from the mouth. The Stylo-pharyngei, which are much farther removed from one another at their origin than at their insertion, draw the sides of the pharynx upwards and outwards, and so increase its transverse diameter; its breadth in the antero-posterior direction being increased by the larynx and tongue being carried forwards in their ascent. As soon as the morsel is received in the pharynx, the Elevator muscles relax, the bag descends, and the Constrictors contract upon it, and convey it gradually downwards into the œsophagus. Besides its action in deglutition, the pharynx also exerts an important influence in the modulation of the voice, especially in the production of the higher tones.

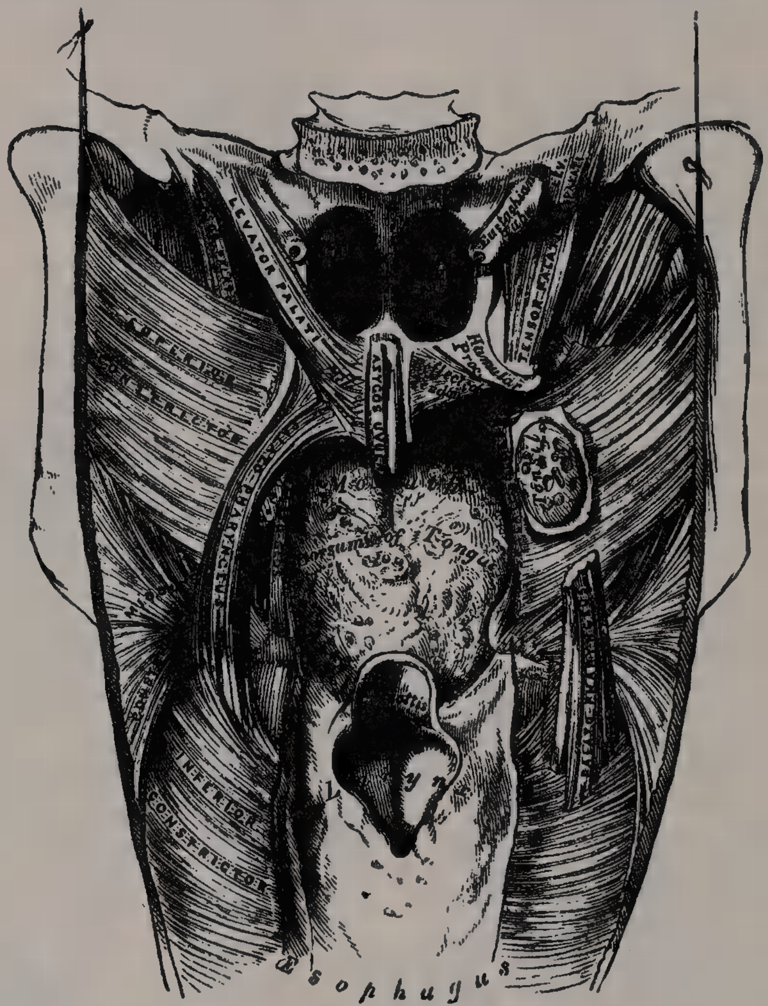
VI. Palatal Region

Levator palati.	Palato-glossus.
Tensor palati.	Palato-pharyngeus.
Azygos uvulæ.	Salpingo-pharyngeus.

Dissection (fig. 402).—Lay open the pharynx from behind, by a vertical incision extending from its upper to its lower part, and partially divide the occipital attachment by a transverse incision on each side of the vertical one; the posterior surface of the soft palate is then exposed. Having fixed the uvula so as to make it tense, the mucous membrane and glands should be carefully removed from the posterior surface of the soft palate and the muscles of this part are at once exposed.

The **Levator palati** is a long, thick, rounded muscle, placed on the outer side of the posterior nares. It arises from the under surface of the apex of the petrous portion of the temporal bone, and from the inner surface of the cartilaginous

Fig. 402.—Muscles of the soft palate. The pharynx being laid open from behind.



portion of the Eustachian tube; after passing above the upper concave margin of the Superior constrictor, it extends obliquely downwards and inwards, its fibres spreading out in the soft palate as far as the middle line, where they blend with those of the opposite side.

Relations.—*Externally*, with the Tensor palati, Superior constrictor, and Eustachian tube. *Internally*, with the mucous membrane of the pharynx. *Posteriorly*, with the posterior fasciculus of the Palato-pharyngeus, the Azygos uvulæ, and the mucous lining of the soft palate.

The **Tensor** or **Circumflexus palati** is a broad, thin, riband-like muscle, placed on the outer side of the Levator palati, and consisting of a vertical and a horizontal portion. The vertical portion arises by a flat lamella from the scaphoid

fossa at the base of the internal pterygoid plate; from the spine of the sphenoid and the outer side of the cartilaginous portion of the Eustachian tube: descending vertically between the internal pterygoid plate and the inner surface of the Internal pterygoid muscle, it terminates in a tendon, which winds round the hamular process, being retained in this situation by some of the fibres of origin of the Internal pterygoid muscle. Between the hamular process and the tendon is a small bursa. The tendon or horizontal portion then passes horizontally inwards, and is inserted into a broad aponeurosis, the *palatine aponeurosis*, and into the transverse ridge on the horizontal portion of the palate bone.

Relations.—*Externally*, with the Internal pterygoid. *Internally*, with the Levator palati, from which it is separated by the Eustachian tube and Superior constrictor, and with the internal pterygoid plate. In the soft palate, its tendon and the palatine aponeurosis is anterior to that of the Levator palati, being covered by the Palato-glossus and the mucous membrane.

Palatine Aponeurosis.—Attached to the posterior border of the hard palate is a thin, firm, fibrous lamella which supports the muscles and gives strength to the soft palate. It is thicker above than below, where it becomes very thin and difficult to define. Laterally, it is continuous with the pharyngeal aponeurosis.

The **Azygos uvulæ** is not a single muscle, as would be inferred from its name, but a pair of narrow cylindrical fleshy fasciculi, placed one on either side of the median line of the soft palate. Each muscle arises from the posterior nasal spine of the palate bone, and from the contiguous tendinous aponeurosis of the soft palate, and descends to be inserted into the uvula.

Relations.—*Anteriorly*, with the tendinous expansion of the Levatores palati; *behind*, with the posterior fasciculus of the Palato-pharyngeus and the mucous membrane.

The next two muscles are exposed by removing the mucous membrane from the pillars of the fauces throughout nearly their whole extent.

The **Palato-glossus (Constrictor isthmi faucium)** is a small fleshy fasciculus, narrower in the middle than at either extremity, forming, with the mucous membrane covering its surface, the anterior pillar of the fauces. It arises from the anterior surface of the soft palate, where it is continuous with the muscle of the opposite side, and, passing downwards, forwards, and outwards in front of the tonsil, is inserted into the side of the tongue, some of its fibres spreading over the dorsum, and others passing deeply into the substance of the organ to intermingle with the Transverse lingualis.

The **Palato-pharyngeus** is a long, fleshy fasciculus, narrower in the middle than at either extremity, forming, with the mucous membrane covering its surface, the posterior pillar of the fauces. It is separated from the Palato-glossus by an angular interval, in which the tonsil is lodged. It arises from the soft palate by an expanded fasciculus, which is divided into two parts by the Levator palati and Azygos uvulæ. The *posterior fasciculus* lies in contact with the mucous membrane, and joins with the corresponding muscle in the middle line; the *anterior fasciculus*, the thicker, lies in the soft palate between the Levator and Tensor, and joins in the middle line the corresponding part of the opposite muscle. Passing outwards and downwards behind the tonsil, the Palato-pharyngeus joins the Stylo-pharyngeus, and is inserted with that muscle into the posterior border of the thyroid cartilage, some of its fibres being lost on the side of the pharynx, and others passing across the middle line posteriorly, to decussate with the muscle of the opposite side.

Relations.—In the soft palate, its *posterior surface* is covered by mucous membrane, from which it is separated by a layer of palatine glands. By its *anterior surface* it is in relation with the Tensor palati. Where it forms the posterior pillars of the fauces, it is covered by mucous membrane, excepting on its outer surface. In the *pharynx* it lies between the mucous membrane and the Constrictor muscles.

The Salpingo-pharyngeus.—This muscle arises from the inferior part of the Eustachian tube near its orifice; it passes downwards and blends with the posterior fasciculus of the Palato-pharyngeus.

In a dissection of the soft palate from its posterior or nasal surface to its anterior or oral surface, the muscles would be exposed in the following order: viz. the posterior fasciculus of the Palato-pharyngeus, covered by the mucous

membrane reflected from the floor of the nasal fossæ; the Azygos uvulæ; the Levator palati; the anterior fasciculus of the Palato-pharyngeus; the aponeurosis of the Tensor palati, and the Palato-glossus covered by a reflection from the oral mucous membrane.

Nerves.—The Tensor palati is supplied by a branch from the otic ganglion; the remaining muscles of this group are in all probability supplied by the bulbar portion of the spinal accessory through the pharyngeal plexus.*

Actions.—During the *first stage* of deglutition, the morsel of food is driven back into the fauces by the pressure of the tongue against the hard palate: the base of the tongue being, at the same time, retracted, and the larynx raised with the pharynx, and carried forwards under it. During the *second stage* the entrance to the larynx is closed, not, as was formerly supposed, by the folding backwards of the epiglottis over it, but, as Anderson Stuart has shown, by the drawing forward of the arytenoid cartilages towards the cushion of the epiglottis—a movement produced by the contraction of the external thyro-arytenoid, the arytenoid and aryteno-epiglottidean muscles.

The morsel of food after leaving the tongue passes on to the posterior or laryngeal surface of the epiglottis, and glides along this for a certain distance; † then the Palato-glossi muscles, the constrictors of the fauces, contract behind the food; the soft palate is slightly raised by the Levator palati, and made tense by the Tensor palati; and the Palato-pharyngei, by their contraction, pull the pharynx upwards over the morsel of food, and come nearly together, the uvula filling up the slight interval between them. By these means the food is prevented from passing into the naso-pharynx; at the same time, the latter muscles form an inclined plane, directed obliquely downwards and backwards, along the under surface of which the morsel descends into the lower part of the pharynx. The Salpingo-pharyngeus raises the upper and lateral part of the pharynx—i.e. that part which is above the point where the Stylo-pharyngeus is attached to the pharynx.

Surgical Anatomy.—After the operation for the closure of a cleft in the palate, the palate muscles, especially the Tensor and Levator palati, have a tendency to retard the healing process by active traction upon the line of suture. To obviate this, it is necessary to divide them. This is best done by making longitudinal incisions, on either side, parallel to the cleft and just internal to the hamular process, in such a position as to avoid the posterior palatine artery.

VII. Anterior Vertebral Region

Rectus capitis anticus major.	Rectus capitis lateralis.
Rectus capitis anticus minor.	Longus colli.

The **Rectus capitis anticus major** (fig. 403), broad and thick above, narrow below, appears like a continuation upwards of the Scalenus anticus. It arises by four tendinous slips from the anterior tubercles of the transverse processes of the third, fourth, fifth, and sixth cervical vertebræ, and ascends, converging towards its fellow of the opposite side, to be inserted into the basilar process of the occipital bone.

Relations.—By its *anterior surface*, with the pharynx, the sympathetic nerve, and the sheath enclosing the internal and common carotid artery, internal jugular vein, and the pneumogastric nerve. By its *posterior surface*, with the Longus colli, the Rectus capitis anticus minor, and the upper cervical vertebræ.

The **Rectus capitis anticus minor** is a short, flat muscle, situated immediately behind the upper part of the preceding. It arises from the anterior surface of the lateral mass of the atlas, and from the root of its transverse process, and passing obliquely upwards and inwards, is inserted into the basilar process immediately behind the preceding muscle.

Relations.—By its *anterior surface*, with the Rectus capitis anticus major. By its *posterior surface*, with the front of the occipito-atlantal articulation.

* 'The Innervation of the Soft Palate,' by William Aldren Turner, M.B. *Journal of Anatomy and Physiology*, vol. xxiii. p. 523.

† Walton (quoted by A. Stuart) maintains that the epiglottis is not essential to the deglutition even of liquids.

The **Rectus capitis lateralis** is a short, flat muscle, which arises from the upper surface of the transverse process of the atlas, and is inserted into the under surface of the jugular process of the occipital bone.

Relations.—By its *anterior surface*, with the internal jugular vein. By its *posterior surface*, with the vertebral artery. On its *outer side* lies the occipital artery; on its *inner side* the suboccipital nerve.

The **Longus colli** is a long, flat muscle, situated on the anterior surface of the spine, between the atlas and the third dorsal vertebra. It is broad in the middle, narrow and pointed at each extremity, and consists of three portions: a superior oblique, an inferior oblique, and a vertical portion. The *superior oblique portion* arises from the anterior tubercles of the transverse processes of the third, fourth, and fifth cervical vertebræ; and, ascending obliquely inwards, is inserted by a

FIG. 403.—The prevertebral muscles.

narrow tendon into the tubercle on the anterior arch of the atlas. The *inferior oblique portion*, the smallest part of the muscle, arises from the front of the bodies of the first two or three dorsal vertebræ; and, ascending obliquely outwards, is inserted into the anterior tubercles of the transverse processes of the fifth and sixth cervical vertebræ. The *vertical portion* lies directly on the front of the spine; it arises, below, from the front of the bodies of the upper three dorsal and lower three cervical vertebræ, and is inserted into the front of the bodies of the second, third, and fourth cervical vertebræ above.

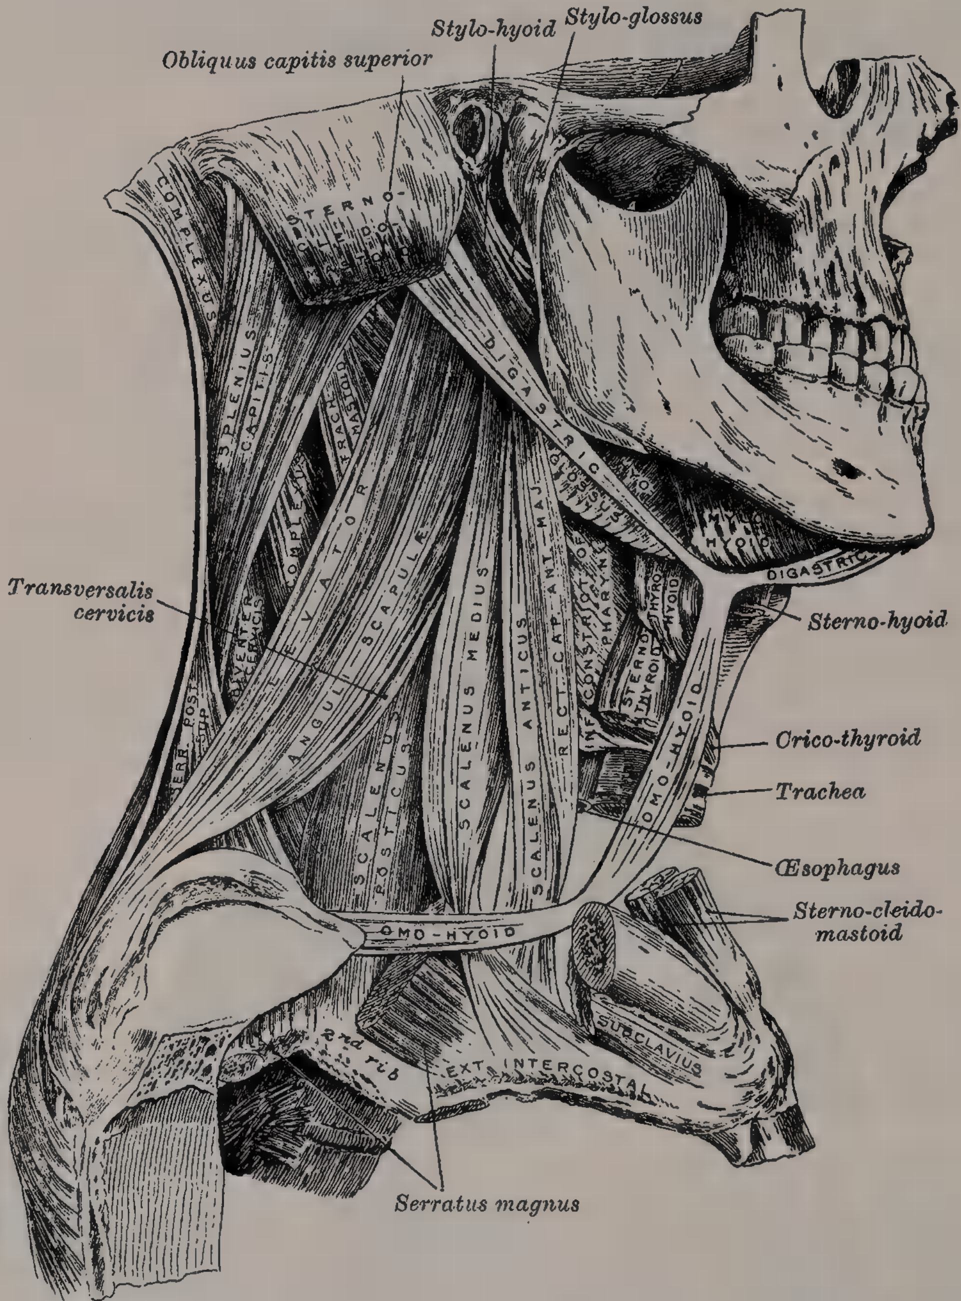
Relations.—By its *anterior surface*, with the prevertebral fascia, the pharynx, the œsophagus, the sympathetic nerve, the sheath of the great vessels of the neck, the inferior thyroid artery, and recurrent laryngeal nerve. By its *posterior surface*, with the cervical and dorsal portions of the spine. Its *inner border* is separated from the opposite muscle by a considerable interval below; but they approach each other above.

VIII. Lateral Vertebral Region

Scalenus anticus. Scalenus medius.
Scalenus posticus.

The **Scalenus anticus** is a conical-shaped muscle, situated deeply at the side of the neck, behind the Sterno-mastoid. It arises from the anterior tubercles of

Fig. 404.—Muscles of the neck. (From a preparation in the Museum of the Royal College of Surgeons of England.)



the transverse processes of the third, fourth, fifth, and sixth cervical vertebræ, and descending, almost vertically, is inserted by a narrow, flat tendon into the scalene tubercle on the inner border of the first rib, and also into the upper surface of the rib between the grooves for the subclavian artery and vein. The lower part of this muscle separates the subclavian artery and vein: the latter being in front, and the former, with the brachial plexus, behind.

Relations.—*In front*, with the clavicle, the Subclavius, Sterno-mastoid, and Omo-hyoid muscles, the transversalis colli, the suprascapular and ascending cervical arteries, the subclavian vein, and the phrenic nerve. By its *posterior surface*, with the cords of the brachial plexus, the subclavian artery and the pleura,

which separate it from the Scalenus medius. It is separated from the Longus colli, on the inner side, by the vertebral artery. On the anterior tubercles of the transverse processes of the cervical vertebræ, between the attachments of the Scalenus anticus and Longus colli, lies the ascending cervical branch of the inferior thyroid artery.

The **Scalenus medius**, the largest and longest of the three Scaleni, arises from the posterior tubercles of the transverse processes of the lower six cervical vertebræ, and descending along the side of the vertebral column is inserted by a broad attachment into the upper surface of the first rib, behind the groove for the subclavian artery, as far back as the tubercle. It is separated from the Scalenus anticus by the subclavian artery below and the cervical nerves above. The posterior thoracic, or nerve of Bell, is formed in the substance of the Scalenus medius and emerges from it. The nerve to the Rhomboids also pierces it.

Relations.—By its *anterior surface*, with the Sterno-mastoid; it is crossed by the clavicle, the Omo-hyoid muscle, subclavian artery, and the cervical nerves. To its *outer side* is the Levator anguli scapulæ, and the Scalenus posticus muscle.

The **Scalenus posticus**, the smallest of the three Scaleni, arises, by two or three separate tendons, from the posterior tubercles of the transverse processes of the lower two or three cervical vertebræ, and, diminishing as it descends, is inserted by a thin tendon into the outer surface of the second rib, behind the attachment of the Serratus magnus. This is the most deeply placed of the three Scaleni, and is occasionally blended with the Scalenus medius.

Nerves.—The Rectus capitis anticus major and minor and the Rectus lateralis are supplied by the first cervical nerve, and from the loop formed between it and the second; the Longus colli and Scaleni, by branches from the anterior divisions of the lower cervical nerves (fifth, sixth, seventh, and eighth) before they form the brachial plexus. The Scalenus medius also receives a filament from the deep external branches of the cervical plexus.

Actions.—The Rectus capitis anticus major and minor are the direct antagonists of the muscles at the back of the neck, serving to restore the head to its natural position after it has been drawn backwards. These muscles also serve to flex the head, and from their obliquity, rotate it, so as to turn the face to one or the other side. The Longus colli flexes and slightly rotates the cervical portion of the spine. The Scaleni muscles, when they take their fixed point from above, elevate the first and second ribs, and are, therefore, inspiratory muscles. When they take their fixed point from below, they bend the spinal column to one or the other side. If the muscles of both sides act, lateral movement is prevented, but the spine is slightly flexed. The Rectus lateralis, acting on one side, bends the head laterally.

Surface Form.—The muscles in the neck, with the exception of the Platysma myoides, are invested by the deep cervical fascia, which softens down their form, and is of considerable importance in connection with deep cervical abscesses and tumours, modifying the direction of their growth and causing them to extend laterally instead of towards the surface. The *Platysma myoides* does not influence surface form except it is in action, when it produces wrinkling of the skin of the neck, which is thrown into oblique ridges parallel with the fasciculi of the muscle. Sometimes this contraction takes place suddenly and repeatedly, as a sort of spasmodic twitching, the result of a nervous habit. The *Sterno-cleido-mastoid* is the most important muscle of the neck as regards its surface form. If the muscle is put into action by drawing the chin downwards and to the opposite shoulder, its surface form will be plainly outlined. The sternal origin will stand out as a sharply defined ridge, while the clavicular origin will present a flatter and less prominent outline. The fleshy middle portion will appear as an oblique roll or elevation, with a thick rounded anterior border gradually becoming less marked above. On the opposite side, i.e. on the side to which the head is turned, the outline is lost, its place being occupied by an oblique groove in the integument. When the muscle is at rest its anterior border is still visible, forming an oblique rounded ridge, terminating below in the sharp outline of the sternal head. The posterior border of the muscle does not show above the clavicular head. The anterior border is defined by drawing a line from the tip of the mastoid process to the sterno-clavicular joint. It is an important surface-marking in the operation of ligature of the common carotid artery and some other operations. Between the sternal and clavicular heads is a slight depression, most marked when the muscle is in action, which overlies the lower part of the internal jugular vein. This is bounded below by the prominent sternal extremity of the clavicle. Between the sternal origins of the two muscles is a V-shaped space, the *suprasternal notch*, more pronounced below,

and becoming toned down above, where the Sterno-hyoid and Sterno-thyroid muscles, lying upon the trachea, become more prominent. Above the hyoid bone, in the middle line, the anterior belly of the *Digastric* to a certain extent influences surface form. It corresponds to a line drawn from the symphysis of the lower jaw to the side of the body of the hyoid bone, and renders this part of the hyo-mental region convex. In the posterior triangle of the neck, the posterior belly of the *Omo-hyoid*, when in action, forms a conspicuous object, especially in thin necks, presenting a cord-like form running across this region, almost parallel with, and a little above, the clavicle.

MUSCLES AND FASCIÆ OF THE TRUNK

The Muscles of the Trunk may be arranged in four groups, corresponding with the region in which they are situated.

I. The Back.
II. The Thorax.
III. The Abdomen.
IV. The Pelvic outlet.

I. Muscles of the Back

The muscles of the back are very numerous, and may be subdivided into five layers.

First Layer

Trapezius.
Latissimus dorsi.

Second Layer

Levator anguli scapulæ.
Rhomboideus minor.
Rhomboideus major.

Third Layer

Serratus posticus superior.
Serratus posticus inferior.
Splenius capitis.
Splenius colli.

Fourth Layer

Sacral and Lumbar Regions
Erector spinæ.

Dorsal Region
Ilio-costalis.
Musculus accessorius ad ilio-costalem.
Longissimus dorsi.
Spinalis dorsi.

Cervical Region
Cervicalis ascendens.
Transversalis cervicis.
Trachelo-mastoid.
Complexus.
Biventer cervicis.
Spinalis colli.

Fifth Layer

Semispinalis dorsi.
Semispinalis colli.
Multifidus spinæ.
Rotatores spinæ.
Interspinales.
Extensor coccygis.
Intertransversales.
Rectus capitis posticus major.
Rectus capitis posticus minor.
Obliquus capitis inferior.
Obliquus capitis superior.

First Layer

Trapezius. Latissimus dorsi.

Dissection (fig. 405).—Place the body in the prone position, with the arms extended over the sides of the table, and the chest and abdomen supported by several blocks, so as to render the muscles tense. Then make an incision along the middle line of the back from the occipital protuberance to the coccyx. Make a transverse incision from the upper end of this to the mastoid process; and a third incision from its lower end, along the crest of the ilium to about its middle. This large intervening space should, for convenience of dissection, be subdivided by a fourth incision, extending obliquely from the spinous process of the last dorsal vertebra, upwards and outwards, to the acromion process. This incision corresponds with the lower border of the Trapezius muscle. The flaps of integument are then to be removed in the direction shown in the figure.

The **superficial fascia** is exposed upon removing the skin from the back. It forms a layer of considerable thickness and strength, in which a quantity of granular pinkish fat is contained. It is continuous with the superficial fascia in other parts of the body. The **deep fascia** is a dense fibrous layer, attached above

to the superior curved line of the occipital bone: in the middle line it is attached to the ligamentum nuchæ, and to the spinous processes and supraspinous ligaments of all the vertebræ below the seventh cervical: laterally, in the neck it is continuous with the deep cervical fascia; over the shoulder it is attached to the spine of the scapula and the acromion process, and is continued downwards over the Deltoid muscle to the arm; on the thorax it is continuous with the deep fascia of the axilla and chest, and on the abdomen with that covering the abdominal muscles: below, it is attached to the crest of the ilium.

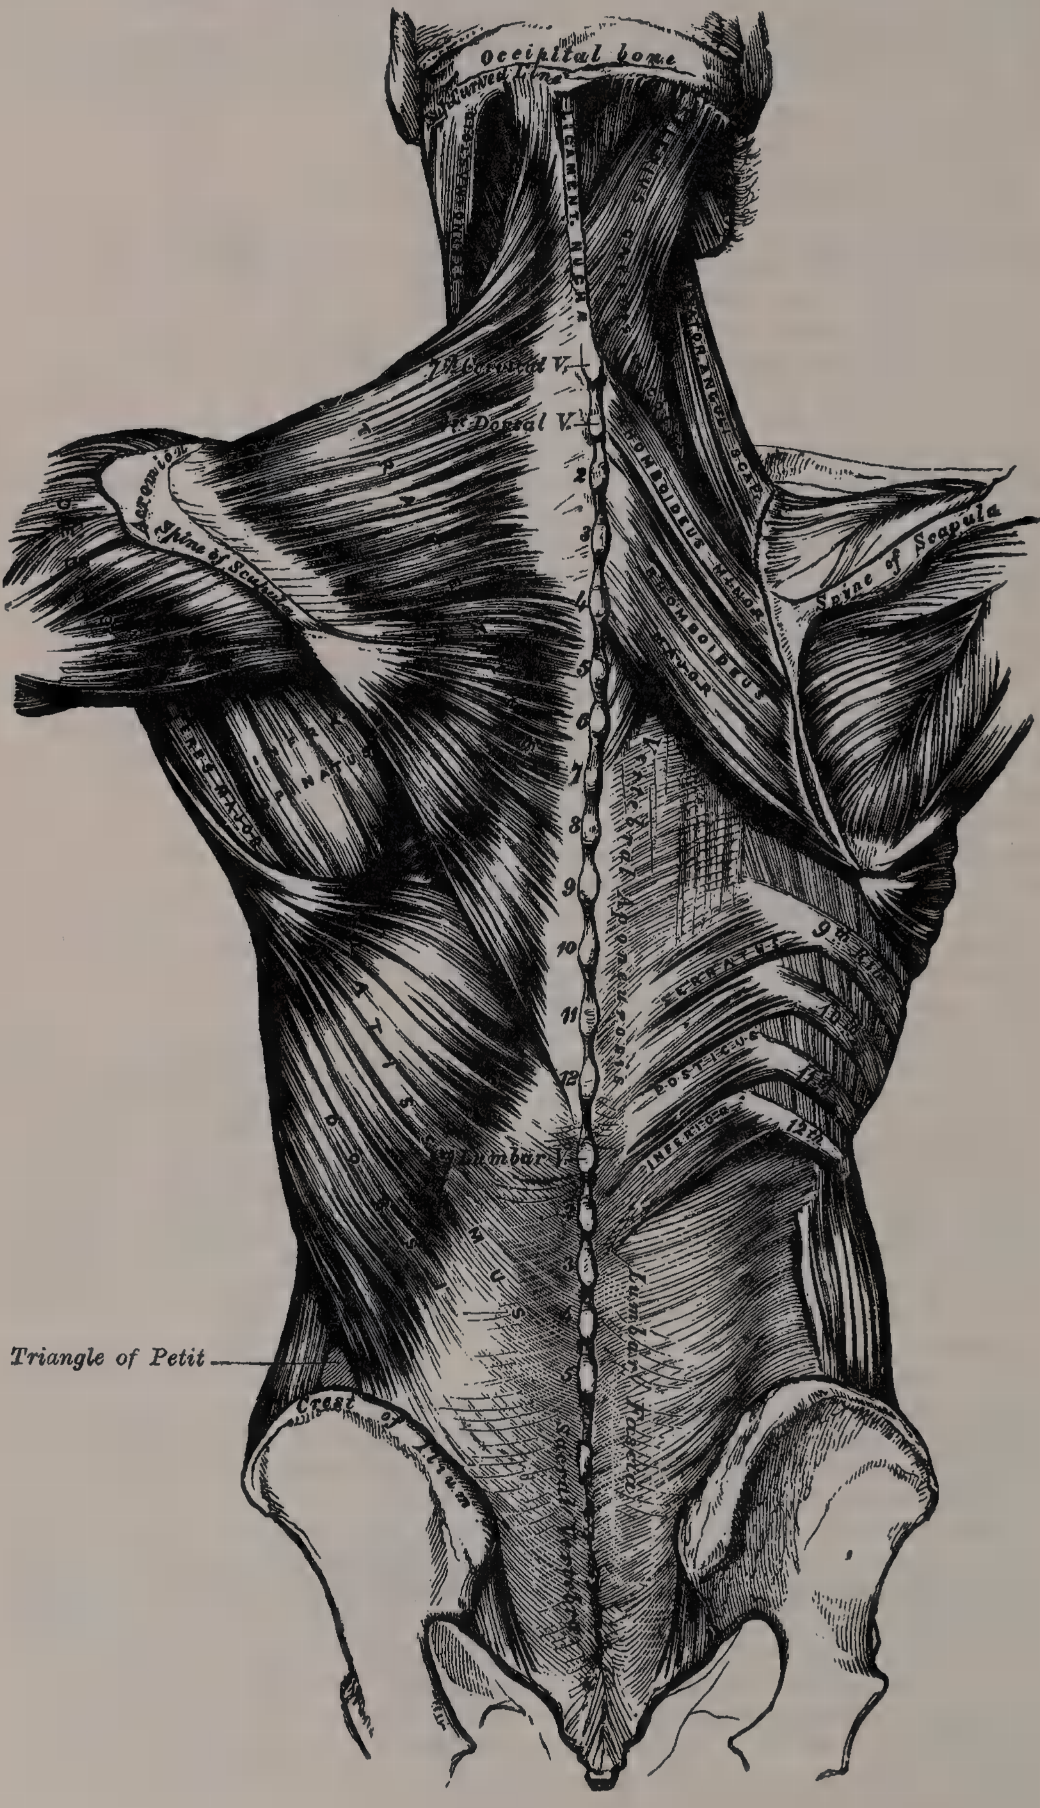
FIG. 405.—Dissection of the muscles of the back.

The **Trapezius** (fig. 406) is a broad, flat, triangular muscle, placed immediately beneath the skin and fascia, and covering the upper and back part of the neck and shoulders. It arises from the external occipital protuberance and the inner third of the superior curved line of the occipital bone; from the ligamentum nuchæ, the spinous process of the seventh cervical, and those of all the dorsal vertebræ; and from the corresponding portion of the supraspinous ligament. From this origin, the superior fibres proceed downwards and outwards, the inferior upwards and outwards; and the middle horizontally; the superior fibres are inserted into the outer third of the posterior border of the clavicle; the middle fibres into the inner margin of the acromion process, and into the superior lip of the posterior border or crest of the spine of the scapula; the inferior fibres converge near the scapula, and terminate in a triangular aponeurosis, which glides over a smooth surface at the inner extremity of the spine, to be inserted into a tubercle at the outer part of this smooth surface. The Trapezius is fleshy in the greater part of its extent, but tendinous at its origin and insertion. At its occipital origin, it is connected to the bone by a thin fibrous lamina, firmly adherent to the skin, and wanting the lustrous, shining appearance of aponeuroses. At its origin from the spines of the vertebræ, it is connected to the bones by means of a broad semi-elliptical aponeurosis, which occupies the space between the sixth cervical and the third dorsal vertebræ, and forms, with the aponeurosis of the opposite muscle, a tendinous ellipse. The rest of the muscle arises by numerous short tendinous fibres. If the Trapezius is dissected on both sides, the two muscles resemble a trapezium, or diamond-shaped quadrangle: two angles corresponding to the shoulders; a third to the occipital protuberance; and the fourth to the spinous process of the last dorsal vertebra.

The clavicular insertion of this muscle varies as to the extent of its attachment: it sometimes advances as far as the middle of the clavicle, and may occasionally become blended with the posterior edge of the Sterno-mastoid, or overlap it. This should be borne in mind in the operation for tying the third part of the subclavian artery.

Relations.—By its *superficial surface*, with the integument. By its *deep surface*, in the neck, with the Complexus, Splenius, Levator anguli scapulæ, and Rhomboideus minor; in the back, with the Rhomboideus major, Supraspinatus, Infraspinatus, the Vertebral aponeurosis (which separates it from the prolongations of the Erector spinæ), and the Latissimus dorsi. The superficial cervical artery, the spinal accessory nerve, and branches from the third and fourth cervical nerves, pass beneath the anterior border of this muscle. The anterior margin of its cervical portion forms the posterior boundary of the posterior triangle of the neck, the other boundaries being the Sterno-mastoid in front, and the clavicle below.

Fig. 406.—Muscles of the back. On the left side, the first layer is exposed; on the right side, the second layer and part of the third.



The **Latissimus dorsi** is a broad flat muscle, which covers the lumbar and the lower half of the dorsal regions, and is gradually contracted into a narrow fasciculus at its insertion into the humerus. It arises by tendinous fibres from the spinous processes of the six inferior dorsal vertebræ and from the posterior layer of the lumbar fascia (see page 469), by which it is attached to the spines of the lumbar and sacral vertebræ, and to the supraspinous ligament. It also arises from the posterior third of the external lip of the crest of the ilium, behind the insertion of the External oblique, and by fleshy digitations from the three or four lower ribs, which are interposed between similar processes of the External oblique muscle (fig. 411, page 484). From this extensive origin the fibres pass in different directions, the upper ones horizontally, the middle obliquely upwards, and the lower vertically upwards, so as to converge and form a thick fasciculus, which crosses the inferior angle of the scapula, and usually receives a few fibres from it. The muscle curves around the lower border of the Teres major, and is twisted upon itself, so that the superior fibres become at first posterior and then inferior, and the vertical fibres at first anterior and then superior. It terminates in a short quadrilateral tendon, about three inches in length, which passes in front of the tendon of the Teres major, and is inserted into the bottom of the bicipital groove of the humerus; its insertion extending higher on the humerus than that of the tendon of the Pectoralis major. The lower border of the tendon of this muscle is united with that of the Teres major, the surfaces of the two being separated near their insertion by a bursa; another bursa is sometimes interposed between the muscle and the inferior angle of the scapula. This muscle at its insertion gives off an expansion to the deep fascia of the arm.

A muscular slip, the *axillary arch*, varying from 3 to 4 inches in length, and from ¼ to ¾ of an inch in breadth, occasionally arises from the upper edge of the Latissimus dorsi about the middle of the posterior fold of the axilla, and crosses the axilla in front of the axillary vessels and nerves, to join the under surface of the tendon of the Pectoralis major, the Coraco-brachialis, or the fascia over the Biceps. The position of this abnormal slip is a point of interest in its relation to the axillary artery, as it crosses the vessel just above the spot usually selected for the application of a ligature, and may mislead the surgeon during the operation. It may be easily recognised by the transverse direction of its fibres. Struthers found it, in 8 out of 105 subjects, occurring seven times on both sides.

There is usually a fibrous slip which passes from the lower border of the tendon of the Latissimus dorsi, near its insertion, to the long head of the Triceps. This is occasionally muscular, and is the representative of the *dorso-epitrochlearis* muscle of apes.

Relations.—Its *superficial surface* is subcutaneous, excepting at its upper part, where it is covered by the Trapezius, and at its insertion, where its tendon is crossed by the axillary vessels and the brachial plexus of nerves. By its *deep surface*, it is in relation with the Lumbar fascia, the Serratus posticus inferior, the lower external intercostal muscles and ribs, inferior angle of the scapula, Rhomboideus major, Infraspinatus, and Teres major. Its outer margin is separated below from the External oblique by a small triangular interval, the base of which is formed by the crest of the ilium, and its floor by the Internal oblique muscle of the abdomen. This is known as the *triangle of Petit*, and is sometimes the site of a lumbar hernia. Another triangle of practical importance is situated behind the scapula. It is bounded above by the Trapezius, below by the Latissimus dorsi, and externally by the vertebral border of the scapula; the floor is partly formed by the Rhomboideus. If the scapula is drawn forwards by folding the arms across the chest, and the trunk bent forwards, a part of the sixth and seventh ribs and the interspace between them become subcutaneous and available for auscultation. The space is therefore known as the *triangle of auscultation.*

Nerves.—The Trapezius is supplied by the spinal accessory, and by branches from the anterior divisions of the third and fourth cervical nerves; the Latissimus dorsi by the sixth, seventh, and eighth cervical nerves through the middle or long subscapular nerve.

Second Layer

Levator anguli scapulæ. Rhomboideus minor
Rhomboideus major.

Dissection.—The Trapezius must be removed, in order to expose the next layer; to effect this, detach the muscle from its attachment to the clavicle and spine of the scapula, and turn it back towards the spine.

The **Levator anguli scapulæ** is situated at the back part and side of the neck. It arises by tendinous slips from the transverse process of the atlas and from the posterior tubercles of the transverse processes of the second, third, and fourth cervical vertebræ; these, becoming fleshy, are united so as to form a flat muscle, which passes downwards and backwards, and is inserted into the posterior border of the scapula, between the superior angle and the triangular smooth surface at the root of the spine.

Relations.—By its *superficial surface*, with the integument, Trapezius, and Sterno-mastoid. By its *deep surface*, with the Splenius colli, Transversalis cervicis, Cervicalis ascendens, and Serratus posticus superior muscles, and with the posterior scapular artery and the nerve to the Rhomboids.

The **Rhomboideus minor** arises from the lower part of the ligamentum nuchæ and the spinous processes of the seventh cervical and first dorsal vertebræ. Passing downwards and outwards, it is inserted into the margin of the triangular smooth surface at the root of the spine of the scapula. This small muscle is usually separated from the Rhomboideus major by a slight cellular interval.

Relations.—By its *superficial* (*posterior*) *surface*, with the Trapezius. By its *deep surface*, with the same structures as the Rhomboideus major.

The **Rhomboideus major** is situated immediately below the preceding, the adjacent margins of the two being occasionally united. It arises by tendinous fibres from the spinous processes of the second, third, fourth, and fifth dorsal vertebræ and the supraspinous ligament, and is inserted into a narrow tendinous arch, attached above to the lower part of the triangular surface at the root of the spine; below, to the inferior angle, the arch being connected to the border of the scapula by a thin membrane. When the arch extends, as it occasionally does, only a short distance, the muscular fibres are inserted into the scapula itself.

Relations.—By its *superficial surface*, with the Latissimus dorsi. By its *deep surface*, with the Serratus posticus superior, the posterior scapular artery, and the nerve to the muscle, the vertebral aponeurosis which separates it from the prolongations of the Erector spinæ, the Intercostal muscles, and ribs.

Nerves.—The Rhomboid muscles are supplied by branches from the anterior division of the fifth cervical nerve; the Levator anguli scapulæ by the anterior division of the third and fourth cervical nerves, and frequently by a branch from the nerve to the Rhomboids.

Actions.—The movements effected by the preceding muscles are numerous, as may be conceived from their extensive attachment. The whole of the *Trapezius* when in action retracts the scapula and braces back the shoulder; if the head is fixed, the upper part of the Trapezius will elevate the point of the shoulder, as in supporting weights; when the lower fibres are brought into action they assist in depressing the bone. The middle and lower fibres of the muscle rotate the scapula, causing elevation of the acromion process. If the shoulders are fixed, both Trapezii, acting together, will draw the head directly backwards; or if only one acts, the head is drawn to the corresponding side.

The *Latissimus dorsi*, when it acts upon the humerus, depresses it, draws it backwards, and at the same time rotates it inwards. It is the muscle which is principally employed in giving a downward blow, as in felling a tree or in sabre practice. If the arm is fixed, the muscle may act in various ways upon the trunk: thus, it may raise the lower ribs and assist in forcible inspiration; or, if both arms are fixed, the two muscles may assist the Abdominal and great Pectoral muscles in suspending and drawing the whole trunk forwards, as in climbing or walking on crutches.

The *Levator anguli scapulæ* raises the superior angle of the scapula, assisting the Trapezius in bearing weights or in shrugging the shoulders. If the shoulder

is fixed, the Levator anguli scapulæ inclines the neck to the corresponding side and rotates it in the same direction. The *Rhomboid* muscles carry the inferior angle backwards and upwards, thus producing a slight rotation of the scapula upon the side of the chest, the Rhomboideus major acting especially on the lower angle of the scapula, through the tendinous arch by which it is inserted. The Rhomboid muscles acting together with the middle and inferior fibres of the Trapezius will draw the scapula directly backwards towards the spine

Third Layer

Serratus posticus superior. Serratus posticus inferior

Splenius { Splenius capitis. Splenius colli.

Dissection.—To bring into view the third layer of muscles, remove the whole of the second, together with the Latissimus dorsi, by cutting through the Levator anguli scapulæ and Rhomboid muscles near their origin, and reflecting them downwards, and by dividing the Latissimus dorsi in the middle by a vertical incision carried from its upper to its lower part, and reflecting the two halves of the muscle.

The **Serratus posticus superior** is a thin, flat, quadrilateral muscle, situated at the upper and back part of the thorax. It arises by a thin and broad aponeurosis from the lower part of the ligamentum nuchæ, and from the spinous processes of the last cervical and two or three upper dorsal vertebræ and from the supraspinous ligament. Inclining downwards and outwards, it becomes muscular, and is inserted, by four fleshy digitations, into the upper borders of the second, third, fourth, and fifth ribs, a little beyond their angles.

Relations.—By its *superficial surface,* with the Trapezius, Rhomboidei, and Levator anguli scapulæ. By its *deep surface,* with the Splenius, and the vertebral aponeurosis, which separates it from the prolongations of the Erector spinæ, and with the Intercostal muscles and ribs.

The **Serratus posticus inferior** is situated at the junction of the dorsal and lumbar regions: it is of an irregularly quadrilateral form, broader than the preceding, and separated from it by a wide interval. It arises by a thin aponeurosis from the spinous processes of the last two dorsal and two or three upper lumbar vertebræ, and from the supraspinous ligament. Passing obliquely upwards and outwards, it becomes fleshy, and divides into four flat digitations, which are inserted into the lower borders of the four lower ribs, a little beyond their angles. The thin aponeurosis of origin is intimately blended with the lumbar fascia.

Relations.—By its *superficial surface,* with the Latissimus dorsi. By its *deep surface,* with the Erector spinæ, ribs, and Intercostal muscles. Its upper margin is continuous with the vertebral aponeurosis.

The *Vertebral aponeurosis* is a thin, fibrous lamina, extending along the whole length of the back part of the thoracic region, serving to bind down the long Extensor muscles of the back which support the spine and head, and separate them from those muscles which connect the spine to the upper extremity. It consists of longitudinal and transverse fibres blended together, forming a thin lamella, which is attached in the median line to the spinous processes of the dorsal vertebræ; externally, to the angles of the ribs; and below, to the upper border of the Serratus posticus inferior and portion of the lumbar fascia, which gives origin to the Latissimus dorsi; above, it passes beneath the Serratus posticus superior and the Splenius, and blends with the deep fascia of the neck.

The *Lumbar fascia* or *aponeurosis* (fig. 406), which may be regarded as the posterior aponeurosis of the Transversalis abdominis muscle, consists of three laminæ, which are attached as follows: the posterior layer, to the spines of the lumbar and sacral vertebræ and the supraspinous ligament; the middle, to the tips of the transverse processes of the lumbar vertebræ and the intertransverse ligaments; the anterior, to the roots of the lumbar transverse processes. The posterior layer is continued above as the vertebral aponeurosis, while inferiorly it is fixed to the outer lip of the iliac crest. With this layer are blended the aponeurotic origin of the Serratus posticus inferior and part of that of the Latissimus dorsi. The middle layer is attached above to the last rib, and below to the iliac crest; the anterior layer is fixed below to the ilio-lumbar ligament

and iliac crest; while above it is thickened to form the external arcuate ligament of the Diaphragm, and stretches from the tip of the last rib to the transverse process of the first or second lumbar vertebra. These three layers, together with the vertebral column, enclose two spaces, the posterior of which is occupied by the Erector spinæ muscle, and the anterior by the Quadratus lumborum.

Now detach the Serratus posticus superior from its origin, and turn it outwards, when the Splenius muscle will be brought into view.

The **Splenius** is a broad sheet situated at the back of the neck and upper part of the dorsal region. At its origin, it is a single muscle, which arises, by tendinous fibres, from the lower half of the ligamentum nuchæ, from the spinous processes of the last cervical and of the six upper dorsal vertebræ, and from the supraspinous ligament. From this origin, the fleshy fibres proceed obliquely upwards and outwards, forming a broad flat muscle, which divides as it ascends into two portions, the Splenius capitis and Splenius colli.

The **Splenius capitis** is inserted, under cover of the Sterno-mastoid, into the mastoid process of the Temporal bone, and into the rough surface on the occipital bone just beneath the superior curved line.

The **Splenius colli** is inserted, by tendinous fasciculi, into the posterior tubercles of the transverse processes of the two or three upper cervical vertebræ.

The Splenius is separated from its fellow of the opposite side by a triangular interval, in which is seen the Complexus.

Relations.—By its *superficial surface*, with the Trapezius, from which it is separated below by the Rhomboidei and the Serratus posticus superior. It is covered at its insertion by the Sterno-mastoid, and at the lower and back part of the neck by the Levator anguli scapulæ. By its *deep surface*, with the Spinalis dorsi, Longissimus dorsi, Semispinalis colli, Complexus, Trachelo-mastoid, and Transversalis cervicis.

Nerves.—The Splenius is supplied from the external branches of the posterior divisions of the middle and lower cervical nerves; the Serratus posticus superior is supplied by branches from the upper three or four intercostal nerves; the Serratus posticus inferior, by branches from the ninth, tenth, and eleventh intercostal nerves.

Actions.—The Serrati are respiratory muscles. The Serratus posticus superior elevates the ribs; it is therefore an inspiratory muscle; while the Serratus posticus inferior draws the lower ribs downwards and backwards, and thus elongates the thorax. It also fixes the lower ribs, thus assisting the inspiratory action of the Diaphragm and resisting the tendency which it has to draw the lower ribs upwards and forwards. It must therefore be regarded as a muscle of inspiration. This muscle is also probably a tensor of the vertebral aponeurosis. The Splenii muscles of the two sides, acting together, draw the head directly backwards, assisting the Trapezius and Complexus; acting separately, they draw the head to one or the other side, and slightly rotate it, turning the face to the same side. They also assist in supporting the head in the erect position.

Fourth Layer

1. Erector spinæ.

a. Outer Column.
Ilio-costalis.
Musculus accessorius.
Cervicalis ascendens.

b. Middle Column.
Longissimus dorsi.
Transversalis cervicis.
Trachelo-mastoid.

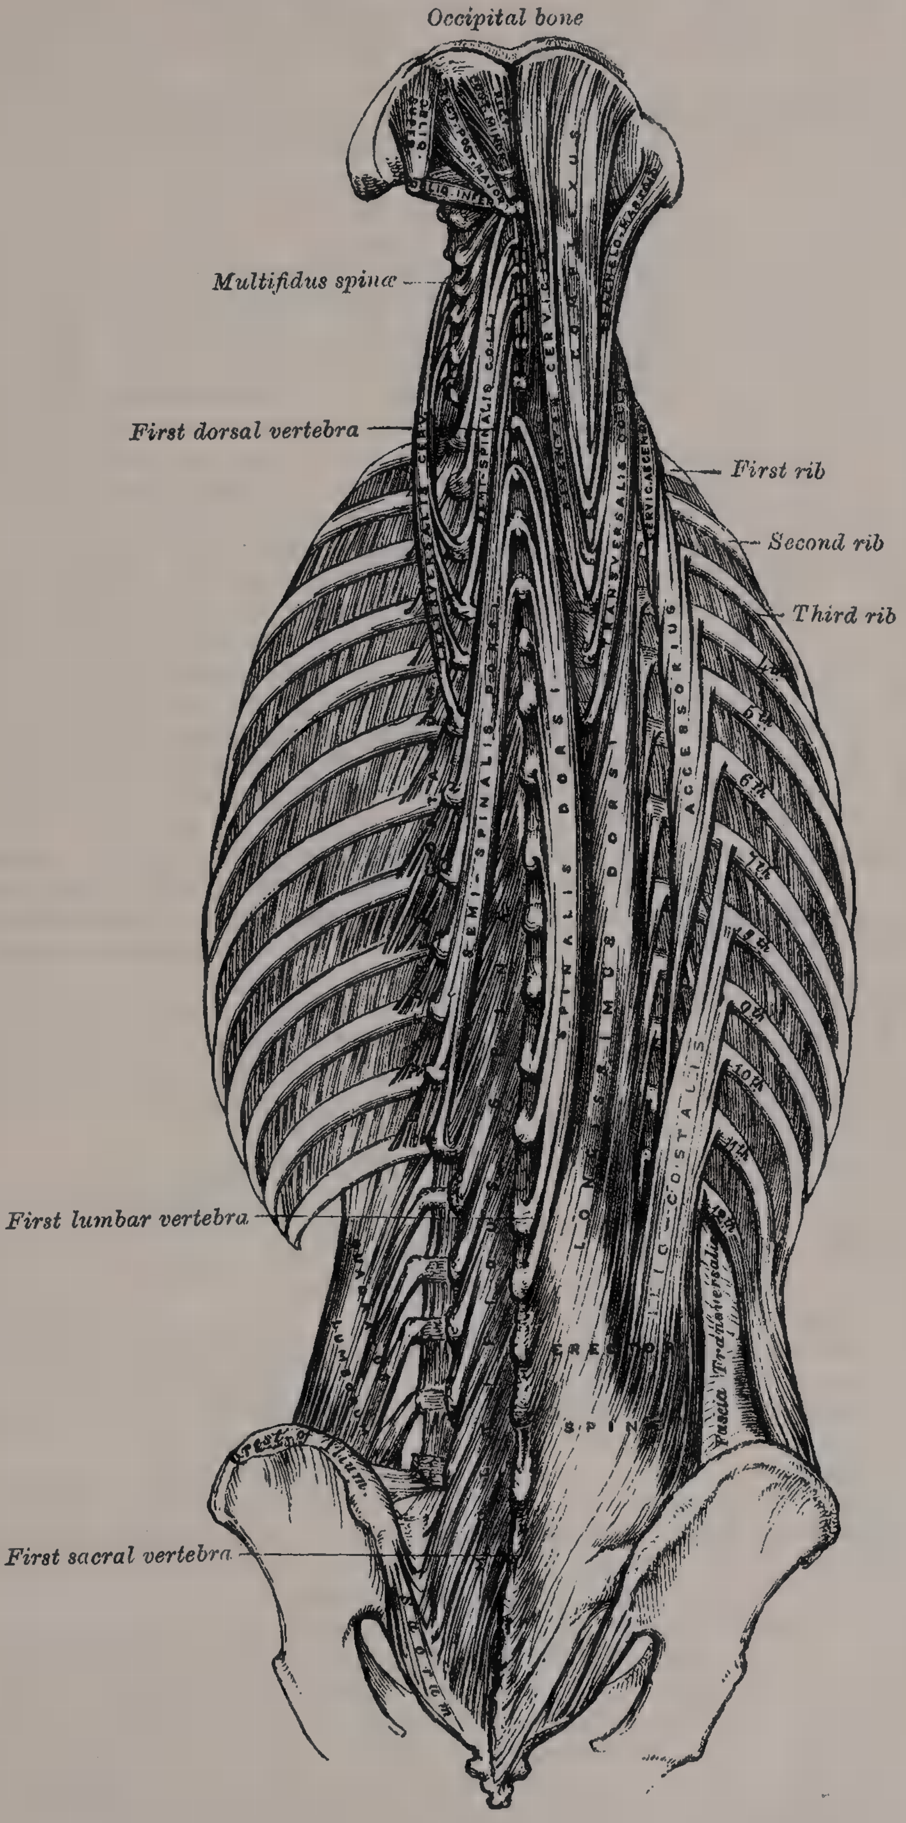
c. Inner Column.
Spinalis dorsi.

2. Complexus.

Dissection.—To expose the muscles of the fourth layer, remove entirely the Serrati and the vertebral and lumbar fasciæ. Then detach the Splenius by separating its attachment to the spinous processes and reflecting it outwards.

The **Erector spinæ** (fig. 407), and its prolongations in the dorsal and cervical regions, fill up the vertebral groove on each side of the spine. It is covered in

Fig. 407.—Muscles of the back. Deep layers.



the lumbar region by the lumbar fascia; in the dorsal region by the Serrati muscles and the vertebral aponeurosis; and in the cervical region by a layer of cervical fascia continued beneath the Trapezius and the Splenius. This large muscular and tendinous mass varies in size and structure at different parts of the spine. In the sacral region, the Erector spinæ is narrow and pointed, and its origin chiefly tendinous in structure. In the lumbar region, the muscle becomes enlarged, and forms a thick fleshy mass. In the dorsal region, it is subdivided into three parts, which gradually diminish in size as they ascend to be inserted into the vertebræ and ribs.

The Erector spinæ arises from the anterior surface of a very broad and thick tendon, which is attached, internally, to the spines of the sacrum, to the spinous processes of the lumbar and the eleventh and twelfth dorsal vertebræ, and the supraspinous ligament; externally, to the back part of the inner lip of the crest of the ilium, and to the series of eminences on the posterior part of the sacrum, which represent the transverse processes, where it blends with the great sacro-sciatic and posterior sacro-iliac ligaments. Some of its fibres are continuous with the fibres of origin of the Gluteus maximus. The muscular fibres form a large fleshy mass, bounded in front by the transverse processes of the lumbar vertebræ, and by the middle lamella of the lumbar fascia. Opposite the last rib it divides into two parts, the Ilio-costalis and the Longissimus dorsi; the Spinalis dorsi is given off from the latter in the upper dorsal region.

The **Ilio-costalis** or **Sacro-lumbalis**, the external portion of the Erector spinæ, is inserted, generally, by six or seven flattened tendons, into the inferior borders of the angles of the six or seven lower ribs. The number of the tendons of this muscle is, however, very variable, and therefore the number of ribs into which it is inserted. If this muscle is reflected outwards, it will be seen to be reinforced by a series of muscular slips, which arise from the angles of the ribs; by means of these the Ilio-costalis is continued upwards to the upper ribs, and the cervical portion of the spine. The accessory portions form two additional muscles, the Musculus accessorius and the Cervicalis ascendens.

The **Musculus accessorius ad ilio-costalem** arises, by separate flattened tendons, from the upper borders of the angles of the six lower ribs: these become muscular, and are finally inserted, by separate tendons, into the upper borders of the angles of the six upper ribs and into the back of the transverse process of the seventh cervical vertebra.

The **Cervicalis ascendens** is the continuation of the Accessorius upwards into the neck; it is situated on the inner side of the tendons of the Accessorius, arising from the angles of the third, fourth, fifth, and sixth ribs, and is inserted by a series of slender tendons into the posterior tubercles of the transverse processes of the fourth, fifth, and sixth cervical vertebræ.

The **Longissimus dorsi** is the middle and largest portion of the Erector spinæ. In the lumbar region, where it is as yet blended with the Ilio-costalis, some of the fibres are attached to the whole length of the posterior surface of the transverse processes, and the accessory processes of the lumbar vertebræ, and to the middle layer of the lumbar fascia. In the dorsal region, the Longissimus dorsi is inserted, by rounded tendons, into the tips of the transverse processes of all the dorsal vertebræ, and by fleshy processes into the lower nine or ten ribs between their tubercles and angles. This muscle is continued upwards, to the cranium and cervical portion of the spine, by means of two additional muscles, the Transversalis cervicis and Trachelo-mastoid.

The **Transversalis cervicis** (*transversalis capitis*), placed on the inner side of the Longissimus dorsi, arises by long thin tendons from the summits of the transverse processes of the upper four or five dorsal vertebræ, and is inserted by similar tendons into the posterior tubercles of the transverse processes of the cervical vertebræ from the second to the sixth inclusive.

The **Trachelo-mastoid** lies on the inner side of the preceding, between it and the Complexus muscle. It arises, by tendons, from the transverse processes of the four or five upper dorsal vertebræ, and the articular processes of the three or four lower cervical. The fibres form a small muscle, which ascends to be inserted into the posterior margin of the mastoid process, beneath the Splenius and Sterno-mastoid muscles. This small muscle is almost always crossed by a tendinous intersection near its insertion into the mastoid process.

The **Spinalis dorsi** is situated at the inner side of the Longissimus dorsi, with

which it is intimately blended, and arises by three or four tendons, from the spinous processes of the first two lumbar and the last two dorsal vertebræ: these, uniting, form a small muscle, which is inserted, by separate tendons, into the spinous processes of the dorsal vertebræ, the number varying from four to eight. It is intimately united with the Semispinalis dorsi, which lies beneath it.

The *Spinalis colli* is an inconstant muscle, which arises from the lower part of the ligamentum nuchæ, the spine of the seventh cervical, and sometimes from those of the first and second dorsal vertebræ, and is inserted into the spinous process of the axis, and occasionally into the spinous processes of the two vertebræ below it. This muscle was found absent in five cases out of twenty-four.

Relations.—The Erector spinæ and its prolongations are bound down to the vertebræ and ribs in the lumbar and dorsal regions by the lumbar fascia and the vertebral aponeurosis. The inner part of these muscles covers the muscles of the fifth layer. In the neck, they are in relation, by their *superficial surface,* with the Trapezius and Splenius; by their *deep surface,* with the Semispinalis dorsi and colli, and the Recti and Obliqui.

The **Complexus** is a broad thick muscle, situated at the upper and back part of the neck, beneath the Splenius, and internal to the Transversalis cervicis and Trachelo-mastoid. It arises, by a series of tendons, from the tips of the transverse processes of the upper six or seven dorsal and the last cervical vertebræ, and from the articular processes of the three cervical above this. The tendons, uniting, form a broad muscle, which passes obliquely upwards and inwards, and is inserted into the innermost depression between the two curved lines of the occipital bone. This muscle, about its middle, is traversed by an imperfect tendinous intersection. The term *Biventer cervicis* is given to the inner portion of the Complexus; this portion is usually separated from the rest of the muscle, and consists of two fleshy bellies connected by an intervening tendon.

Relations.—The Complexus is covered by the Splenius and the Trapezius. It lies on the Rectus capitis posticus major and minor, the Obliquus capitis superior and inferior, and on the Semispinalis colli, from which it is separated by the profunda cervicis artery, the princeps cervicis artery, and branches of the posterior primary divisions of the cervical nerves. The Biventer cervicis is separated from its fellow of the opposite side by the ligamentum nuchæ.

Fifth Layer

The fifth layer, or rather group, of muscles comprises the

Semispinalis dorsi.	Extensor coccygis.
Semispinalis colli.	Intertransversales.
Multifidus spinæ.	Rectus capitis posticus major.
Rotatores spinæ.	Rectus capitis posticus minor.
Interspinales.	Obliquus capitis inferior.

Obliquus capitis superior.

Dissection.—Remove the muscles of the preceding layer by dividing and turning aside the Complexus; then detach the Spinalis and Longissimus dorsi from their attachments, divide the Erector spinæ at its connection below to the sacral and lumbar spines, and turn it outwards. The muscles filling up the interval between the spinous and transverse processes are then exposed.

The **Semispinalis dorsi** (fig. 407) consists of thin, narrow, fleshy fasciculi, interposed between tendons of considerable length. It arises by a series of small tendons from the transverse processes of the lower dorsal vertebræ, from the sixth to the tenth inclusive; and is inserted, by five or six tendons, into the spinous processes of the upper four dorsal and lower two cervical vertebræ.

The **Semispinalis colli,** thicker than the preceding, arises by a series of tendinous and fleshy fibres from the transverse processes of the upper five or six dorsal vertebræ, and is inserted into the cervical spinous processes, from the axis to the fifth inclusive. The fasciculus connected with the axis is the largest and is chiefly muscular in structure.

Relations.—By their *superficial surface,* from below upwards, with the Spinalis dorsi, Longissimus dorsi, Splenius, Complexus, the profunda cervicis

artery, the princeps cervicis artery, and the internal branches of the posterior divisions of the first, second, and third cervical nerves. By their *deep surface*, with the Multifidus spinæ.

The **Multifidus spinæ** consists of a number of fleshy and tendinous fasciculi, which fill up the groove on either side of the spinous processes of the vertebræ, from the sacrum to the axis. In the sacral region, these fasciculi arise from the back of the sacrum, as low as the fourth sacral foramen, and from the aponeurosis of origin of the Erector spinæ; from the inner surface of the posterior superior spine of the ilium, and posterior sacro-iliac ligaments; in the lumbar regions, from the mammillary processes; in the dorsal region, from the transverse processes; and in the cervical region, from the articular processes of the four lower vertebræ. Each fasciculus, passing obliquely upwards and inwards, is inserted into the whole length of the spinous process of one of the vertebræ above. These fasciculi vary in length: the most superficial, the longest, pass from one vertebra to the third or fourth above; those next in order pass from one vertebra to the second or third above; while the deepest connect two contiguous vertebræ.

Relations.—By its *superficial surface*, with the Longissimus dorsi, Spinalis dorsi, Semispinalis dorsi, and Semispinalis colli. By its *deep surface*, with the laminæ and spinous processes of the vertebræ, and with the Rotatores spinæ in the dorsal region.

The **Rotatores spinæ** are found only in the dorsal region of the spine, beneath the Multifidus spinæ; they are eleven in number on each side. Each muscle is small and somewhat quadrilateral in form; it arises from the upper and back part of the transverse process, and is inserted into the lower border and outer surface of the lamina of the vertebra above, the fibres extending as far inwards as the root of the spinous process. The first is found between the first and second dorsal; the last, between the eleventh and twelfth. Sometimes the number of these muscles is diminished by the absence of one or more from the upper or lower end.

The **Interspinales** are short muscular fasciculi, placed in pairs between the spinous processes of the contiguous vertebræ, one on each side of the interspinous ligament. In the *cervical region*, they are most distinct, and consist of six pairs, the first being situated between the axis and third vertebra, and the last between the last cervical and the first dorsal. They are small narrow bundles, attached, above and below, to the apices of the spinous processes. In the *dorsal region*, they are found between the first and second vertebræ, and sometimes between the second and third; and below, between the eleventh and twelfth. In the *lumbar region*, there are four pairs of these muscles in the intervals between the five lumbar vertebræ. There is also occasionally one in the interspinous space, between the last dorsal and first lumbar, and between the fifth lumbar and the sacrum.

The **Extensor coccygis** is a slender muscular fasciculus, which is not always present; it extends over the lower part of the posterior surface of the sacrum and coccyx. It arises by tendinous fibres from the last bone of the sacrum, or first piece of the coccyx, and passes downwards to be inserted into the lower part of the coccyx. It is a rudiment of the Extensor muscle of the caudal vertebræ of the lower animals.

The **Intertransversales** are small muscles placed between the transverse processes of the vertebræ. In the *cervical region* they are most developed, consisting of rounded muscular and tendinous fasciculi, which are placed in pairs, passing between the anterior and the posterior tubercles respectively of the transverse processes of two contiguous vertebræ, separated from one another by the anterior division of the cervical nerve, which lies in the groove between them. In this region there are seven pairs of these muscles, the first pair being between the atlas and axis, and the last pair between the seventh cervical and first dorsal vertebræ. In the *dorsal region* they are least developed, consisting chiefly of rounded tendinous cords in the intertransverse spaces of the upper dorsal vertebræ; but between the transverse processes of the lower three dorsal vertebræ, and between the transverse processes of the last dorsal and the first lumbar, they are muscular in structure. In the *lumbar region* they are arranged in pairs, on either side of the spine; one set occupying the entire interspace between the transverse processes of the lumbar vertebræ, the *intertransversales*

laterales; the other set, *intertransversales mediales*, passing from the accessory process of one vertebra to the mammillary process of the vertebra below.*

The **Rectus capitis posticus major** arises by a pointed tendinous origin from the spinous process of the axis, and, becoming broader as it ascends, is inserted into the outer part of the inferior curved line of the occipital bone and the surface of bone immediately below it. As the muscles of the two sides pass upwards and outwards, they leave between them a triangular space, in which are seen the Recti capitis postici minores muscles.

Relations.—By its *superficial surface*, with the Complexus; and, at its insertion, with the Superior oblique. By its *deep surface*, with part of the Rectus capitis posticus minor, the posterior arch of the atlas, the posterior occipito-atlantal ligament, and part of the occipital bone.

The **Rectus capitis posticus minor**, the smallest of the four muscles in this region, is of a triangular shape; it arises by a narrow pointed tendon from the tubercle on the posterior arch of the atlas, and, becoming broader as it ascends, is inserted into the inner part of the inferior curved line of the occipital bone and the surface between it and the foramen magnum.

Relations.—By its *superficial surface*, with the Complexus and the Rectus capitis posticus major. By its *deep surface*, with the posterior occipito-atlantal ligament.

The **Obliquus capitis inferior**, the larger of the two Oblique muscles, arises from the apex of the spinous process of the axis, and passes outwards and slightly upwards, to be inserted into the lower and back part of the transverse process of the atlas.

Relations.—By its *superficial surface*, with the Complexus and with the posterior division of the second cervical nerve which turns round its lower border. By its *deep surface*, with the vertebral artery, and posterior atlanto-axial ligament.

The **Obliquus capitis superior**, narrow below, wide and expanded above, arises by tendinous fibres from the upper surface of the transverse process of the atlas, joining with the insertion of the preceding, and, passing obliquely upwards and inwards, is inserted into the occipital bone, between the two curved lines, external to the Complexus.

Relations.—By its *superficial surface*, with the Complexus and Trachelo-mastoid and occipital artery. By its *deep surface*, with the posterior occipito-atlantal ligament.

The Suboccipital triangle.—Between the two oblique muscles and the Rectus capitis posticus major a triangular interval exists, the *suboccipital triangle*. This triangle is bounded, above and internally, by the Rectus capitis posticus major; above and externally, by the Obliquus capitis superior; below and externally, by the Obliquus capitis inferior. It is covered in by a layer of dense fibro-fatty tissue, situated beneath the Complexus muscle. The floor is formed by the posterior occipito-atlantal ligament and the posterior arch of the atlas. It contains the vertebral artery, as it runs in a deep groove on the upper surface of the posterior arch of the atlas; and the posterior division of the suboccipital nerve.

Nerves.—The fourth and fifth layers of the muscles of the back are supplied by the posterior primary divisions of the spinal nerves.

Actions.—When both the Spinales dorsi contract, they extend the dorsal region of the spine; when only one contracts, it helps to bend the dorsal portion of the spine to one side. The Erector spinæ, comprising the Ilio-costalis and the Longissimus dorsi with their accessory muscles, serves, as its name implies, to maintain the spine in the erect posture; it also serves to bend the trunk backwards when it is required to counterbalance the influence of any weight at the front of the body—as, for instance, when a heavy weight is suspended from the neck, or when there is any great abdominal distension, as in pregnancy or dropsy; the peculiar gait under such circumstances depends upon the spine being drawn backwards, by the counterbalancing action of the Erector spinæ muscles. The muscles which form the continuation of the Erector spinæ upwards steady the head and neck, and fix them in the upright position. If the

* The student is referred to an article on the morphology of the human intertransverse muscles, by J. Dunlop Lickley; *Journal of Anatomy and Physiology*, vol. xxxix. 1904.

Ilio-costalis and Longissimus dorsi of one side act, they serve to draw down the chest and spine to the corresponding side. The Cervicales ascendentes, taking their fixed points from the cervical vertebræ, elevate those ribs to which they are attached; taking their fixed points from the ribs, both muscles help to extend the neck; while one muscle bends the neck to its own side. The Transversales cervicis, when both muscles act, taking their fixed points from below, bend the neck backwards. The Trachelo-mastoid, when both muscles act, taking their fixed points from below, bend the head backwards; while, if only one muscle acts, the face is turned to the side on which the muscle is acting, and then the head is bent to the shoulder. The two Recti muscles draw the head backwards. The Rectus capitis posticus major, owing to its obliquity, rotates the cranium, with the atlas, round the odontoid process, turning the face to the same side. The Multifidus spinæ acts successively upon the different parts of the spine: thus, the sacrum furnishes a fixed point from which the fasciculi of this muscle act upon the lumbar region; these then become the fixed points for the fasciculi moving the dorsal region, and so on throughout the entire length of the spine; it is by the successive contraction and relaxation of the separate fasciculi of this and other muscles that the spine preserves the erect posture without the fatigue that would necessarily have been produced had this position been maintained by the action of a single muscle. The Multifidus spinæ, besides preserving the erect position of the spine, serves to rotate it, so that the front of the trunk is turned to the side opposite to that from which the muscle acts, this muscle being assisted in its action by the Obliquus externus abdominis. The Complexi draw the head directly backwards; if one muscle acts, it draws the head to one side, and rotates it so that the face is turned to the opposite side. The Superior oblique draws the head backwards; and, from the obliquity in the direction of its fibres, will slightly rotate the cranium, turning the face to the opposite side. The Obliquus capitis inferior rotates the atlas, and with it the cranium, round the odontoid process, turning the face to the same side. The Semispinales, when the muscles of the two sides act together, help to extend the spine; when the muscles of one side only act, they rotate the dorsal and cervical parts of the spine, turning the body to the opposite side. The Interspinales by approximating the spinous process help to extend the spine. The Intertransversales approximate the transverse processes, and help to bend the spine to one side. The Rotatores spinæ assist the Multifidus spinæ to rotate the spine, so that the front of the trunk is turned to the side opposite to that from which the muscle acts.

Surface Form.—The surface forms produced by the muscles of the back are numerous and difficult to analyse unless they are considered in systematic order. The most superficial layer, consisting of large strata of muscular substance, influences to a certain extent the surface form, and at the same time reveals the forms of the layers beneath. The *Trapezius* at the upper part of the back, and in the neck, covers over and softens down the outline of the underlying muscles. Its anterior border forms the posterior boundary of the posterior triangle of the neck. It presents a slight undulating ridge which passes downwards and forwards from the occiput to the junction of the middle and outer third of the clavicle. The tendinous ellipse formed by a part of the origin of the two muscles at the back of the neck is always to be seen as an oval depression, more marked when the muscle is in action. A slight dimple on the skin opposite the interval between the spinous processes of the third and fourth dorsal vertebræ marks the triangular aponeurosis by which the inferior fibres are inserted into the root of the spine of the scapula. From this point the inferior border of the muscle may be traced as an undulating ridge to the spinous process of the twelfth dorsal vertebra. In like manner, the *Latissimus dorsi* softens down and modulates the underlying structures at the lower part of the back and lower part of the side of the chest. In this way it modulates the outline of the Erector spinæ; of the Serratus posticus inferior, which is sometimes to be discerned through it, and is sometimes entirely obscured by it; of part of the Serratus magnus and Superior oblique, which it covers, and of the convex oblique ridges formed by the ribs with the intervening intercostal spaces. The anterior border of the muscle is the only part which gives a distinct surface form. This border may be traced, when the muscle is in action, as a rounded edge, starting from the crest of the ilium, and passing obliquely forwards and upwards to the posterior border of the axilla, where it combines with the Teres major in forming a thick rounded fold, the posterior boundary of the axillary space. The muscles in the second layer influence to a very considerable extent the surface form of the back of the neck and upper part of the trunk. The *Levator anguli scapulæ* reveals itself as a prominent divergent line, running downwards and outwards, from the transverse processes

of the upper cervical vertebræ to the angle of the scapula, covered over and toned down by the overlying Trapezius. The *Rhomboïdei* produce, when in action, a vertical eminence between the vertebral border of the scapula and the spinal furrow, varying in intensity according to the condition of contraction or relaxation of the Trapezius muscle, by which they are for the most part covered. The lowermost part of the Rhomboideus major is uncovered by the Trapezius and forms on the surface an oblique ridge running upwards and inwards from the inferior angle of the scapula. Of the muscles of the third layer of the back, the *Serratus posticus superior* does not in any way influence surface form. The *Serratus posticus inferior,* when in strong action, may occasionally be revealed as an elevation beneath the Latissimus dorsi. The *Splenii* by their divergence serve to broaden out the upper part of the back of the neck and produce a local fulness in this situation, but do not otherwise influence surface form. Beneath all these muscles those of the fourth layer—the *Erector spinæ* and its continuations—influence the surface form in a decided manner. In the loins, the Erector spinæ, bound down by the lumbar fascia, forms a rounded vertical eminence, which determines the depth of the spinal furrow, and which below tapers to a point on the posterior surface of the sacrum and becomes lost there. In the back it forms a flattened plane which gradually becomes lost. In the neck the only part of this group of muscles which influences surface form is the *Trachelo-mastoid*, which produces a short convergent line across the upper part of the posterior triangle of the neck, appearing from under cover of the posterior border of the Sterno-mastoid and being lost below beneath the Trapezius.

II. Muscles and Fasciæ of the Thorax

The muscles belonging exclusively to this region are few in number. They are, the

Intercostales externi.	Triangularis sterni.
Intercostales interni.	Levatores costarum.
Infracostales.	Diaphragm.

Intercostal fasciæ.—A thin but firm layer of fascia covers the outer surface of the External intercostal and the inner surface of the Internal intercostal muscles; and a third layer, the *middle intercostal fascia,* more delicate, is interposed between the two planes of muscular fibres. These are the intercostal fasciæ: they are best marked in those situations where the muscular fibres are deficient, as between the External intercostal muscles and sternum, in front; and between the Internal intercostals and spine, behind.

The **Intercostal muscles** (fig. 422) are two thin planes of muscular and tendinous fibres, placed one over the other, filling up the intercostal spaces, and being directed obliquely between the margins of the adjacent ribs. They have received the name 'external' and 'internal,' from the position they bear to one another. The tendinous fibres are longer and more numerous than the muscular: hence the walls of the intercostal spaces possess very considerable strength, to which the crossing of the muscular fibres materially contributes.

The **External intercostals** are eleven in number on each side. They extend from the tubercles of the ribs, behind, to the commencement of the cartilages of the ribs, in front, where they terminate in a thin membrane, the *anterior intercostal membrane,* which is continued forwards to the sternum. They arise from the lower border of each rib, and are inserted into the upper border of the rib below. In the two lowest spaces they extend to the end of the cartilages, and in the upper two or three spaces they do not quite extend to the ends of the ribs. Their fibres are directed obliquely downwards and forwards, in a similar direction to those of the External oblique muscle of the abdomen. They are thicker than the Internal intercostals.

Relations.—By their *outer surface,* with the muscles which immediately invest the chest, viz. the Pectoralis major and minor, Serratus magnus, and Rhomboideus major, Serratus posticus superior and inferior, Scalenus posticus, Ilio-costalis, Longissimus dorsi, Cervicalis ascendens, Transversalis cervicis, Levatores costarum, Obliquus externus abdominis, and the Latissimus dorsi. By their *internal surface,* with the intercostal vessels and nerve, the Internal intercostal muscles, and the posterior intercostal membrane.

The **Internal intercostals** are also eleven in number on each side. They commence anteriorly at the sternum, in the interspaces between the cartilages of the true ribs, and from the anterior extremities of the cartilages of the false ribs, and extend backwards as far as the angles of the ribs; whence they are continued

to the vertebral column by a thin aponeurosis, the *posterior intercostal membrane.* They arise from the ridge on the inner surface of each rib, as well as from the corresponding costal cartilage, and are inserted into the upper border of the rib below. Their fibres are directed obliquely downwards and backwards, passing in the opposite direction to the fibres of the External intercostal muscles.

Relations.—By their *external surface,* with the intercostal vessels and nerves, and the External intercostal muscles; near the sternum, with the anterior intercostal membrane, and the Pectoralis major. By their *internal surface,* with the pleura costalis, Triangularis sterni, and Diaphragm.

The **Infracostales (subcostales)** consist of muscular and aponeurotic fasciculi, which vary in number and length: they are placed on the inner surface of the ribs, where the Internal intercostal muscles cease; they arise from the inner surface of one rib, and are inserted into the inner surface of the first, second, or third rib below. Their fibres run in the same direction as those of the Internal intercostals. They are most frequent between the lower ribs.

The **Triangularis sterni** (fig. 408) is a thin plane of muscular and tendinous fibres, situated upon the inner wall of the front of the chest. It arises from the lower third of the posterior surface of the sternum, from the posterior surface of the ensiform cartilage, and from the sternal ends of the costal cartilages of the three or four lower true ribs. Its fibres diverge upwards and outwards, to be inserted by digitations into the lower border and inner surfaces of the costal cartilages of the second, third, fourth, fifth, and sixth ribs. The lowest fibres of this muscle are horizontal in their direction, and are continuous with those of the Transversalis: those which succeed are oblique, while the superior fibres are almost vertical. This muscle varies much in its attachment, not only in different bodies, but on opposite sides of the same body.

Fig. 408.—Posterior surface of sternum and costal cartilages, showing Triangularis sterni muscle. (From a preparation in the Museum of the Royal College of Surgeons of England.)

Relations.—*In front,* with the sternum, ensiform cartilage, costal cartilages, Internal intercostal muscles, and internal mammary vessels. *Behind,* with the pleura, pericardium, and anterior mediastinum.

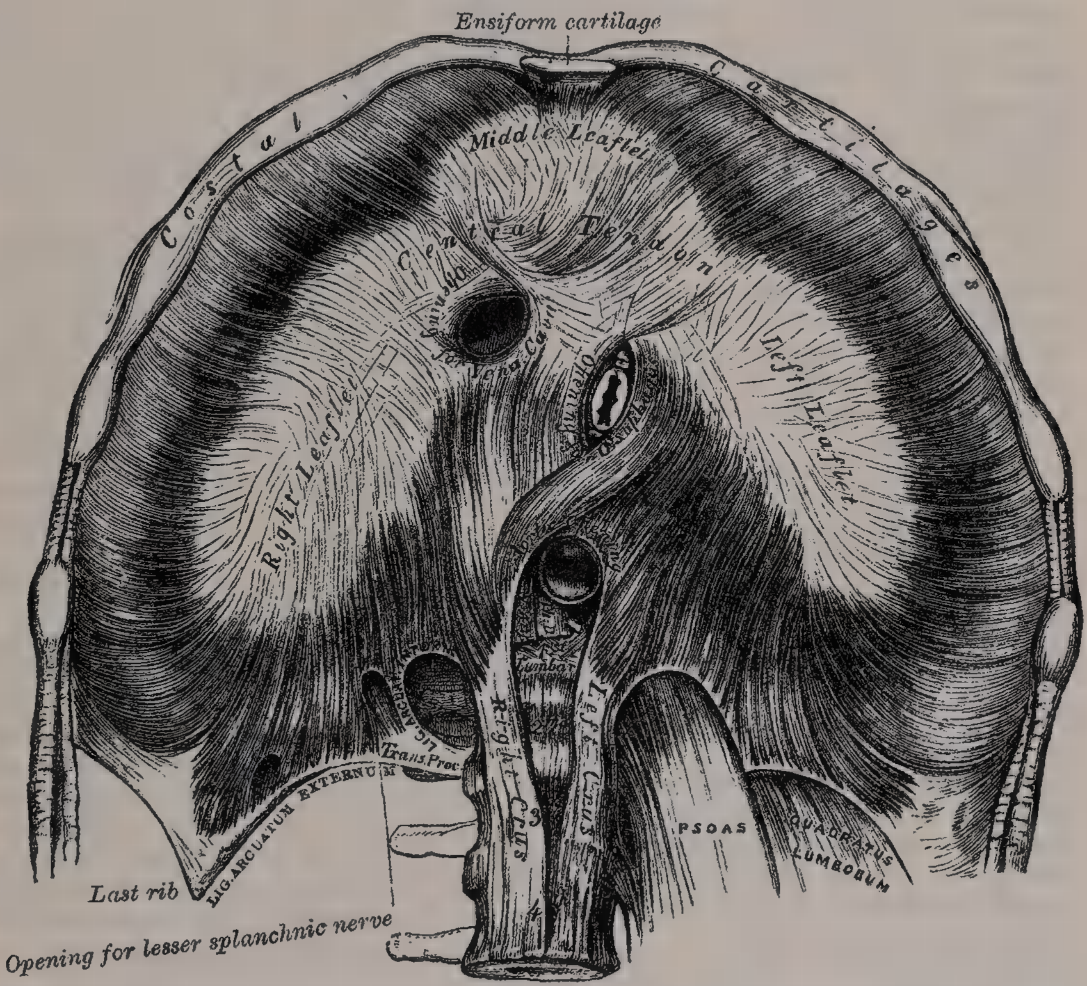
The **Levatores costarum** (fig. 407), twelve in number on each side, are small tendinous and fleshy bundles, which arise from the extremities of the transverse processes of the seventh cervical and eleven upper dorsal vertebræ, and, passing obliquely downwards and outwards like the fibres of the External intercostals, are inserted into the upper border of the rib below them, between the tubercle and the angle. The inferior Levatores divide into two fasciculi, one of which is inserted as above described; the other fasciculus passes down to the second rib

below its origin; thus, each of the lower ribs receives fibres from the transverse processes of two vertebræ.

Nerves.—The muscles of this group are supplied by the intercostal nerves.

The **Diaphragm** (*διάφραγμα, a partition wall*) (fig. 409) is a dome-shaped musculo-fibrous septum, consisting of muscular fibres externally, which arise from the circumference of the thoracic cavity and pass upwards and inwards to converge to a central tendon. It separates the thorax from the abdomen, forming the floor of the former cavity and the roof of the latter. It arises from the whole of the internal circumference of the thorax: being attached, in front, by two fleshy slips to the ensiform cartilage; on either side, to the inner surface of the cartilages and bony portions of the six inferior ribs, interdigitating with the Transversalis abdominis; and behind, to two aponeurotic arches, named the *ligamenta arcuata*; and by the *crura*, to the lumbar vertebræ. The fibres from these sources vary in length; those arising from the ensiform appendix are very

Fig. 409.—The Diaphragm. Under surface.



short and occasionally aponeurotic; those from the ligamenta arcuata, and more especially those from the cartilages of the ribs at the side of the chest, are longer, describe well-marked curves as they ascend, and finally converge to be inserted into the circumference of the central tendon. Between the origin from the ensiform appendix and that from the cartilages of the adjoining ribs, the fibres of the Diaphragm are deficient, the interval being filled by areolar tissue; this interval transmits the superior epigastric branch of the internal mammary artery, covered on the thoracic side by the pleuræ; on the abdominal, by the peritoneum. A triangular gap is sometimes seen between the fibres springing from the internal and those arising from the external arcuate ligament. When it exists the kidney is only separated from the pleura by fatty and areolar tissue.

The *ligamentum arcuatum internum* is a tendinous arch, thrown across the upper part of the Psoas magnus muscle, on each side of the spine. It is

connected, by one end, to the outer side of the body of the first or second lumbar vertebra, being continuous with the outer side of the tendon of the corresponding crus; and, by the other end, to the front of the transverse process of the first, and sometimes also to that of the second, lumbar vertebra.

The *ligamentum arcuatum externum* is the thickened upper margin of the anterior lamella of the lumbar fascia; it arches across the upper part of the Quadratus lumborum, being attached, by one extremity, to the front of the transverse process of the first lumbar vertebra; and, by the other, to the apex and lower margin of the last rib.

The Crura.—The Diaphragm is connected to the spine by two *crura* or *pillars*, which are situated on the bodies of the lumbar vertebræ, on each side of the aorta. The crura, at their origin, are tendinous in structure: the right crus, larger and longer than the left, arising from the anterior surface of the bodies and intervertebral substances of the three upper lumbar vertebræ; the left, from the two upper; both blending with the anterior common ligament of the spine. These tendinous portions of the crura pass forwards and inwards and gradually converge to meet in the middle line, forming an arch, the *ligamentum arcuatum medium*,* beneath which pass the aorta, vena azygos major, and thoracic duct. From this tendinous arch muscular fibres arise, which diverge, the outermost being directed upwards and outwards to the central tendon; the innermost decussating in front of the aorta, and then diverging, so as to surround the œsophagus before ending in the central tendon. The fibres derived from the right crus are the most numerous, and pass in front of those derived from the left.

The *Central* or *Trefoil Tendon* of the Diaphragm is a thin but strong tendinous aponeurosis, situated near the centre of the vault formed by the muscle, but somewhat closer to the front of the chest than the back, so that the posterior muscular fibres are the longer. It is situated immediately below the pericardium, with which it is partly blended. It is shaped somewhat like a trefoil leaf, consisting of three divisions, or leaflets, separated from one another by slight indentations. The right leaflet is the largest; the middle one, directed towards the ensiform cartilage, the next in size; and the left, the smallest. In structure, the tendon is composed of several planes of fibres, which intersect one another at various angles, and unite into straight or curved bundles—an arrangement which affords it additional strength.

The *Openings* in the Diaphragm consist of three large and several smaller apertures. The former are the aortic, the œsophageal, and the vena caval.

The *aortic opening* is the lowest and the most posterior of the three large apertures connected with this muscle, being at the level of the twelfth dorsal vertebra. It is situated slightly to the left of the middle line, immediately in front of the spinal column, and is, therefore, *behind* the Diaphragm. It is an osseo-aponeurotic aperture, formed by the ligamentum arcuatum medium thrown across the front of the bodies of the vertebræ, from the crus on one side to that on the other, and transmits the aorta, vena azygos major, and thoracic duct. Sometimes the vena azygos major is transmitted upwards through the right crus. Occasionally some tendinous fibres are prolonged across the bodies of the vertebræ from the inner part of the lower end of the crura, passing behind the aorta, and thus converting the opening into a fibrous ring.

The *œsophageal opening* is situated at the level of the tenth dorsal vertebra; it is elliptical in form, muscular in structure, and formed by the decussating fibres of the two crura, which act as a sort of sphincter. It is placed above, in front, and a little to the left of the preceding. It transmits the œsophagus and pneumogastric nerves and some small œsophageal arteries. The anterior margin of this aperture is occasionally tendinous, being formed by the margin of the central tendon.

The *opening for the vena cava* (*foramen quadratum*) is the highest, and is situated about the level of the disc between the eighth and ninth dorsal vertebræ; it is quadrilateral in form, tendinous in structure, and placed at the junction of the right and middle leaflets of the central tendon, its margins being adherent to the wall of the inferior vena cava.

The *right crus* transmits the greater and lesser splanchnic nerves of the right side; the *left crus* transmits the greater and lesser splanchnic nerves of the left

side, and the vena azygos minor. The gangliated cords of the sympathetic usually enter the abdominal cavity by passing behind the internal arcuate ligaments. The superior epigastric branch of the internal mammary artery, and some lymphatics from the convex surface of the liver and the abdominal wall, pass through the triangular interspace behind the ensiform cartilage, where the muscular fibres of the Diaphragm are deficient.

The *Serous Membranes* in relation with the Diaphragm are four in number: three lining its upper or thoracic surface; one, its abdominal. The three serous membranes on its upper surface are the pleura on either side, and the serous layer of the pericardium, which covers the middle portion of the tendinous centre. The serous membrane covering the greater part of its under surface is a portion of the general peritoneal membrane of the abdominal cavity.

The Diaphragm is arched, being convex towards the chest, and concave to the abdomen. The *right portion* is accurately moulded over the convex surface of the liver; resting upon its upper surface is the concave base of the right lung. The *left portion* is lower than the right by about three-quarters of an inch. It supports the base of the left lung, and covers the great end of the stomach, the spleen, and left kidney. The *central portion*, which supports the heart, is on a slightly lower level than the two lateral portions.

Nerves.—The Diaphragm is supplied by the phrenic and lower intercostal nerves and the phrenic plexus of the sympathetic.

Actions.—The Intercostals are the chief agents in the movement of the ribs in ordinary respiration. When the first rib is elevated and fixed by the Scaleni, the External intercostals raise the other ribs, especially their fore part, and so increase the capacity of the chest from before backwards; at the same time they evert their lower borders, and so enlarge the thoracic cavity transversely. The Internal intercostals, at the side of the thorax, depress the ribs, and invert their lower borders, and so diminish the thoracic cavity; but at the fore part of the chest these muscles assist the External intercostals in raising the cartilages.* The Levatores costarum assist the External intercostals in raising the ribs. The Triangularis sterni draws down the costal cartilages; it is therefore an expiratory muscle.

The Diaphragm is the principal muscle of inspiration. When in a condition of rest the muscle presents a domed surface, concave towards the abdomen; and consists of a circumferential muscular and a central tendinous part. When the muscular fibres contract, they become less arched, or nearly straight, and thus cause the central tendon to descend, and in consequence the level of the floor of the chest is lowered, the vertical diameter of the chest being proportionately increased. In this descent the different parts of the tendon move unequally. The left leaflet descends to the greatest extent; the right to a less extent, on account of the liver; and the central leaflet the least, because of its connection to the pericardium. In descending, the Diaphragm presses on the abdominal viscera, and so to a certain extent causes a projection of the abdominal wall; but in consequence of these viscera not yielding completely, the central tendon becomes a fixed point, and enables the circumferential muscular fibres to act *from* it, and so elevate the lower ribs and expand the lower part of the thoracic cavity; and Duchenne has shown that the Diaphragm has the power of

* The view of the action of the Intercostal muscles given in the text is that which is taught by Hutchinson (*Cycl. of Anat. and Phys.* art. 'Thorax'), and is usually adopted in our schools. It is, however, much disputed. Hamberger believed that the External intercostals act as elevators of the ribs, or muscles of inspiration, while the Internal act in expiration. Haller taught that both sets of muscles act in common—viz. as muscles of inspiration—and this view is adopted by many of the best anatomists of the Continent, and appears supported by many observations made on the human subject under various conditions of disease, and on living animals after the muscles have been exposed under chloroform. The reader may consult an interesting paper by Cleland in the *Journal of Anat. and Phys.* No. II., May 1867, p. 209, 'On the Hutchinsonian Theory of the Action of the Intercostal Muscles.' He refers to Henle, Luschka, Budge, and Bäumler, *Observations on the Action of the Intercostal Muscles*, Erlangen, 1860. (In *New Syd. Soc.'s Year-Book* for 1861, p. 69.) W. W. Keen has come to the conclusion, from experiments made upon a criminal executed by hanging, that the External intercostals are muscles of expiration, as they pulled the ribs down, while the Internal intercostals pulled the ribs up, and are muscles of inspiration. (*Trans. Coll. Phys. Philadelphia*, Third Series, vol. i., 1875, p. 97.)

elevating the ribs, to which it is attached, by its contraction, if the abdominal viscera are *in situ*, but that if these organs are removed, this power is lost. When at the end of inspiration, the Diaphragm relaxes, the thoracic walls return to their natural position in consequence of their elastic reaction and of the elasticity and weight of the displaced viscera.*

In all expulsive acts the Diaphragm is called into action, to give additional power to each expulsive effort. Thus, before sneezing, coughing, laughing, and crying; before vomiting; previous to the expulsion of the urine and fæces, or of the fœtus from the womb, a deep inspiration takes place.

The height of the Diaphragm is constantly varying during respiration; it also varies according to the degree of distension of the stomach and intestines, and the size of the liver. After a forced expiration, the right arch is on a level, in front, with the fourth costal cartilage; at the side, with the fifth, sixth, and seventh ribs; and behind, with the eighth rib; the left arch being usually from one to two ribs' breadth below the level of the right one. In a forced inspiration, it descends from one to two inches; its slope would then be represented by a line drawn from the ensiform cartilage towards the tenth rib.

Muscles of Inspiration and Expiration.—The muscles which assist the action of the Diaphragm in ordinary tranquil inspiration are the Intercostals and the Levatores costarum, as above stated, and the Scaleni. When the need for more forcible action exists, the shoulders and the base of the scapula are fixed, and then the powerful muscles of forced inspiration come into play; the chief of these are the Trapezius, the Pectoralis minor, the Serratus posticus superior and inferior, and the Rhomboidei. The lower fibres of the Serratus magnus may possibly assist slightly in dilating the chest by raising and everting the ribs. The Sterno-mastoid also, when the head is fixed, assists in forced inspiration, by drawing up the sternum, and by fixing the clavicle, and thus affording a fixed point for the action of the muscles of the chest. The Ilio-costalis and Quadratus lumborum assist in forced inspiration by fixing the last rib (see page 493).

The ordinary action of expiration is hardly effected by muscular force, but results from a return of the walls of the thorax to a condition of rest, owing to their elasticity and to that of the lungs. Forced expiratory actions are performed mainly by the flat muscles (Obliqui and Transversalis) of the abdomen, assisted also by the Rectus. Other muscles of forced expiration are the Internal intercostals and the Triangularis sterni (as above mentioned).

III. Muscles of the Abdomen

The muscles of the abdomen may be divided into two groups: 1. The superficial muscles of the abdomen; 2. The deep muscles of the abdomen.

1. Superficial Muscles

The muscles of this group are, the

Obliquus Externus.	Transversalis.
Obliquus Internus.	Rectus.
Pyramidalis.	

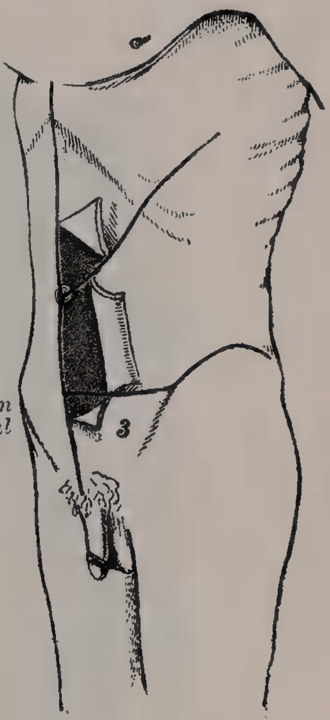
Dissection (fig. 410).—To dissect the abdominal muscles, make a vertical incision from the ensiform cartilage to the symphysis pubis; a second incision from the umbilicus obliquely upwards and outwards to the outer surface of the chest, as high as the lower border of the fifth or sixth rib; and a third, commencing midway between the umbilicus and pubes, transversely outwards to the anterior superior iliac spine, and along the crest of the ilium as far as its posterior third. Then reflect the three flaps included between these incisions from within outwards, in the lines of direction of the muscular fibres. If necessary, the abdominal muscle may be made tense by inflating the peritoneal cavity through the umbilicus.

The **superficial fascia** of the abdomen consists over the greater part of the abdominal wall of a single layer of fascia, which contains a variable amount of fat; but as this layer approaches the groin it is easily divisible into two, between

* For a detailed description of the general relations of the Diaphragm, and its action, refer to Sibson's *Medical Anatomy*.

which are found the superficial vessels and nerves and the superficial inguinal lymphatic glands. The superficial layer (*fascia of Camper*) is thick, areolar in texture, containing adipose tissue in its meshes, the quantity of which varies in different subjects. Below, it passes over Poupart's ligament, and is continuous with the superficial fascia of the thigh. In the male, this fascia is continued over the penis and outer surface of the cord to the scrotum, where it helps to form the dartos. As it passes to the scrotum it changes its character, becoming thin, destitute of adipose tissue, and of a pale reddish colour, and in the scrotum it acquires some involuntary muscular fibres. From the scrotum it may be traced backwards to be continuous with the superficial fascia of the perinæum. In the female, this fascia is continued into the labia majora. The deeper layer (*fascia of Scarpa*) is thinner and more membranous in character than the superficial layer, and contains a considerable quantity of yellow elastic fibres. It is loosely connected by areolar tissue to the aponeurosis of the External oblique, but in the middle line it is more intimately adherent to the linea alba and to the symphysis pubis, and is prolonged on to the dorsum of the penis, forming the suspensory ligament; above, it is continuous with the superficial fascia over the rest of the trunk; below, it blends with the fascia lata of the thigh a little below Poupart's ligament; internally and below, it is continued over the penis and spermatic cord to the scrotum, where it helps to form the dartos. From the scrotum it may be traced backwards to be continuous with the deep layer of the superficial fascia of the perinæum (fascia of Colles). In the female, it is continued into the labia majora.

FIG. 410.—Dissection of abdomen.

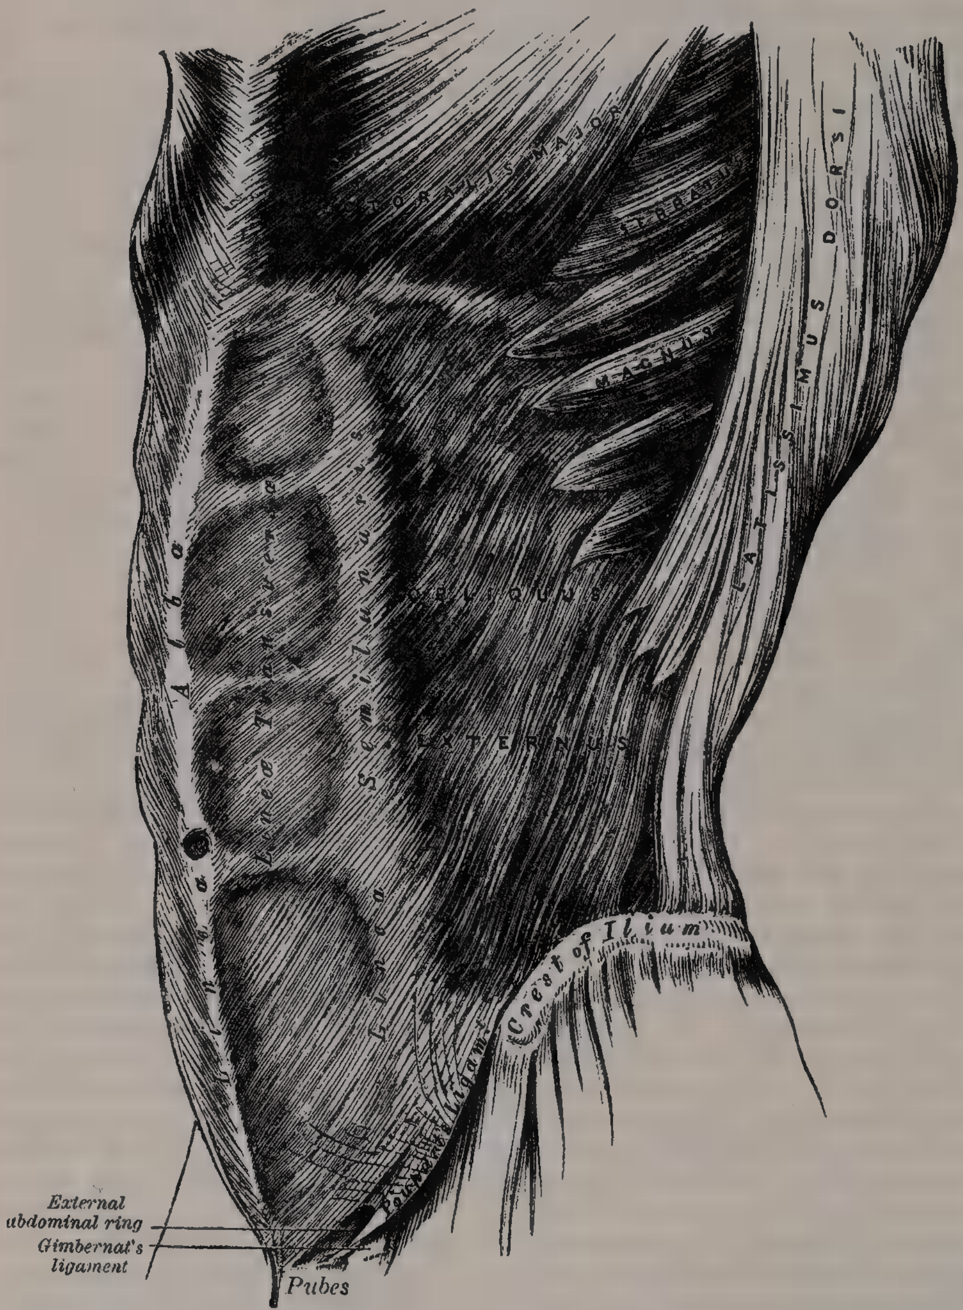


The **Obliquus externus abdominis** (fig. 411) is situated on the side and fore part of the abdomen; being the largest and the most superficial of the three flat muscles in this region. It is broad, thin, and irregularly quadrilateral, its muscular portion occupying the side, its aponeurosis the anterior wall of the abdomen. It arises, by eight fleshy digitations, from the external surfaces and lower borders of the eight inferior ribs; these digitations are arranged in an oblique line which runs downwards and backwards; the upper ones being attached close to the cartilages of the corresponding ribs; the lowest to the apex of the cartilage of the last rib; the intermediate ones, to the ribs at some distance from their cartilages. The five superior serrations increase in size from above downwards, and are received between corresponding processes of the Serratus magnus; the three lower ones diminish in size from above downwards, receiving between them corresponding processes from the Latissimus dorsi. From these attachments the fleshy fibres proceed in various directions. Those from the lowest ribs pass nearly vertically downwards, to be inserted into the anterior half of the outer lip of the crest of the ilium; the middle and upper fibres, directed downwards and forwards, terminate in an aponeurosis, opposite a line drawn from the prominence of the ninth costal cartilage to the anterior superior spinous process of the ilium.

The **Aponeurosis of the External oblique** is a thin but strong membranous structure, the fibres of which are directed obliquely downwards and inwards. It is joined with that of the opposite muscle along the median line, and covers the whole of the front of the abdomen; above, it is connected with the lower border of the Pectoralis major; below, its fibres are closely aggregated together, and extend obliquely across from the anterior superior spine of the ilium to the spine of the os pubis and the linea ilio-pectinea. In the median line, it interlaces with the aponeurosis of the opposite muscle, forming the linea alba, which extends from the ensiform cartilage to the symphysis pubis.

That portion of the aponeurosis which extends between the anterior superior spine of the ilium and the spine of the os pubis is a thick band, folded inwards, and continuous below with the fascia lata; it is called *Poupart's ligament.* The portion which is reflected from Poupart's ligament at the spine of the os pubis along the pectineal line is called *Gimbernat's ligament.* From the point of attachment of the latter to the pectineal line, a few fibres pass upwards and

FIG. 411.—The External oblique muscle.



inwards, behind the inner pillar of the ring, to the linea alba. They diverge as they ascend, and form a thin triangular fibrous layer, which is called the *triangular fascia.*

In the aponeurosis of the External oblique, immediately above the crest of the os pubis, is a triangular opening, the *external abdominal ring,* formed by a separation of the fibres of the aponeurosis in this situation.

Relations.—By its *external surface,* with the superficial fascia, superficial epigastric and circumflex iliac vessels, and some cutaneous nerves. By its *internal surface,* with the Internal oblique, the lower part of the eight inferior ribs, and Intercostal muscles, the Cremaster, the spermatic cord in the male,

and round ligament in the female. Its *posterior border*, extending from the last rib to the crest of the ilium, is fleshy throughout and free; it is occasionally overlapped by the Latissimus dorsi, though generally a triangular interval exists between the two muscles near the crest of the ilium, in which is seen a portion of the Internal oblique. This triangle, *Petit's triangle*, is therefore bounded in front by the External oblique, behind by the Latissimus dorsi, below by the crest of the ilium, while its floor is formed by the Internal oblique (fig. 406).

The following parts of the aponeurosis of the External oblique muscle require to be further described, viz. the external abdominal ring, the intercolumnar fibres and fascia, Poupart's ligament, Gimbernat's ligament, and the triangular fascia.

The External or Superficial abdominal ring.—Just above, and to the outer side of the crest of the os pubis, an interval is seen in the aponeurosis of the External oblique, called the *External abdominal ring.* The aperture is oblique in direction, somewhat triangular in form, and corresponds with the course of the fibres of the aponeurosis. It usually measures from base to apex about an inch, and transversely about half an inch. It is bounded below by the crest of the os pubis; above, by a series of curved fibres, the *intercolumnar,* which pass across the upper angle of the ring, so as to increase its strength; and on each side, by the margins of the opening in the aponeurosis, which are called the *columns* or *pillars of the ring.*

The external pillar, which is at the same time inferior from the obliquity of its direction, is the stronger; it is formed by that portion of Poupart's ligament which is inserted into the spine of the os pubis; it is curved so as to form a kind of groove, upon which the spermatic cord rests. The internal or superior pillar is a broad, thin, flat band which is attached to the front of the symphysis pubis, interlacing with its fellow of the opposite side, that of the right side being superficial.

The external abdominal ring gives passage to the spermatic cord and ilio-inguinal nerve in the male, and to the round ligament of the uterus and the ilio-inguinal nerve in the female: it is much larger in men than in women, on account of the large size of the spermatic cord, and hence the greater frequency of inguinal hernia in men.

The **intercolumnar fibres** are a series of curved tendinous fibres, which arch across the lower part of the aponeurosis of the External oblique. They have received their name from stretching across between the two pillars of the external ring, describing a curve with the convexity downwards. They are much thicker and stronger at the outer margin of the external ring, where they are connected to Poupart's ligament, than internally, where they are inserted into the linea alba. They are more strongly developed in the male than in the female. The intercolumnar fibres increase the strength of the lower part of the aponeurosis, and prevent the divergence of the pillars from one another.

These intercolumnar fibres, as they pass across the external abdominal ring, are themselves connected together by delicate fibrous tissue, thus forming a fascia which, as it is attached to the pillars of the ring, covers it in, and is called the *intercolumnar fascia.* This **intercolumnar fascia** is continued down as a tubular prolongation around the spermatic cord and testis, and encloses them in a distinct sheath; hence it is also called the *external spermatic fascia.* The external abdominal ring is only seen as a distinct aperture after the external spermatic fascia has been removed from its pillars.

The sac of an inguinal hernia, in passing through the external abdominal ring, receives an investment from the intercolumnar fascia.

Poupart's ligament is the lower border of the aponeurosis of the External oblique muscle, which extends from the anterior superior spine of the ilium to the spine of the os pubis. From this latter point it is reflected backwards and outwards to be attached to the pectineal line for about half an inch, forming Gimbernat's ligament. Its general direction is curved downwards towards the thigh, where it is continuous with the fascia lata. Its outer half is rounded and oblique in direction. Its inner half gradually widens at its attachment to the os pubis, is more horizontal in direction, and lies beneath the spermatic cord.

Nearly the whole of the space included between the crural arch and the

innominate bone is filled in by the parts which descend from the abdomen into the thigh. These will be referred to again on a subsequent page.

Gimbernat's ligament is that part of the aponeurosis of the External oblique muscle which is reflected backwards and outwards from the spine of the os pubis to be inserted into the pectineal line. It is about half an inch in length, larger in the male than in the female, almost horizontal in direction in the erect posture, and of a triangular form with the base directed outwards. Its base, or outer margin, is concave, thin, and sharp, and forms the inner boundary of the crural ring. Its apex corresponds to the spine of the os pubis. Its posterior margin is attached to the pectineal line, and is continuous with the pubic portion of the fascia lata. Its anterior margin is attached to Poupart's ligament. Its surfaces are directed upwards and downwards.

The **triangular fascia** of the abdomen is a layer of tendinous fibres of a triangular shape, formed by an expansion from Gimbernat's ligament and the outer pillar of the ring. It passes inwards beneath the spermatic cord, and expands into a somewhat fan-shaped fascia, lying behind the inner pillar of the external abdominal ring, and in front of the conjoined tendon, and interlaces with the ligament of the other side at the linea alba.

Ligament of Cooper.—This is a strong ligamentous band, which was first described by Sir Astley Cooper. It extends upwards and backwards from the base of Gimbernat's ligament along the ilio-pectineal line, to which it is attached. It is strengthened by the fascia transversalis, by the pectineal aponeurosis, and by a lateral expansion from the lower attachment of the linea alba (adminiculum lineæ albæ).

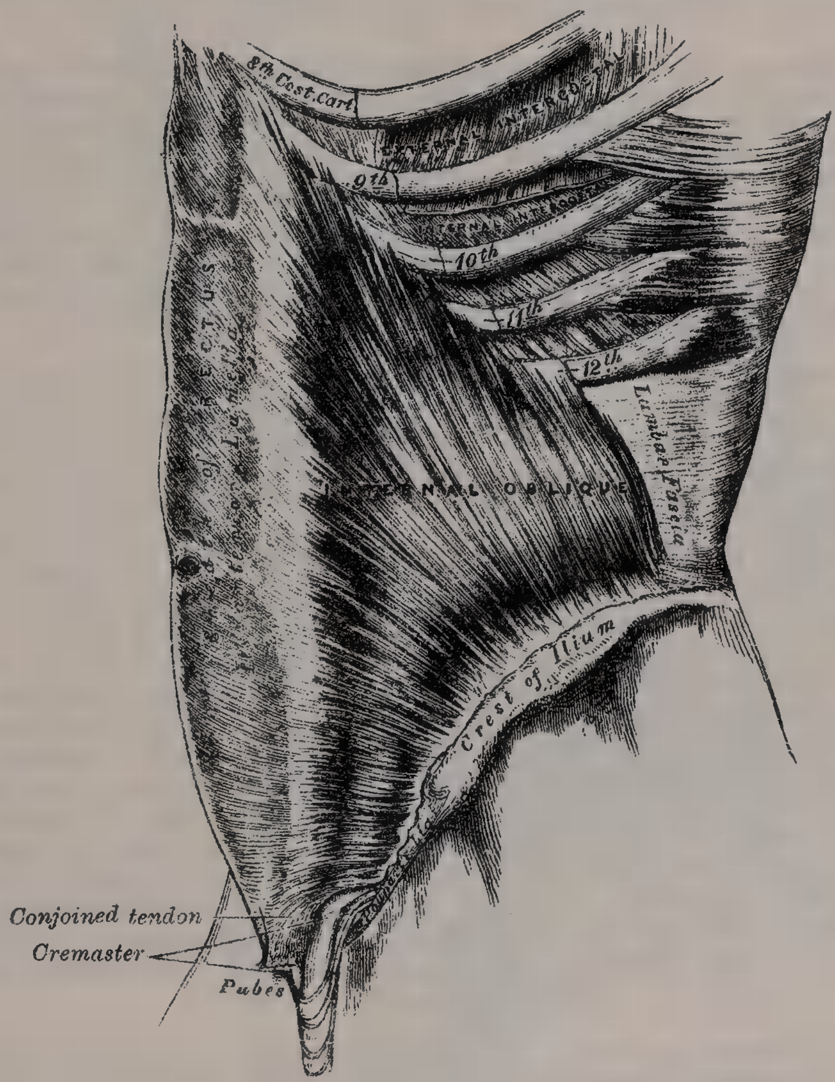
Dissection.—Detach the External oblique by dividing it across, just in front of its attachment to the ribs, as far as its posterior border, and separate it below from the crest of the ilium as far as the anterior superior spine; then detach the muscle carefully from the Internal oblique, which lies beneath it, and turn it towards the opposite side.

The **Obliquus internus abdominis** (fig. 412), thinner and smaller than the preceding, beneath which it lies, is of an irregularly quadrilateral form, and situated at the side and fore part of the abdomen. It arises, by fleshy fibres, from the outer half of Poupart's ligament, being attached to the groove on its upper surface; from the anterior two-thirds of the middle lip of the crest of the ilium, and from the posterior lamella of the lumbar fascia. From this origin the fibres diverge: those from Poupart's ligament, few in number, and paler in colour than the rest, arch downwards and inwards across the spermatic cord in the male and the round ligament in the female, and, becoming tendinous, are inserted, conjointly with those of the Transversalis, into the crest of the os pubis and inner part of the ilio-pectineal line behind Gimbernat's ligament, forming what is known as the conjoined tendon of the Internal oblique and Transversalis; those from the anterior third of the iliac origin are horizontal in their direction, and, becoming tendinous along the lower fourth of the linea semilunaris, pass in front of the Rectus muscle to be inserted into the linea alba; those which arise from the middle third of the origin from the crest of the ilium pass obliquely upwards and inwards, and terminate in an aponeurosis, which divides at the outer border of the Rectus muscle into two lamellæ, which are continued forwards, one in front and the other behind this muscle, to the linea alba: the posterior lamella being also connected to the cartilages of the seventh, eighth, and ninth ribs; the most posterior fibres pass almost vertically upwards, to be inserted into the lower borders of the cartilages of the three lower ribs, being continuous with the Internal intercostal muscles.

The *conjoined tendon* of the Internal oblique and Transversalis is mainly formed by the lower part of the tendon of the Transversalis, and is inserted into the crest of the os pubis and ilio-pectineal line, immediately behind the external abdominal ring, serving to protect what would otherwise be a weak point in the abdominal wall. Sometimes this tendon is insufficient to resist the pressure from within, and is carried forward in front of the protrusion through the external abdominal ring, forming one of the coverings of direct inguinal hernia; or the hernia forces its way through the fibres of the conjoined tendon. The conjoined tendon is sometimes divided into an outer and an inner portion—the former being termed the *ligament of Hesselbach*; the latter, the *ligament of Henle*.

The aponeurosis of the Internal oblique is continued forward to the middle line of the abdomen, where it joins with the aponeurosis of the opposite muscle at the linea alba, and extends from the margin of the thorax to the os pubis. At the outer margin of the Rectus muscle, this aponeurosis, for the upper three-fourths of its extent, divides into two lamellæ, which pass, one in front and the other behind the muscle, enclosing it in a sheath, and reuniting on its inner border at the linea alba; the anterior layer is blended with the aponeurosis of the External oblique muscle; the posterior layer with that of the Transversalis. Along the lower fourth, the aponeurosis ceases to split, and passes altogether in front of the Rectus without any separation, and thus a deficiency is left in

FIG. 412.—The Internal oblique muscle.



the sheath of the muscle behind; this is marked above by a sharp lunated margin, having its concavity downwards, and known as the *semilunar fold of Douglas*.

Relations.—By its *external surface*, with the External oblique, Latissimus dorsi, spermatic cord, and external ring. By its *internal surface*, with the Transversalis muscle, the lower intercostal vessels and nerves, the ilio-hypogastric and the ilio-inguinal nerves. Near Poupart's ligament, it lies on the fascia transversalis, internal ring, and spermatic cord.

The **Cremaster muscle** is a thin muscular layer, composed of a number of fasciculi which arise from the middle of Poupart's ligament where its fibres are continuous with those of the Internal oblique and also occasionally with the Transversalis. It passes along the outer side of the spermatic cord, descends with it through the external abdominal ring upon the front and sides of the cord, and forms a series of loops which differ in thickness and length in

different subjects. Those at the upper part of the cord are exceedingly short, but they become in succession longer and longer, the longest reaching down as low as the testicle, where a few are inserted into the tunica vaginalis. These loops are united together by areolar tissue, and form a thin covering over the cord and testis, the *cremasteric fascia.* The fibres ascend along the inner side of the cord, and are inserted by a small pointed tendon into the spine and crest of the os pubis and front of the sheath of the Rectus muscle.

It will be observed that the origin and insertion of the Cremaster is precisely similar to that of the lower fibres of the Internal oblique. This fact affords an easy explanation of the manner in which the testicle and cord are invested by this muscle. At an early period of fœtal life the testis is placed at the lower and back part of the abdominal cavity, but during its descent towards the scrotum, which takes place before birth, it carries on it some fibres from the lower part of the muscle, which accompany the testicle and cord into the scrotum.

Dissection.—Detach the Internal oblique in order to expose the Transversalis beneath. This may be effected by dividing the muscle above, at its attachment to the ribs; below, at its connection with Poupart's ligament and the crest of the ilium; and behind, by a vertical incision extending from the last rib to the crest of the ilium. The muscle should previously be made tense by drawing upon it with the fingers of the left hand, and if its division is carefully effected, the cellular interval between it and the Transversalis, as well as the direction of the fibres of the latter muscle, will afford a clear guide to their separation; above the crest of the ilium the ascending branches of the deep circumflex iliac vessels are interposed between them, and form an important guide in separating them. The muscle should then be thrown inwards towards the linea alba.

The **Transversalis muscle** (fig. 413), so called from the direction of its fibres, is the most internal of the flat muscles of the abdomen, being placed immediately beneath the Internal oblique. It arises by fleshy fibres from the outer third of Poupart's ligament; from the anterior three-fourths of the inner lip of the crest of the ilium; from the inner surface of the cartilages of the six lower ribs, interdigitating with the Diaphragm; and from the lumbar aponeurosis, which may be regarded as the posterior aponeurosis of the muscle, and which has been seen to divide into three lamellæ (see page 469). The muscle terminates in front in a broad aponeurosis, the lower fibres of which curve downwards and inwards, and are inserted, together with those of the Internal oblique, into the lower part of the linea alba, the crest of the os pubis and pectineal line, forming what is known as the conjoined tendon of the Internal oblique and Transversalis. Throughout the rest of its extent the aponeurosis passes horizontally inwards, and is inserted into the linea alba; its upper three-fourths passing behind the Rectus muscle, blending with the posterior lamella of the Internal oblique; its lower fourth passing in front of the Rectus.

Relations.—By its *external surface*, with the Internal oblique, the lower intercostal nerves, and the inner surface of the cartilages of the lower ribs. By its *internal surface*, with the fascia transversalis, which separates it from the extra-peritoneal fat and parietal layer of the peritoneum. Its lower border forms the upper boundary of the inguinal canal.

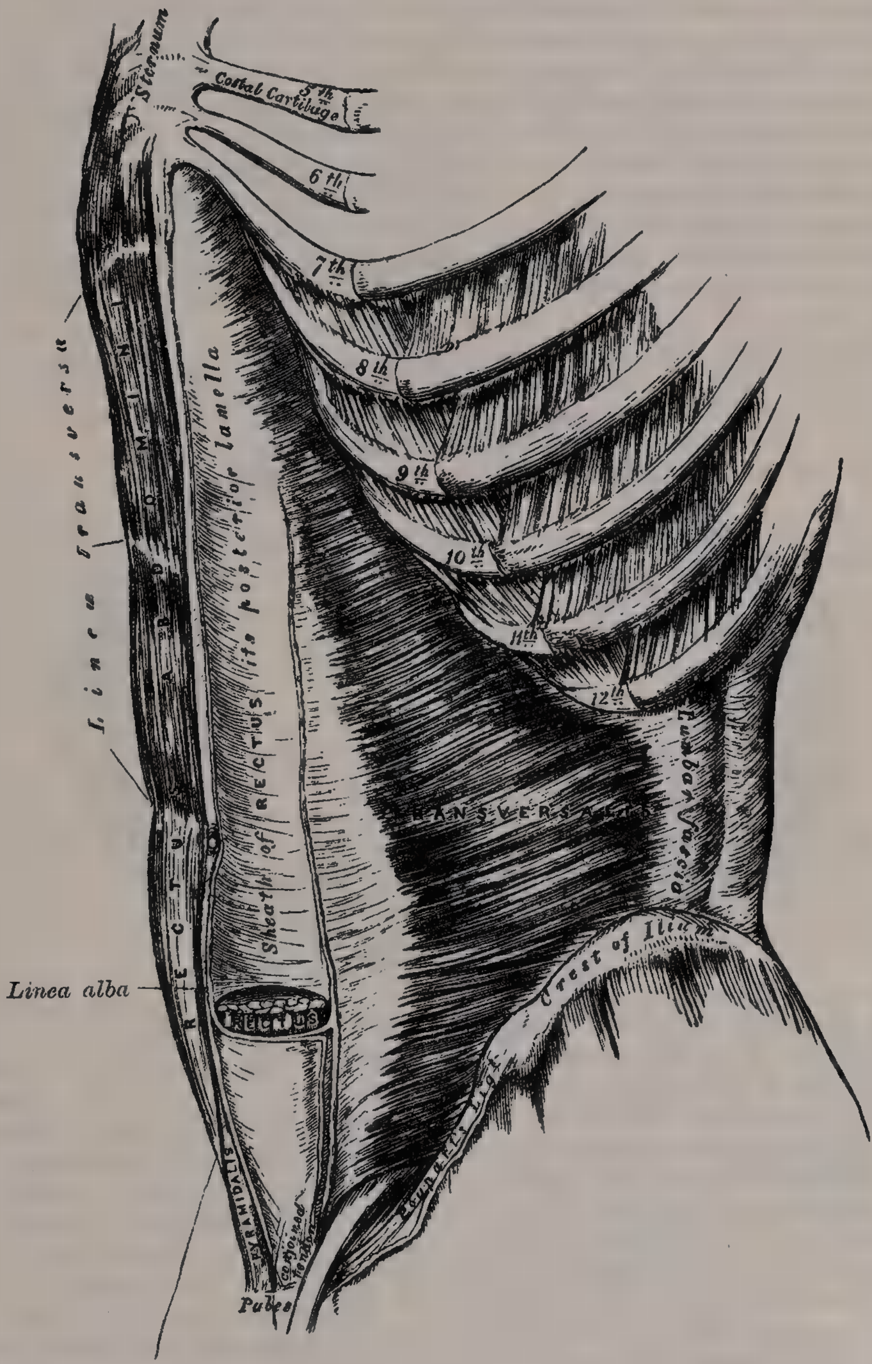
Dissection.—To expose the Rectus muscle, open its sheath by a vertical incision extending from the margin of the thorax to the os pubis, and then reflect the two portions from the surface of the muscle, which is easily done, excepting at the lineæ transversæ, where so close an adhesion exists that the greatest care is requisite in separating them. Now raise the outer edge of the muscle, in order to examine the posterior layer of the sheath. By dividing the muscle in the centre, and turning its lower part downwards, the point where the posterior wall of the sheath terminates in the fold of Douglas will be seen.

The **Rectus abdominis** is a long flat muscle, which extends along the whole length of the front of the abdomen, being separated from its fellow of the opposite side by the linea alba. It is much broader, but thinner, above than below, and arises by two tendons, the external or larger being attached to the crest of the os pubis; the internal, smaller portion, interlacing with its fellow of the opposite side, and being connected with the ligaments covering the front of the symphysis pubis. The fibres ascend, and the muscle is inserted by three portions of unequal size into the cartilages of the fifth, sixth, and seventh ribs.

The upper portion, attached principally to the cartilage of the fifth rib, usually has some fibres of insertion into the anterior extremity of the rib itself. Some fibres are occasionally connected with the costo-xiphoid ligaments, and side of the ensiform cartilage.

The Rectus muscle is traversed by tendinous intersections, three in number, which have received the name of *lineæ transversæ*. One of these is usually situated opposite the umbilicus, and two above that point; of the latter, one

FIG. 413.—The Transversalis, Rectus, and Pyramidalis muscles.



corresponds to the extremity of the ensiform cartilage, and the other is about midway between the ensiform cartilage and the umbilicus. These intersections pass transversely or obliquely across the muscle in a zigzag course; they rarely extend completely through its substance; they may pass only halfway across it, and are intimately adherent in front to the sheath in which the muscle is enclosed. Sometimes one or two additional lines may be seen, one usually below the umbilicus; the position of the other, when it exists, is variable. These additional lines are for the most part incomplete.

The Rectus is enclosed in a sheath (fig. 414) formed by the aponeuroses of the Oblique and Transversalis muscles, which are arranged in the following manner. When the aponeurosis of the Internal oblique arrives at the outer margin of the Rectus, it divides into two lamellæ, one of which passes in front of the Rectus, blending with the aponeurosis of the External oblique; the other, behind it, blending with the aponeurosis of the Transversalis; and these, joining again at its inner border, are inserted into the linea alba. This arrangement of the aponeurosis exists from the costal margin to midway between the umbilicus and symphysis pubis, where the posterior wall of the sheath terminates in a thin curved margin, the *semilunar fold of Douglas*, the concavity of which looks downwards towards the pubes: below this level the aponeuroses of all three muscles pass in front of the Rectus without any separation. The extremities of the fold of Douglas descend as pillars to the os pubis. The inner pillar is attached to the symphysis pubis; the outer pillar, which was named by Braune the ligament of Hesselbach, passes downwards as a distinct band on the inner side of the internal abdominal ring, and there its fibres divide into two sets, internal and external: the internal fibres are attached to the ascending ramus of the os pubis and the pectineal fascia; the external ones pass to the Psoas fascia, to the deep surface of Poupart's ligament, and to the tendon of the Transversalis on the outer side of the ring. The Rectus muscle, in the situation

FIG. 414.—A transverse section of the abdomen in the lumbar region.

where its sheath is deficient, is separated from the peritoneum by the transversalis fascia. Since the tendon of the Internal oblique muscle only reaches as high as the costal margin, it follows that above this level the sheath of the Rectus is deficient behind, the muscle resting directly on the cartilages of the ribs, and being covered merely by the tendon of the External oblique.

The **Pyramidalis** is a small muscle, triangular in shape, placed at the lower part of the abdomen, in front of the Rectus, and contained in the same sheath with that muscle. It arises by tendinous fibres from the front of the os pubis and the anterior pubic ligament; the fleshy portion of the muscle passes upwards, diminishing in size as it ascends, and terminates by a pointed extremity, which is inserted into the linea alba, midway between the umbilicus and the os pubis. This muscle may be wanting on one or both sides; the lower end of the Rectus then becomes proportionately increased in size. Occasionally it has been found double on one side, or the muscles of the two sides are of unequal size. Sometimes it extends higher than what is stated above.

Besides the Rectus and Pyramidalis muscles, the sheath of the Rectus contains the superior and deep epigastric arteries, the terminations of the lumbar arteries and of the lower intercostal arteries and nerves.

Nerves.—The abdominal muscles are supplied by the lower intercostal nerves. The Transversalis and Internal oblique also receive filaments from the

hypogastric branch of the ilio-hypogastric and sometimes from the ilio-inguinal. The Cremaster is supplied by the genital branch of the genito-crural.

In the description of the abdominal muscles, mention has frequently been made of the linea alba, lineæ semilunares, and lineæ transversæ; when the dissection of the muscles is completed, these structures should be examined.

The **linea alba** is a tendinous raphé seen along the middle line of the abdomen, extending from the ensiform cartilage to the symphysis pubis, to which it is attached. It is placed between the inner borders of the Recti muscles, and is formed by the blending of the aponeuroses of the Obliqui and Transversales muscles. It is narrow below, corresponding to the linear interval existing between the Recti; but broader above, as these muscles diverge from one another in their ascent, becoming of considerable breadth after great distension of the abdomen from pregnancy or ascites. At its lower end the linea alba has a double insertion—its superficial fibres passing in front of the inner heads of the Recti to the symphysis pubis, while its deeper fibres form a triangular lamella, which is attached behind the Recti to the posterior lip of the crest of the pubis, and which is named the *adminiculum lineæ albæ*. It presents numerous apertures for the passage of vessels and nerves; the largest of these is the umbilicus, which in the fœtus transmits the umbilical vessels, but in the adult is obliterated, the cicatrix being stronger than the neighbouring parts; hence umbilical hernia occurs in the adult *near* the umbilicus, while in the fœtus it occurs *at* the umbilicus. The linea alba is in relation, in front, with the integument, to which it is adherent, especially at the umbilicus; behind, it is separated from the peritoneum by the transversalis fascia, which above the umbilicus is adherent to it, but below is separated from it by a certain amount of fat, which must not be mistaken for extra-peritoneal fat.

The **lineæ semilunares** are two curved tendinous lines placed one on each side of the linea alba. Each corresponds with the outer border of the Rectus muscle, extends from the cartilage of the ninth rib to the pubic spine, and is formed by the aponeurosis of the Internal oblique at its point of division to enclose the Rectus, where it is reinforced in front by the External oblique, and behind by the Transversalis.

The **lineæ transversæ** are narrow transverse lines which intersect the Recti muscles, as already mentioned; they connect the lineæ semilunares with the linea alba.

Actions.—The abdominal muscles perform a threefold action.

When the pelvis and thorax are fixed, they compress the abdominal viscera, by constricting the cavity of the abdomen, in which action they are materially assisted by the descent of the Diaphragm. By these means assistance is given in expelling the fœtus from the uterus, the fæces from the rectum, the urine from the bladder, and the contents of the stomach in vomiting.

If the pelvis and spine are fixed, these muscles compress the lower part of the thorax, materially assisting expiration. If the pelvis alone is fixed, the thorax is bent directly forward, when the muscles of both sides act, or to either side when those of the two sides act alternately, rotation of the trunk at the same time taking place to the opposite side.

If the thorax is fixed, these muscles, acting together, draw the pelvis upwards, as in climbing; or, acting singly, they draw the pelvis upwards, and bend the vertebral column to one side or the other. The Recti muscles, acting from below, depress the thorax, and consequently flex the vertebral column; when acting from above, they flex the pelvis upon the vertebral column. The Pyramidales are tensors of the linea alba.

The **transversalis fascia** is a thin aponeurotic membrane which lies between the inner surface of the Transversalis muscle and the extra-peritoneal fat. It forms part of the general layer of fascia which lines the abdominal parietes, and is directly continuous with the iliac and pelvic fasciæ. In the inguinal region, the transversalis fascia is thick and dense in structure and joined by fibres from the aponeurosis of the Transversalis muscle, but it becomes thin and cellular as it ascends to the Diaphragm, and blends with the fascia covering the under aspect of this muscle. In front, it unites across the middle line with the fascia on the opposite side of the body; and behind, it becomes lost in the fat which covers the posterior surfaces of the kidneys. Below, it has the following attachments:

posteriorly, it is connected to the whole length of the crest of the ilium, between the attachments of the Transversalis and Iliacus muscles; between the anterior superior spine of the ilium and the femoral vessels it is connected to the posterior margin of Poupart's ligament, and is there continuous with the iliac fascia. Internal to the femoral vessels it is thin and attached to the os pubis and pectineal line, behind the conjoined tendon, with which it is united; corresponding to the region where the femoral vessels pass into the thigh, this fascia descends in front of them, forming the anterior wall of the femoral sheath. Beneath Poupart's ligament it is strengthened by a band of fibrous tissue, which is only loosely connected to Poupart's ligament, and is specialised as the *deep crural arch.* The spermatic cord in the male and the round ligament in the female pass through this fascia; the point where they pass through is called the *internal abdominal ring.* This opening is not visible externally owing to a prolongation of the transversalis fascia on these structures, forming the *infundibuliform fascia.*

The **Internal** or **deep abdominal ring** is situated in the transversalis fascia, midway between the anterior superior spine of the ilium and the symphysis pubis, and about half an inch above Poupart's ligament. It is of an oval form, the extremities of the oval directed upwards and downwards, varies in size in different subjects, and is much larger in the male than in the female. It is bounded, above and externally, by the arched fibres of the Transversalis; below and internally, by the deep epigastric vessels. It transmits the spermatic cord in the male and the round ligament in the female. From its circumference a thin funnel-shaped membrane, the *infundibuliform fascia,* is continued round the cord and testis, enclosing them in a distinct covering.

When the sac of an oblique inguinal hernia passes through the internal or deep abdominal ring, the infundibuliform process of the transversalis fascia forms one of its coverings.

Extra-peritoneal Connective Tissue.—Between the inner surface of the general layer of the fascia which lines the interior of the abdominal and pelvic cavities, and the peritoneum, there is a considerable amount of connective tissue, which is termed the *extra-peritoneal* or *subperitoneal connective tissue,* and which, according to Anderson and Makins, is 'a portion of a widespread system of mesoblastic connective tissue, which surrounds the great vessels of the trunk.' It may be described as consisting of two portions, parietal and visceral.

The *parietal* portion lines the cavity in varying quantities in different situations. It is especially abundant on the posterior wall of the abdomen, and particularly around the kidneys, where it contains much fat. On the anterior wall of the abdomen, with the exception of the pubic region, and on the roof of the abdomen, it is scanty, and here the transversalis fascia is more closely connected with the peritoneum. In the pelvis, there is a considerable amount of extra-peritoneal connective tissue.

The *visceral* portion follows the course of the branches of the abdominal aorta between the layers of the mesenteries and other folds of peritoneum which connect the various viscera to the abdominal wall, and assists in fixing them. The two portions are directly continuous with each other.

The deep crural arch.—Curving over the vessels, just at the point where they become femoral, on the abdominal side of Poupart's ligament and loosely connected with it, is a thickened band of fibres called the deep crural arch. It is apparently a thickening of the fascia transversalis, joining externally the centre of Poupart's ligament, and arching across the front of the crural sheath to be inserted by a broad attachment into the spine of the os pubis and ilio-pectineal line, behind the conjoined tendon. In some subjects this structure is not very prominently marked, and not infrequently it is altogether wanting.

Surface Form.—The skin of the abdomen is thin and sensitive. In the male, it is often thickly hair-clad, especially towards the lower part of the middle line. In the female, the hairs are confined to the pubes. After distension from pregnancy or other causes, the skin presents transverse white lines, which are quite smooth, being destitute of papillæ. These are known as *striæ gravidarum.*

The only muscles of the abdomen which have any considerable influence on surface form are the External oblique and Rectus muscles. With regard to the External oblique, the upper digitations of its origin from the ribs are well marked in a muscular subject, intermingled with the serrations of the Serratus magnus; the lower digitations are not

visible, being covered by the thick border of the Latissimus dorsi. Its attachment to the crest of the ilium, in conjunction with the Internal oblique, forms a thick oblique roll, which determines the iliac furrow. Sometimes on the front of the lateral region of the abdomen an undulating outline marks the spot where the muscular fibres terminate and the aponeurosis commences. The outer border of the Rectus is defined by the *linea semilunaris*, which may be exactly determined by putting the muscle into action. It corresponds with a curved line, with its convexity outwards, drawn from the end of the cartilage of the ninth rib to the spine of the os pubis, so that the centre of the line, at or near the umbilicus, is three inches from the median line. The inner border of the Rectus corresponds to the *linea alba*, marked on the surface of the body by a groove, the *abdominal furrow*, which extends from the infrasternal fossa to, or to a little below, the umbilicus, where it gradually becomes lost. The surface of the Rectus presents three transverse furrows, the *lineæ transversæ*. The upper two of these, one opposite or a little below the tip of the ensiform cartilage, and another, midway between this point and the umbilicus, are usually well marked; the third, opposite the umbilicus, is not so distinct. The umbilicus, situated in the linea alba, varies in position as regards its height. It is always situated above a zone drawn round the body opposite the highest point of the crest of the ilium, generally being about three-quarters of an inch to an inch above this line. It usually corresponds, therefore, to the fibro-cartilage between the third and fourth lumbar vertebræ.

2. Deep Muscles of the Abdomen

Psoas magnus.	Iliacus.
Psoas parvus.	Quadratus lumborum.

The Psoas magnus, the Psoas parvus, and the Iliacus muscles, with the fascia covering them, will be described with the Muscles of the Lower Extremity (see page 541).

The fascia covering the Quadratus lumborum.—This is the most anterior of the three layers of the lumbar aponeurosis. It is a thin layer of fascia which, passing over the anterior surface of the Quadratus lumborum, is attached, internally, to the bases of the transverse processes of the lumbar vertebræ; below, to the ilio-lumbar ligament; and above, to the apex and lower border of the last rib.

The portion of this fascia which extends from the transverse process of the first lumbar vertebra to the apex and lower border of the last rib, constitutes the ligamentum arcuatum externum.

The **Quadratus lumborum** (fig. 407, page 471) is situated in the lumbar region. It is irregularly quadrilateral in shape, and broader below than above. It arises by aponeurotic fibres from the ilio-lumbar ligament and the adjacent portion of the crest of the ilium for about two inches, and is inserted into the lower border of the last rib for about half its length and, by four small tendons, into the apices of the transverse processes of the four upper lumbar vertebræ. Occasionally a second portion of this muscle is found situated in front of the preceding. It arises from the upper borders of the transverse processes of three or four of the lower lumbar vertebræ, and is inserted into the lower margin of the last rib. The Quadratus lumborum is contained in a sheath formed by the anterior and middle lamellæ of the lumbar aponeurosis.

Relations.—Its *anterior surface* (or rather the fascia which covers its anterior surface) is in relation with the colon, the kidney, the Psoas muscle, and the Diaphragm. Between the fascia and the muscle are the last dorsal, ilio-hypogastric and ilio-inguinal nerves. Its *posterior surface* is in relation with the middle lamella of the lumbar fascia, which separates it from the Erector spinæ. The Quadratus lumborum extends, however, beyond the outer border of the Erector spinæ.

Nerve-supply.—The anterior divisions of the last dorsal and first and second lumbar nerves.

Actions.—The Quadratus lumborum draws down the last rib, and acts as a muscle of inspiration by helping to fix the origin of the Diaphragm. If the thorax and spine are fixed, it may act upon the pelvis, raising it towards its own side when only one muscle is put in action; and when both muscles act together, either from below or above, they flex the trunk.

IV. Muscles of the Pelvic Outlet

The muscles of this region are situated at the pelvic outlet in the ischio-rectal region and the perinæum. They include the following:

1. Muscles of the ischio-rectal region.
2. Muscles of the perinæum: A. In the Male; B. In the Female.

1. Muscles of the Ischio-rectal Region

Corrugator cutis ani. Internal sphincter ani.
External sphincter ani. Levator ani.
Coccygeus.

The Corrugator cutis ani.—Around the anus is a thin stratum of involuntary muscular fibre, which radiates from the orifice. Internally, the fibres fade off into the submucous tissue, while externally they blend with the true skin. By its contraction it raises the skin into ridges around the margin of the anus.

The **External sphincter ani** is a thin, flat plane of muscular fibres, elliptical in shape and intimately adherent to the integument surrounding the margin of the anus. It measures about three or four inches in length, from its anterior to its posterior extremity, being about an inch in breadth, opposite the anus. It consists of two strata, superficial and deep. The *superficial*, constituting the main portion of the muscle, arises from a narrow tendinous band, the *ano-coccygeal raphé*, which stretches from the tip of the coccyx to the posterior margin of the anus; it forms two flattened planes of muscular tissue, which encircle the anus and meet in front to be inserted into the central tendinous point of the perinæum, joining with the Transversus perinæi, the Levator ani, and the Accelerator urinæ. The *deeper portion* forms a complete sphincter to the anal canal. Its fibres surround the canal, closely applied to the deep Sphincter, and in front blend with the other muscles at the central point of the perinæum. In a considerable proportion of cases the fibres decussate in front of the anus, and are continuous with the Transversus perinæi. Posteriorly, they are not attached to the coccyx, the fibres of opposite sides being continuous behind the anal canal. The upper edge of the muscle is ill-defined, since fibres are given off from it to join the Levator ani.

Nerve-supply.—A branch from the anterior division of the fourth sacral and the inferior hæmorrhoidal branch of the internal pudic.

Actions.—The action of this muscle is peculiar: 1. It is, like other muscles, always in a state of tonic contraction, and having no antagonistic muscle it keeps the anal canal and orifice closed. 2. It can be put into a condition of greater contraction under the influence of the will, so as to more firmly occlude the anal aperture in expiratory efforts, unconnected with defæcation. 3. Taking its fixed point at the coccyx, it helps to fix the central point of the perinæum, so that the Accelerator urinæ may act from this fixed point.

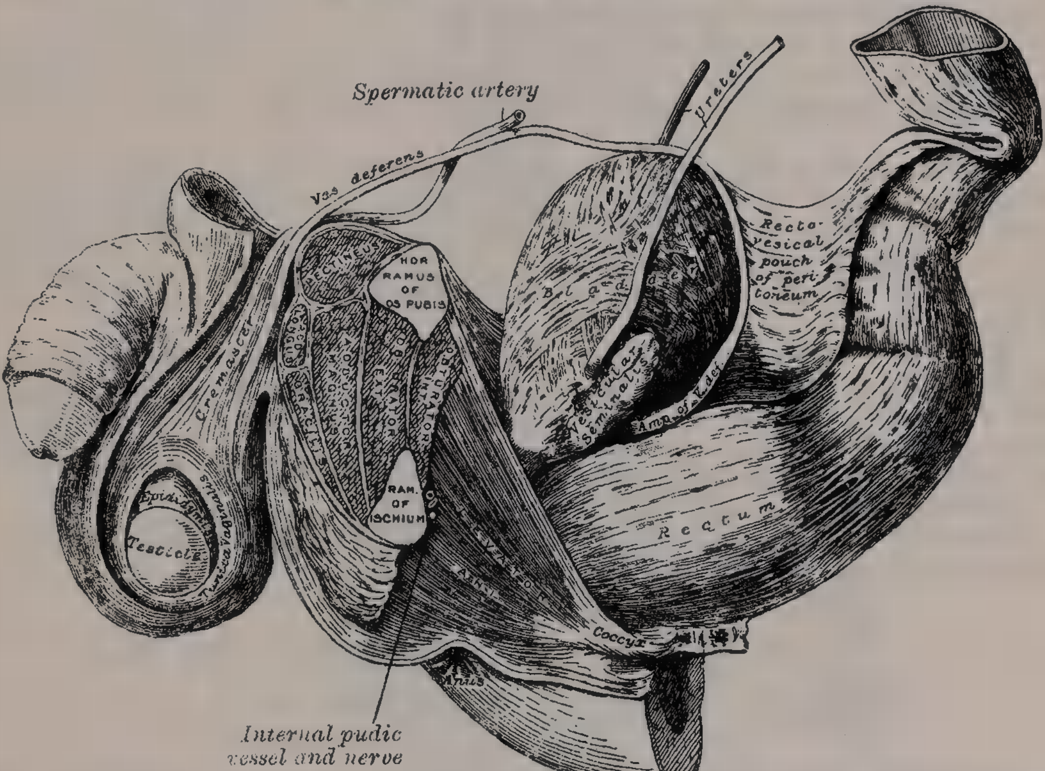
The **Internal sphincter ani** is a muscular ring which surrounds the anal canal for about an inch; its inferior border being contiguous with, but quite separate from, the External sphincter. This muscle is about two lines in thickness, and is formed by an aggregation of the involuntary circular fibres of the intestine. It surrounds the canal for about an inch, and terminates about a quarter of an inch from the external orifice. It is paler in colour and less coarse in texture than the External sphincter.

Actions.—Its action is entirely involuntary. It helps the External sphincter to occlude the anal aperture.

The **Levator ani** (fig. 415) is a broad, thin muscle, situated on each side of the pelvis. It is attached to the inner surface of the sides of the true pelvis, and descending unites with its fellow of the opposite side to form the greater part of the floor of the pelvic cavity. It supports the viscera in this cavity and surrounds the various structures which pass through it. It arises, in front, from the posterior surface of the body of the os pubis on the outer side of the symphysis; behind, from the inner surface of the spine of the ischium; and between these two points, from the pelvic fascia. Posteriorly, this fascial origin corresponds, more or less closely, with the 'white line'—i.e. with the angle of division between the obturator and recto-vesical layers of the pelvic fascia—but in

front, the muscle arises from the fascia at a varying distance above the 'white line,' in some cases reaching nearly as high as the canal for the obturator vessels and nerve. The fibres pass downwards to the middle line of the floor of the pelvis, and are inserted, the most posterior into the side of the last two segments of the coccyx; those placed more anteriorly unite with the muscle of the opposite side, in a median fibrous raphé (*ano-coccygeal raphé*), which extends between the coccyx and the margin of the anus. The middle fibres, which form the larger portion of the muscle, are inserted into the side of the rectum, blending with the fibres of the Sphincter muscles; lastly, the anterior fibres, the longest, descend upon the side of the prostate gland to unite beneath it with the muscle of the opposite side, blending with the fibres of the External sphincter and Transversus perinæi muscles at the central tendinous point of the perinæum.

FIG. 415.—Side view of pelvis, showing Levator ani.
(From a preparation in the Museum of the Royal College of Surgeons of England.)



Peter Thompson * has not been able to satisfy himself that any of the fibres of the Levator ani terminate in the rectal walls.

The anterior portion is occasionally separated from the rest of the muscle by connective tissue. From this circumstance, as well as from its peculiar relation with the prostate gland, descending by its side, and surrounding it as in a sling, it has been described by Santorini and others as a distinct muscle, under the name of *Levator prostatæ*. In the female, the anterior fibres of the Levator ani descend upon the side of the vagina.

Relations.—By its *upper* or *pelvic surface*, with the recto-vesical fascia, which separates it from the prostate, rectum, and peritoneum. By its *lower* or *perineal surface*, it forms the inner boundary of the ischio-rectal fossa, and is covered by a thin layer of fascia, the *ischio-rectal* or *anal fascia*, given off from the obturator fascia. Its *posterior border* is free and separated from the Coccygeus muscle by a cellular interspace. Its *anterior border* is separated from the muscle of the opposite side by a triangular space, through which the urethra, and in the female the vagina, passes from the pelvis.

The Levator ani may be divided into ilio-coccygeal and pubo-coccygeal parts.

The *ilio-coccygeus* arises from the ischial spine and from the posterior part of the pelvic fascia, and is attached to the coccyx and ano-coccygeal raphé: it is usually thin,

* *The Myology of the Pelvic Floor*, 1899.

and may fail entirely, or be largely replaced by fibrous tissue. An accessory slip at its posterior part is sometimes named the *ilio-sacralis*. The *pubo-coccygeus* arises from the back of the pubis and from the anterior part of the pelvic fascia, and 'is directed backwards almost horizontally along the side of the anal canal towards the coccyx and sacrum, to which it finds attachment. Between the termination of the vertebral column and the anus, the two pubo-coccygei muscles come together and form a thick, fibro-muscular layer lying on the raphé formed by the ilio-coccygei' (Thompson). The greater part of this muscle is inserted into the coccyx and into the last one or two pieces of the sacrum. This insertion into the vertebral column is, however, not admitted by all observers. The fibres which form a sling for the rectum are named the *pubo-rectalis* or *sphincter recti*. They arise from the lower part of the symphysis pubis, and from the upper layer of the triangular ligament. They meet with the corresponding fibres of the opposite side around the lower part of the rectum, and form for it a strong sling. The pre-anal fibres of the Levator ani form the Levator prostatæ muscle.

Nerve-supply.—A branch from the anterior division of the fourth sacral nerve and a branch from the pudic nerve, which is sometimes derived from the perineal, sometimes from the inferior hæmorrhoidal division.

Actions.—This muscle constricts the lower end of the rectum and vagina. It elevates and inverts the lower end of the rectum after it has been protruded and everted during the expulsion of the fæces. It is also a muscle of forced expiration.

The **Coccygeus** is situated behind and parallel with the preceding. It is a triangular plane of muscular and tendinous fibres, arising, by its apex, from the spine of the ischium and lesser sacro-sciatic ligament, and inserted, by its base, into the margin of the coccyx and into the side of the lower piece of the sacrum. It assists the Levator ani and Pyriformis in closing in the back part of the outlet of the pelvis.

Relations.—By its *inner* or *pelvic surface*, with the rectum. By its *external surface*, with the lesser sacro-sciatic ligament. The *lower border* is in relation with the posterior border of the Levator ani, but separated from it by a cellular interval: its *upper border* is in relation with the lower border of the Pyriformis, but separated from it by the sciatic and internal pudic vessels and nerve.

Nerve-supply.—A branch from the fourth and fifth sacral nerves.

Action.—The Coccygei muscles raise and support the coccyx, after it has been pressed backwards during defæcation or parturition.

2. A. Muscles and Fasciæ of the Perinæum in the Male

Transversus perinæi.	Erector penis.
Accelerator urinæ.	Compressor urethræ.

Superficial fascia.—The superficial fascia of the perinæum consists of two layers, superficial and deep, as in other regions of the body.

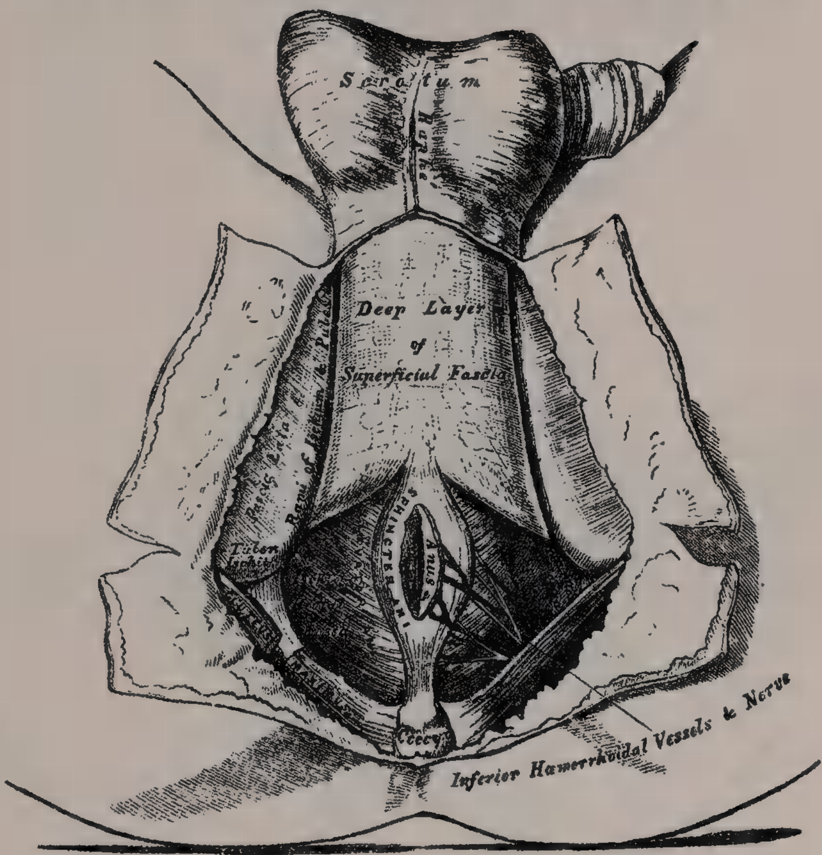
The *superficial layer* is thick, loose, areolar in texture, and contains much adipose tissue in its meshes, the amount of which varies in different subjects. In front, it is continuous with the dartos of the scrotum; behind, it is continuous with the subcutaneous areolar tissue surrounding the anus; and, on either side, with the same fascia on the inner side of the thighs. In the middle line, it is adherent to the skin of the raphé and to the deep layer of the superficial fascia. This layer should be carefully removed after it has been examined, when the deep layer will be exposed.

The *deep layer of superficial fascia* (Fascia of Colles) is thin, aponeurotic in structure, and of considerable strength, serving to bind down the muscles of the root of the penis. It is continuous, in front, with the dartos of the scrotum, the deep fascia of the penis, the fascia of the spermatic cord, and Scarpa's fascia upon the anterior wall of the abdomen; on either side it is firmly attached to the margins of the rami of the os pubis and ischium, external to the crus penis, and as far back as the tuberosity of the ischium; posteriorly, it curves round the Transversus perinæi muscles to join the lower margin of the triangular ligament. In the middle line, it is connected with the superficial fascia and the median septum of the Accelerator urinæ muscle. This fascia not only covers the muscles in this region, but sends upwards a vertical septum from its deep surface, which separates the back part of the subjacent space into two, the septum being incomplete in front.

The central tendinous point of the Perinæum.—This is a fibrous point in the middle line of the perinæum, between the urethra and the rectum, and about half an inch in front of the anus. At this point five muscles converge and are attached: viz. the External sphincter ani, the Accelerator urinæ, the two Transversi perinæi, and the anterior fibres of the Levator ani; so that by the contraction of these muscles, which extend in different directions, it serves as a fixed point of support.

The **Transversus perinæi** is a narrow muscular slip, which passes more or less transversely across the perineal space in front of the anus. It arises by tendinous fibres from the inner and fore part of the tuberosity of the ischium, and, passing inwards, is inserted into the central tendinous point of the perinæum, joining in this situation with the muscle of the opposite side, the External sphincter ani behind, and the Accelerator urinæ in front. In some cases, the fibres of the

Fig. 416.—The perinæum.
The integument and superficial layer of superficial fascia reflected.



deeper layer of the Sphincter ani decussate in front of the anus and are continued into this muscle. Occasionally it gives off fibres, which join with the Accelerator urinæ of the same side.

Nerve-supply.—The perineal branch of the internal pudic.

Actions.—The simultaneous contraction of the two muscles serves to fix the central tendinous point of the perinæum.

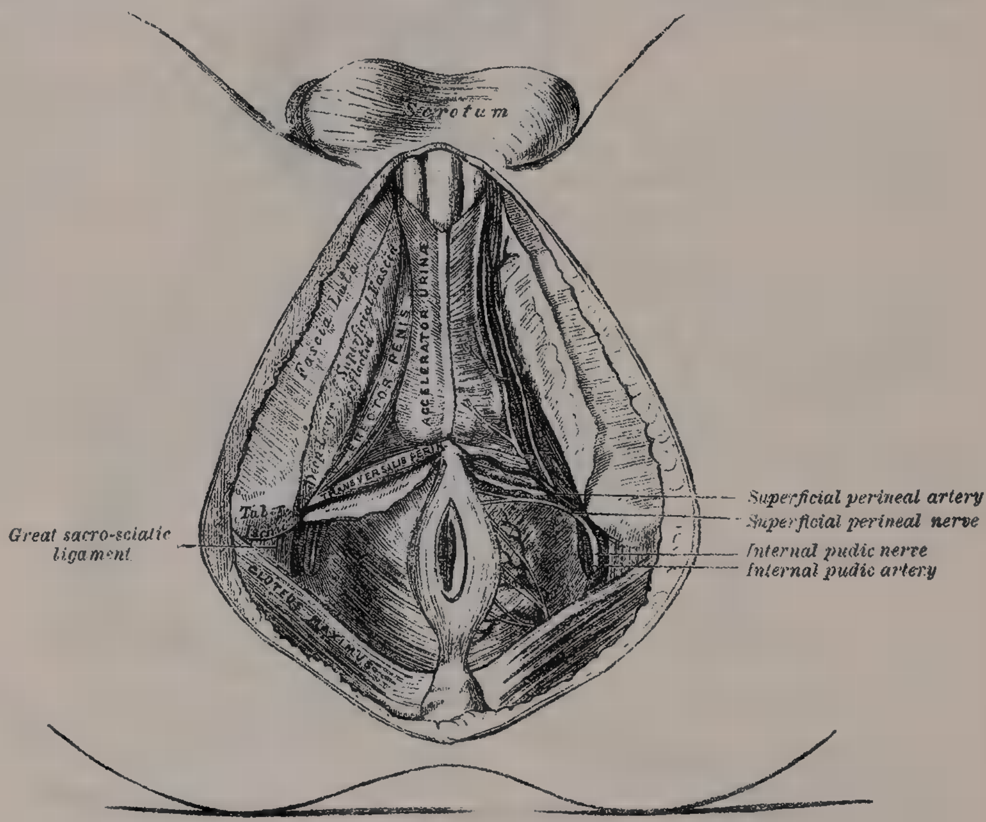
The **Accelerator urinæ** (*Bulbo-cavernosus*) is placed in the middle line of the perinæum, in front of the anus. It consists of two symmetrical halves, united along the median line by a tendinous raphé. It arises from the central tendon of the perinæum, and from the median raphé in front. From this point its fibres diverge like the plumes of a quill-pen; the most posterior form a thin layer, which is lost on the superficial surface of the triangular ligament; the middle fibres encircle the bulb and adjacent parts of the corpus spongiosum, and join with the fibres of the opposite side, on the upper part of the corpus spongiosum, in a strong aponeurosis; the anterior fibres, the longest and most distinct, spread out over the sides of the corpus cavernosum, to be inserted partly into that body, anterior to the Erector penis, and occasionally extending to the os pubis; and partly

terminating in a tendinous expansion, which covers the dorsal vessels of the penis. The latter fibres are best seen by dividing the muscle longitudinally, and dissecting it outwards from the surface of the urethra.

Actions.—This muscle serves to empty the canal of the urethra, after the bladder has expelled its contents; during the greater part of the act of micturition its fibres are relaxed, and it only comes into action at the end of the process. The middle fibres are supposed, by Krause, to assist in the erection of the corpus spongiosum, by compressing the erectile tissue of the bulb. The anterior fibres, according to Tyrrel, also contribute to the erection of the penis, as they are inserted into, and continuous with, the fascia of the penis, compressing the dorsal vein during the contraction of the muscle.

The **Erector penis** (*Ischio-cavernosus*) covers the crus penis. It is an elongated muscle, broader in the middle than at either extremity, and situated on either side of the lateral boundary of the perinæum. It arises by tendinous and fleshy fibres from the inner surface of the tuberosity of the ischium, behind

FIG. 417.—The superficial muscles and vessels of the perinæum.



the crus penis; and from the rami of the pubis and ischium on each side of the crus. From these points fleshy fibres succeed, which end in an aponeurosis which is inserted into the sides and under surface of the crus penis.

Nerve-supply.—The perineal branch of the internal pudic.

Action.—The Erector penis compresses the crus penis, and retards the return of the blood through the veins, and thus serves to maintain the organ erect.

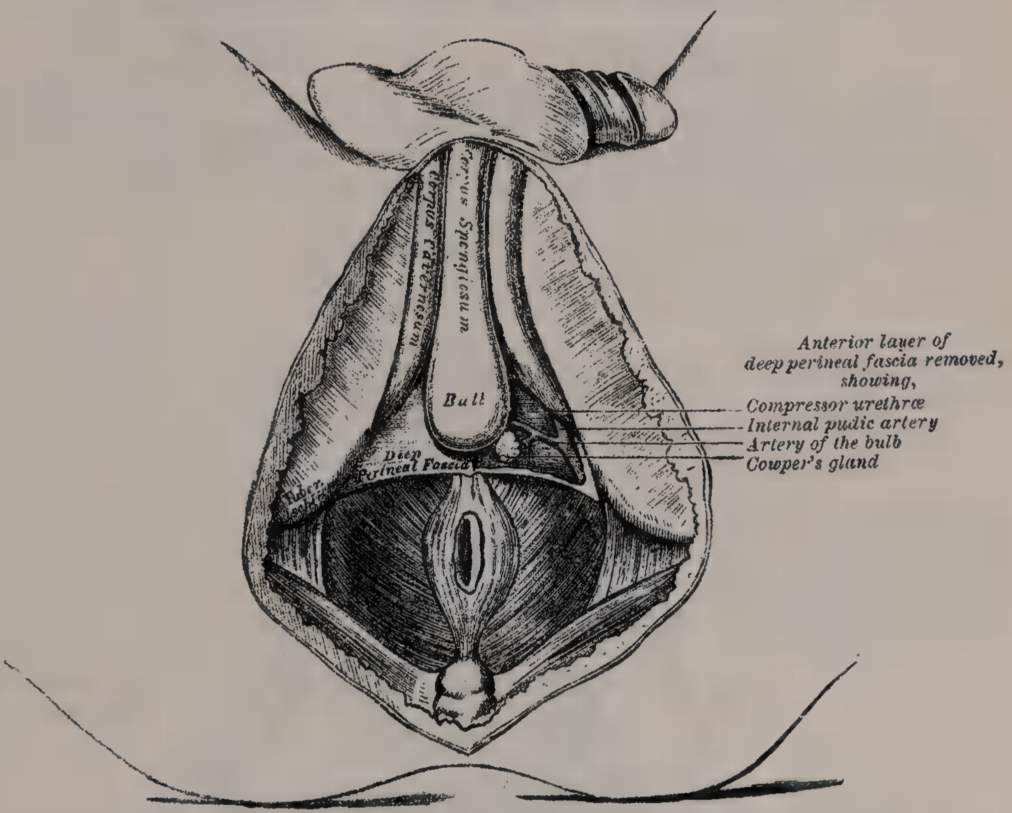
Between the muscles just examined a triangular space exists, bounded internally by the Accelerator urinæ, externally by the Erector penis, and behind by the Transversus perinæi. The floor of this space is formed by the triangular ligament of the urethra (deep perineal fascia), and running from behind forwards in it are the superficial perineal vessels and nerves, and the long pudendal nerve. The transverse perineal artery courses along the posterior boundary of the space on the Transversus perinæi muscle.

The **triangular ligament of the urethra** (*deep perineal fascia*) is stretched almost horizontally across the pubic arch, so as to close in the front part of the outlet of the pelvis. It consists of two dense membranous laminæ, which are united along their posterior borders, but are separated in front by intervening

structures. The superficial of these two layers, the *inferior layer of the triangular ligament*, is triangular in shape, about an inch and a half in depth. Its apex is directed forwards, and is separated from the subpubic ligament by an oval opening for the transmission of the dorsal vein of the penis. Its lateral margins are attached on each side to the rami of the os pubis and ischium, above the crura penis. Its base is directed towards the rectum, and connected to the central tendinous point of the perinæum. It is continuous with the deep layer of the superficial fascia behind the Transversus perinæi muscle, and with a thin fascia which covers the cutaneous surface of the Levator ani muscle (*anal fascia*).

This layer of the triangular ligament is perforated, about an inch below the symphysis pubis, by the urethra, the aperture for which is circular in form and about three or four lines in diameter; by the arteries to the bulb and the ducts of Cowper's glands close to the urethral orifice; by the arteries to the corpora cavernosa—one on each side close to the pubic arch and about halfway along

FIG. 418.—Triangular ligament or deep perineal fascia.
On the left side the superficial layer has been removed.



the attached margin of the ligament; by the dorsal arteries and nerves of the penis near the apex of the ligament. Its base is also perforated by the superficial perineal vessels and nerves, while between its apex and the subpubic ligament the dorsal vein of the penis passes upwards into the pelvis.

If the superficial or inferior layer of the triangular ligament is detached on either side, the following structures will be seen between it and the deep layer: the dorsal vein of the penis; the membranous portion of the urethra, and the Compressor urethræ muscle; Cowper's glands and their ducts; the pudic vessels and dorsal nerve of penis; the artery and nerve of the bulb, and a plexus of veins.

The deep layer of the ligament (*superior layer of the triangular ligament*) is derived from the obturator fascia and stretches across the pubic arch. If the obturator fascia is traced inwards after covering the Obturator internus muscle, it will be found to be attached by some of its deeper or anterior fibres to the inner margin of the ischio-pubic ramus, while its superficial or posterior fibres pass over this attachment to form the superior layer of the triangular ligament. Behind, this layer of the fascia is continuous with the inferior layer and with the

fascia of Colles, and in front it is continuous with the recto-vesical fascia on the prostate gland. It is pierced by the urethra, or rather consists of two halves which are separated in the middle line by the urethra passing between them.

The **Compressor urethræ** (*Constrictor urethræ*) surrounds the whole length of the membranous portion of the urethra, and is contained between the two layers of the triangular ligament. It arises, by aponeurotic fibres, from the junction of the rami of the os pubis and ischium, to the extent of half or three-quarters of an inch: each segment of the muscle passes inwards, and divides into two fasciculi, which surround the urethra from the prostate gland behind, to the bulbous portion of the urethra in front; and unite, at the upper and lower surfaces of this tube, with the muscle of the opposite side, by means of a tendinous raphé.

Nerve-supply.—The perineal branch of the internal pudic.

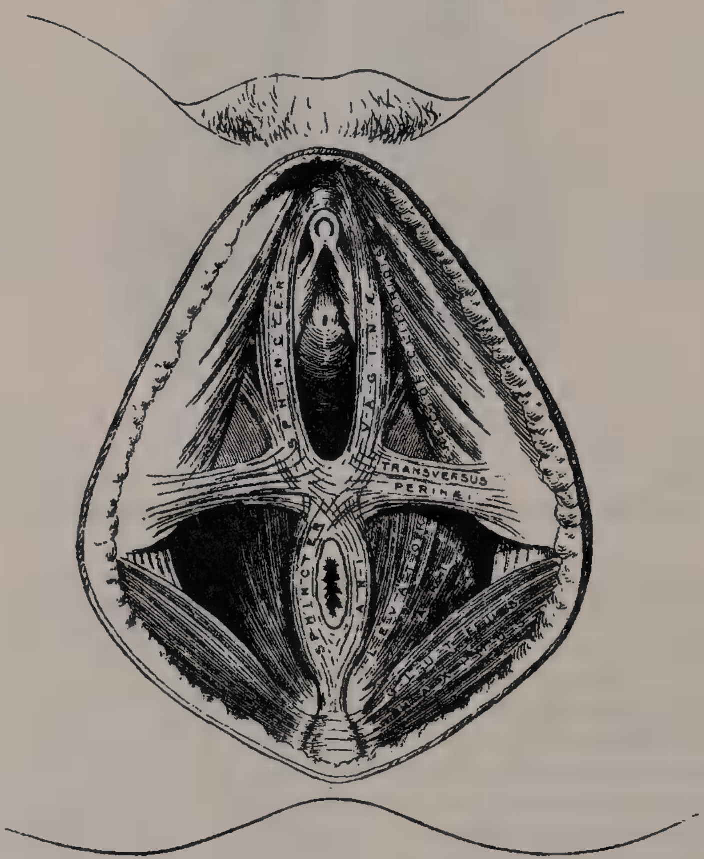
Actions.—The muscles of both sides act together as a sphincter, compressing the membranous portion of the urethra. During the transmission of fluids they, like the Acceleratores urinæ, are relaxed, and only come into action at the end of the process to eject the last drops of the fluid.

2. B. Muscles of the Perinæum in the Female (fig. 419)

Transversus perinæi.	Erector clitoridis.
Sphincter vaginæ.	Compressor urethræ.

The **Transversus perinæi** in the **female** is a narrow muscular slip, which passes more or less transversely across the back part of the perineal space. It arises by a small tendon from the inner and fore part of the tuberosity of the ischium, and,

Fig. 419.—Muscles of the female perinæum.



passing inwards, is inserted into the central point of the perinæum, joining in this situation with the muscle of the opposite side, the External sphincter ani behind, and the Sphincter vaginæ in front.

Nerve-supply.—The perineal branch of the internal pudic.

Action.—The simultaneous contraction of the two muscles serves to fix the central tendinous point of the perinæum.

The **Sphincter vaginæ** surrounds the orifice of the vagina, and is analogous to the Accelerator urinæ in the male. It covers the outer aspect of the vestibular bulbs, and is attached posteriorly to the central tendinous point of the perinæum, where it blends with the External sphincter ani. Its fibres pass forwards on each side of the vagina, to be inserted into the corpora cavernosa of the clitoris, a fasciculus crossing over the body of the organ so as to compress the dorsal vein.

Nerve-supply.—The perineal branch of the internal pudic.

Actions.—The Sphincter vaginæ diminishes the orifice of the vagina. The anterior fibres contribute to the erection of the clitoris, as they are inserted into and are continuous with the fascia of the clitoris, compressing the dorsal vein during the contraction of the muscle.

The **Erector clitoridis** (*Ischio-cavernosus*) corresponds with the Erector penis in the male, but is smaller. It covers the unattached surface of the crus clitoridis. It is an elongated muscle, broader at the middle than at either extremity, and situated on either side of the lateral boundary of the perinæum. It arises by tendinous and fleshy fibres from the inner surface of the tuberosity of the ischium, behind the crus clitoridis; from the surface of the crus; and from the adjacent portion of the ramus of the ischium. From these points fleshy fibres succeed, and end in an aponeurosis, which is inserted into the sides and under surface of the crus clitoridis.

Nerve-supply.—The perineal branch of the internal pudic.

Actions.—The Erector clitoridis compresses the crus clitoridis and retards the return of blood through the veins, and thus serves to maintain the organ erect.

The **triangular ligament** (*deep perineal fascia*) in the female is not so strong as in the male. It is attached to the pubic arch, its apex being connected with the subpubic ligament. It is divided in the middle line by the aperture of the vagina, with the external coat of which it becomes blended, and in front of this is perforated by the urethra. Its posterior border is continuous, as in the male, with the deep layer of the superficial fascia around the Transversus perinæi muscle.

Like the triangular ligament in the male it consists of two layers, between which are to be found the following structures: the dorsal vein of the clitoris, a portion of the urethra and the Compressor urethræ muscle, the glands of Bartholin and their ducts; the pudic vessels and the dorsal nerve of the clitoris; the arteries of the bulbi vestibuli, and a plexus of veins.

The **Compressor urethræ** (*Constrictor urethræ*) arises on each side from the margin of the descending ramus of the os pubis. The fibres, passing inwards, divide into two sets: those of the fore part of the muscle are directed across the subpubic arch in front of the urethra to blend with the muscular fibres of the opposite side; while those of the hinder and larger part pass inwards to blend with the wall of the vagina behind the urethra.

Nerve-supply.—The perineal branch of the internal pudic.

MUSCLES AND FASCIÆ OF THE UPPER EXTREMITY

The Muscles of the Upper Extremity are divisible into groups, corresponding with the different regions of the limb.

I. Of the Thoracic Region

1. *Anterior Thoracic Region*

Pectoralis major. Pectoralis minor.
Subclavius.

2. *Lateral Thoracic Region*

Serratus magnus.

II. Of the Shoulder and Arm

3. *Acromial Region*

Deltoid.

4. *Anterior Scapular Region*

Subscapularis.

5. *Posterior Scapular Region*

Supraspinatus. Teres minor.
Infraspinatus. Teres major.

6. *Anterior Humeral Region*

Coraco-brachialis. Biceps.
Brachialis anticus.

7. *Posterior Humeral Region*

Triceps. Subanconeus.

III. Of the Forearm

8. *Anterior Radio-ulnar Region*

Superficial Layer.
- Pronator radii teres.
- Flexor carpi radialis.
- Palmaris longus.
- Flexor carpi ulnaris.
- Flexor sublimis digitorum.

Deep Layer.
- Flexor profundus digitorum.
- Flexor longus pollicis.
- Pronator quadratus.

9. *Radial Region*

Supinator longus (Brachio-radialis).
Extensor carpi radialis longior.
Extensor carpi radialis brevior.

10. *Posterior Radio-ulnar Region*

Superficial Layer.
- Extensor communis digitorum.
- Extensor minimi digiti.
- Extensor carpi ulnaris.
- Anconeus.

Deep Layer.
- Supinator brevis.
- Extensor ossis metacarpi pollicis.
- Extensor brevis pollicis.
- Extensor longus pollicis.
- Extensor indicis.

IV. Of the Hand

11. *Radial Region*

Abductor pollicis.
Opponens pollicis.
Flexor brevis pollicis.
Adductor obliquus pollicis.
Adductor transversus pollicis.

12. *Ulnar Region*

Palmaris brevis.
Abductor minimi digiti.
Flexor brevis minimi digiti.
Opponens minimi digiti.

13. *Middle Palmar Region*

Lumbricales. Interossei palmares.
Interossei dorsales.

Dissection of Pectoral Region and Axilla (fig. 420).—The arm being drawn away from the side nearly at right angles with the trunk, and rotated outwards, make a vertical incision through the integument in the median line of the chest, from the upper to the lower part of the sternum; a second incision along the lower border of the Pectoral muscle, from the ensiform cartilage to the inner side of the axilla; a third, from the sternum along the clavicle, as far as its centre; and a fourth, from the middle of the clavicle obliquely downwards, along the interspace between the Pectoral and Deltoid muscles, as low as the fold of the armpit. The flap of integument is then to be dissected off in the direction indicated in the figure, but not entirely removed, as it should be replaced on completing the dissection. If a transverse incision is now made from the lower end of the sternum to the side of the chest, as far as the posterior fold of the armpit, and the integument reflected outwards, the axillary space will be more completely exposed.

I. Muscles and Fasciæ of the Thoracic Region

1. *Anterior Thoracic Region*

Pectoralis major. Pectoralis minor.
Subclavius.

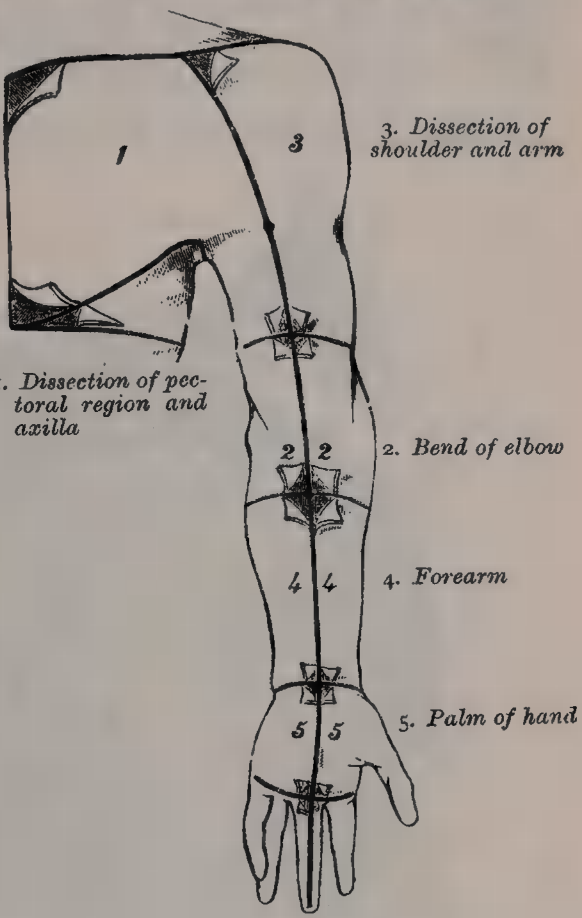
The **superficial fascia** of the thoracic region is a loose cellulo-fibrous layer, enclosing masses of fat in its spaces. It is continuous with the superficial fascia of the neck and upper extremity above, and of the abdomen below. Opposite the mamma, it divides into two layers, one of which passes in front, the other behind that gland; and from both of these layers numerous septa pass into its substance, supporting its various lobes: from the anterior layer, fibrous processes pass orwards to the integument and nipple. These processes were called by Sir A. Cooper the *ligamenta suspensoria*, from the support they afford to the gland in this situation.

The **deep fascia** of the thoracic region is a thin aponeurotic lamina, covering the surface of the great Pectoral muscle, and sending numerous prolongations between its fasciculi: it is attached, in the middle line, to the front of the sternum; and, above, to the clavicle; externally and below it becomes continuous with the fascia over the shoulder, axilla, and thorax. It is very thin over the upper part of the muscle, thicker in the interval between the Pectoralis major and Latissimus dorsi, where it closes in the axillary space, and divides at the outer margin of the latter muscle into two layers, one of which passes in front, and the other behind it; these proceed as far as the spinous processes of the dorsal

vertebræ, to which they are attached. As the fascia leaves the lower edge of the Pectoralis major to pass across the floor of the axilla it sends a layer upwards under cover of the muscle: this lamina splits to envelop the Pectoralis minor, at the upper edge of which it becomes continuous with the costo-coracoid membrane. The hollow of the armpit, seen when the arm is abducted, is mainly produced by the traction of this fascia on the axillary floor, and hence it is sometimes named the *suspensory ligament* of the axilla. At the lower part of the thoracic region the deep fascia is well developed, and is continuous with the fibrous sheath of the Recti muscles.

Surgical Anatomy.—The axillary fascia prevents the extension of the pus, in cases of suppuration in the axilla, in a downward direction, and the matter has a tendency to spread upwards, beneath the Pectoral muscles, towards the root of the neck. Early evacuation is therefore necessary. The incision should be made midway between the anterior and posterior axillary folds, so as to avoid the long thoracic and subscapular vessels.

FIG. 420.—Dissection of upper extremity.



The **Pectoralis major** (fig. 421) is a broad, thick, triangular muscle, situated at the upper and fore part of the chest and in front of the axilla. It arises from the anterior surface of the sternal half of the clavicle; from half the breadth of the anterior surface of the sternum, as low down as the attachment of the cartilage of the sixth or seventh rib; this portion of its origin consists of aponeurotic fibres, which intersect those of the opposite muscle; it also arises from the cartilages of all the true ribs, with the exception, frequently, of the first, or of the seventh, or both; and from the aponeurosis of the External oblique muscle of the abdomen. The fibres from this extensive origin converge towards its insertion, giving to the muscle a radiated appearance. Those fibres which arise from the clavicle pass obliquely outwards and downwards, and are usually separated from the rest by a slight interval: those from the lower part of the sternum, and the cartilages of the lower true ribs, pass upwards and outwards; while the middle fibres pass horizontally. They all terminate in a flat tendon, about two inches broad, which is inserted into the outer bicipital ridge of the humerus. This tendon consists of two laminæ, placed one in front of the other, and usually blended together below. The anterior, the thicker, receives the clavicular and upper half of the sternal portion of the muscle; and its fibres are inserted in the same order as that in which they arise: that is to say, the outermost fibres of origin from the clavicle are inserted at the uppermost part of the bicipital ridge; the upper fibres of origin from the sternum pass down to the lowermost part of this anterior lamina of the tendon and extend as low as the tendon of the Deltoid and join with it. The posterior lamina of the tendon receives the attachment of the lower half of the sternal portion and the deeper part of the muscle from the costal cartilages. These deep fibres, and particularly those from the lower costal cartilages, ascend the higher, turning backwards successively behind the superficial and upper ones, so that the tendon appears to be twisted. The posterior lamina reaches higher on the humerus than the anterior one, and from it an expansion is given off which covers the bicipital groove and blends with the capsule of the shoulder-joint. From the deepest fibres of this lamina at its

insertion an expansion is given off which lines the bicipital groove of the humerus, while from the lower border of the tendon a third expansion passes downwards to the fascia of the arm.

Relations.—By its *anterior surface*, with the integument, the superficial fascia, the Platysma, some of the branches of the descending cervical nerves, the mammary gland, and the deep fascia. By its *posterior surface*: its *thoracic portion*, with the sternum, the ribs and costal cartilages, the costo-coracoid membrane, the Subclavius, Pectoralis minor, Serratus magnus, and the Intercostals; its *axillary portion* forms the anterior wall of the axillary space, and

Fig. 421.—Muscles of the chest and front of the arm. Superficial view.

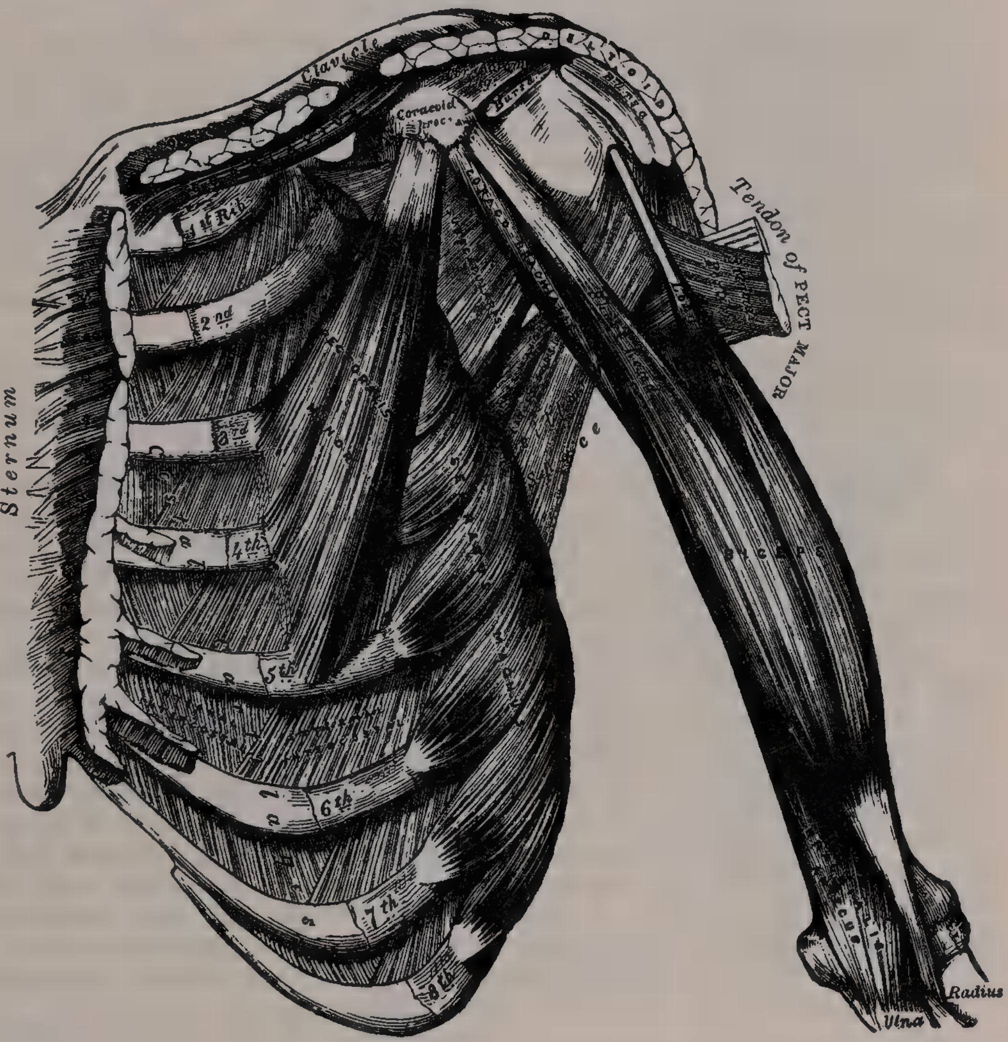
covers the axillary vessels and nerves, the Biceps and Coraco-brachialis muscles. Its *upper border* lies parallel with the Deltoid, from which it is separated by a slight interspace in which lie the cephalic vein and humeral branch of the acromio-thoracic artery. Its *lower border* forms the anterior margin of the axilla, being at first separated from the Latissimus dorsi by a considerable interval; but both muscles gradually converge towards the outer part of the space.

Dissection.—Detach the Pectoralis major by dividing the muscle along its attachment to the clavicle, and by making a vertical incision through its substance a little external to

its line of attachment to the sternum and costal cartilages. The muscle should then be reflected outwards, and its tendon carefully examined. The Pectoralis minor is now exposed, and immediately above it, in the interval between its upper border and the clavicle, a strong fascia, the *costo-coracoid membrane.*

The **costo-coracoid membrane** is a strong fascia, situated under cover of the clavicular portion of the Pectoralis major muscle. It occupies the interval between the Pectoralis minor and Subclavius muscles, and protects the axillary vessels and nerves. Traced upwards, it splits to enclose the Subclavius muscle, and its two layers are attached to the clavicle, one in front of and the other behind the muscle; the latter layer fuses with the deep cervical fascia and with the sheath of the axillary vessels. Internally, it blends with the fascia covering

FIG. 422.—Muscles of the chest and front of the arm, with the boundaries of the axilla.



the first two intercostal spaces, and is attached also to the first rib internal to the origin of the Subclavius muscle. Externally, it is very thick and dense, and is attached to the coracoid process. The portion extending from its attachment to the first rib to the coracoid process is often whiter and denser than the rest; this is sometimes called the *costo-coracoid ligament*. Below this, it is thin, and at the upper border of the Pectoralis minor it splits into two layers to invest the muscle; from the lower border of the Pectoralis minor it is continued downwards to join the axillary fascia, and outwards to join the fascia over the short head of the Biceps. The costo-coracoid membrane is pierced by the cephalic vein, the acromio-thoracic artery and vein, superior thoracic artery, and external anterior thoracic nerve.

The **Pectoralis minor** (fig. 422) is a thin, flat, triangular muscle, situated at the upper part of the thorax, beneath the Pectoralis major. It arises by three

tendinous digitations, from the upper margin and outer surface of the third, fourth, and fifth ribs, near their cartilages, and from the aponeurosis covering the Intercostal muscles; the fibres pass upwards and outwards, and converge to form a flat tendon, which is inserted into the inner border and upper surface of the coracoid process of the scapula.

Relations.—By its *anterior surface,* with the Pectoralis major, the external anterior thoracic nerve, and the thoracic branches of the acromio-thoracic artery. By its *posterior surface,* with the ribs, Intercostal muscles, Serratus magnus, the axillary space, and the axillary vessels and brachial plexus of nerves. Its upper border is separated from the clavicle by a narrow triangular interval which is occupied by the costo-coracoid membrane. In this space are the first part of the axillary vessels and nerves. Running parallel to the lower border of the muscle is the long thoracic artery.

The costo-coracoid membrane should now be removed, when the Subclavius muscle will be seen.

The **Subclavius** is a small triangular muscle, placed in the interval between the clavicle and the first rib. It arises by a short, thick tendon from the first rib and its cartilage at their junction, in front of the rhomboid ligament; the fleshy fibres proceed obliquely upwards and outwards, to be inserted into the groove on the under surface of the clavicle between the rhomboid and conoid ligaments.

Relations.—By its *upper surface,* with the clavicle. By its *deep surface,* it is separated from the first rib by the subclavian vessels and brachial plexus of nerves. Its *anterior surface* is separated from the Pectoralis major by the costo-coracoid membrane, which, with the clavicle, forms an osseo-fibrous sheath in which the muscle is enclosed.

If the costal attachment of the Pectoralis minor is divided across, and the muscle reflected outwards, the axillary vessels and nerves are brought fully into view, and should be examined.

Nerves.—The Pectoralis major is supplied by the external and internal anterior thoracic nerves; through these nerves the muscle receives filaments from all the spinal nerves entering into the formation of the brachial plexus; the Pectoralis minor receives its fibres from the eighth cervical and first dorsal nerves through the internal anterior thoracic nerve. The Subclavius is supplied by a filament derived from the fifth and sixth cervical nerves.

Actions.—If the arm has been raised by the Deltoid, the Pectoralis major will, conjointly with the Latissimus dorsi and Teres major, depress it to the side of the chest. If acting alone, it adducts and draws forwards the arm, bringing it across the front of the chest, and at the same time rotates it inwards. The Pectoralis minor depresses the point of the shoulder, drawing the scapula downwards and inwards to the thorax, and throwing the inferior angle backwards. The Subclavius depresses the shoulder, drawing the clavicle downwards and forwards. When the arms are fixed, all three muscles act upon the ribs, drawing them upwards and expanding the chest, and thus becoming very important agents in forced inspiration. Asthmatic patients always assume an attitude which fixes the shoulders, so that all these muscles may be brought into action to assist in dilating the cavity of the chest.

2. *Lateral Thoracic Region*

Serratus magnus.

The **Serratus magnus** (fig. 423) is a thin, irregularly quadrilateral muscle, situated between the ribs and the scapula at the upper and lateral part of the chest. It arises by fleshy digitations from the outer surfaces and upper borders of the eight or nine upper ribs, and from the aponeurosis covering the intercostal muscles between them. Each digitation (except the first) arises from the corresponding rib; the first digitation arises from the first and second ribs, and from the fascia covering the first intercostal space. From this extensive attachment the fibres pass backwards, closely applied to the chest-wall, and reach the vertebral border of the scapula, and are inserted into its ventral aspect in the following manner. The first digitation, arising from the first and second

ribs, is inserted into a triangular area on the ventral aspect of the superior angle. The next two digitations (i.e. from the second and third ribs) spread out to form a thin triangular sheet, the base of which is directed backwards and is inserted into nearly the whole length of the ventral aspect of the vertebral border. The lower five or six digitations converge to form a fan-shaped mass, the apex of which is inserted, by muscular and by tendinous fibres, into a triangular impression on the ventral aspect of the inferior angle. The lower four slips interdigitate at their origin with the upper five slips of the External oblique muscle of the abdomen.

Fig. 423.—Serratus magnus. (From a preparation in the Museum of the Royal College of Surgeons of England.)

Relations. — This muscle is partly covered, in front, by the Pectoral muscles and by the mammary gland; behind, by the Subscapularis. The axillary vessels and nerves lie upon its upper part, while its *deep surface* rests upon the ribs and Intercostal muscles.

Nerve.—The Serratus magnus is supplied by the posterior thoracic nerve, which is derived from the fifth, sixth, and seventh cervical nerves.

Actions.—The Serratus magnus, as a whole, carries the scapula forwards, and at the same time raises the vertebral border of the bone. It is therefore concerned in the action of pushing. Its lower and stronger fibres move forwards the lower angle and assist the Trapezius in rotating the bone at the sterno-clavicular joint, and thus assist this muscle in raising the acromion and supporting weights upon the shoulder. It is also an assistant to the Deltoid in raising the arm, inasmuch as during the action of this latter muscle it fixes the scapula and so steadies the glenoid cavity on which the head of the humerus rotates. After the Deltoid has raised the arm to a right angle with the trunk, the Serratus magnus and the Trapezius, by rotating the scapula, raise the arm into an almost vertical position. It is possible that when the shoulders are fixed the lower fibres of the Serratus magnus may assist in raising and everting the ribs; but it is not the important inspiratory muscle which it was formerly believed to be.

Surgical Anatomy.—When the muscle is paralysed, the vertebral border, and especially the lower angle of the scapula, leave the ribs and stand out prominently on the surface, giving a peculiar 'winged' appearance to the back. The patient is unable to raise the arm, and an attempt to do so is followed by a further projection of the lower angle of the scapula from the back of the thorax.

Dissection.—After completing the dissection of the axilla, if the muscles of the back have been dissected, the upper extremity should be separated from the trunk. Saw through the clavicle at its centre, and then cut through the muscles which connect the scapula and arm with the trunk, viz. the Pectoralis minor in front, Serratus magnus at the side, and the Levator anguli scapulæ, the Rhomboids, Trapezius, and Latissimus dorsi behind. These muscles should be cleaned and traced to their respective insertions. Then make an incision through the integument, commencing at the outer third of the clavicle, and extending along the margin of that bone, the acromion process, and spine of the scapula; the integument should be dissected from above downwards and outwards, when the fascia covering the Deltoid is exposed (fig. 420, 3).

II. Muscles and Fasciæ of the Shoulder and Arm

The **superficial fascia** of the upper extremity is a thin fibro-cellular layer, containing the superficial veins and lymphatics, and the cutaneous nerves. It is most distinct in front of the elbow, where it contains very large superficial veins and nerves; in the hand it is hardly demonstrable, the integument being closely adherent to the deep fascia by dense fibrous bands. Subcutaneous bursæ are found in this fascia over the acromion, the olecranon, and the knuckles.

The deep fascia of the upper extremity comprises the aponeurosis of the shoulder, arm, and forearm, the anterior and posterior annular ligaments of the carpus, and the palmar fascia. These will be considered in the description of the muscles of the several regions.

3. *Acromial Region*

Deltoid.

The **deep fascia** covering the Deltoid (deltoid aponeurosis) is a fibrous layer, which covers the outer surface of the muscle, thick and strong behind, where it is continuous with the Infraspinatus fascia, thinner over the rest of its extent. It sends numerous prolongations between the fasciculi of the muscle. In front, it is continuous with the fascia covering the great Pectoral muscle; behind, with that covering the Infraspinatus; above, it is attached to the clavicle, the acromion, and spine of the scapula; below, it is continuous with the deep fascia of the arm.

The **Deltoid** (fig. 421) is a large, thick, triangular muscle, which gives the rounded outline to the shoulder, and has received its name from its resemblance to the Greek letter Δ reversed. It covers the shoulder-joint in front, behind, and on its outer side. It arises from the outer third of the anterior border and upper surface of the clavicle; from the outer margin and upper surface of the acromion process; and from the lower lip of the posterior border of the spine of the scapula, as far back as the triangular surface at its inner end. From this extensive origin the fibres converge towards their insertion, the middle passing vertically, the anterior obliquely backwards, the posterior obliquely forwards; they unite to form a thick tendon, which is inserted into a rough triangular prominence on the middle of the outer side of the shaft of the humerus. At its insertion the muscle gives off an expansion to the deep fascia of the arm. This muscle is remarkably coarse in texture, and the arrangement of its muscular fibres is somewhat peculiar; the central portion of the muscle—that is to say, the part arising from the acromion process—consists of oblique fibres, which arise in a bipenniform manner from the sides of tendinous intersections, generally four in number, which are attached above to the acromion process and pass downwards parallel to one another in the substance of the muscle. The oblique muscular fibres thus formed are inserted into similar tendinous intersections, generally three in number, which pass upwards from the insertion of the muscle into the humerus and alternate with the descending septa. The portions of the muscle which arise from the clavicle and spine of the scapula are not arranged in this manner, but pass from their origin above, to be inserted into the margins of the inferior tendon.

Relations.—By its *superficial surface*, with the integument, the superficial and deep fasciæ, Platysma, and supra-acromial nerves. Its *deep surface* is separated from the capsule of the shoulder-joint by a large synovial bursa, and covers the coracoid process, coraco-acromial ligament, Pectoralis minor, Coraco-brachialis, both heads of the Biceps, the tendon of the Pectoralis major, the insertions of the Supraspinatus, Infraspinatus, and Teres minor, the scapular and external heads of the Triceps, the circumflex vessels and nerve, and the upper part of the shaft of the humerus. Its *anterior border* is separated at its upper part from the Pectoralis major by a cellular interspace, which lodges the cephalic vein and humeral branch of the acromio-thoracic artery: lower down the two muscles are in close contact. Its *posterior border* rests on the Infraspinatus and Triceps muscles.

Nerves.—The Deltoid is supplied by the fifth and sixth cervical through the circumflex nerve.

Actions.—The Deltoid raises the arm directly from the side, so as to bring it

at right angles with the trunk. Its anterior fibres, assisted by the Pectoralis major, draw the arm forwards; and its posterior fibres, aided by the Teres major and Latissimus dorsi, draw it backwards.

Surgical Anatomy.—The Deltoid is very liable to atrophy, and when in this condition simulates dislocation of the shoulder-joint, as there is flattening of the shoulder and apparent prominence of the acromion process; the distance also between the acromion process and the head of the bone is increased, and the tips of the fingers can be inserted between them. Atrophy of the Deltoid may be due to disuse or loss of trophic influence, either from injury to the circumflex nerve or cord lesions, as in infantile paralysis.

Dissection.—Divide the Deltoid across, near its upper part, by an incision carried along the margin of the clavicle, the acromion process, and spine of the scapula, and reflect it downwards, when the structures under cover of it will be seen.

4. *Anterior Scapular Region*

Subscapularis.

The **subscapular fascia** is a thin membrane attached to the entire circumference of the subscapular fossa, and affording attachment by its inner surface to some of the fibres of the Subscapularis muscle: when this is removed, the Subscapularis muscle is exposed.

The **Subscapularis** (fig. 422) is a large triangular muscle, which fills up the subscapular fossa, arising from its internal two-thirds, with the exception of a narrow margin along the posterior border, and the surfaces at the superior and inferior angles which afford attachment to the Serratus magnus: it also arises from the lower two-thirds of the groove on the axillary border of the bone. Some fibres arise from tendinous laminæ, which intersect the muscle, and are attached to ridges on the bone; and others from an aponeurosis, which separates the muscle from the Teres major and the long head of the Triceps. The fibres pass outwards, and, gradually converging, terminate in a tendon, which is inserted into the lesser tuberosity of the humerus and the front of the capsular ligament of the shoulder-joint. The tendon of the muscle is separated from the neck of the scapula and anterior part of the capsular ligament of the shoulder-joint by a large bursa, which communicates with the cavity of the joint by an aperture in the capsular ligament.

Relations.—The *anterior surface* of this muscle forms a considerable part of the posterior wall of the axilla, and is in relation with the Serratus magnus, Coraco-brachialis, and Biceps, the axillary vessels and brachial plexus of nerves, and the subscapular vessels and nerves. Its *posterior surface* is in relation with the scapula and the capsular ligament of the shoulder-joint. Its *lower border* is contiguous with the Teres major and Latissimus dorsi.

Nerves.—The Subscapularis is supplied by the fifth and sixth cervical nerves through the upper and lower subscapular nerves.

Actions.—The Subscapularis rotates the head of the humerus inwards; when the arm is raised, it draws the humerus forwards and downwards. It is a powerful defence to the front of the shoulder-joint, preventing displacement of the head of the bone.

5. *Posterior Scapular Region* (fig. 424)

Supraspinatus.	Teres minor.
Infraspinatus.	Teres major.

Dissection.—To expose these muscles, and to examine their mode of insertion into the humerus, detach the Deltoid and Trapezius from their attachment to the spine of the scapula and acromion process. Remove the clavicle by dividing the ligaments connecting it with the coracoid process, and separate it at its articulation with the scapula: divide the acromion process near its root with a saw. The fragments being removed, the tendons of the posterior Scapular muscles will be fully exposed, and can be examined. A block should be placed beneath the shoulder-joint, so as to make the muscles tense.

The **supraspinous fascia** is a thick and dense membranous layer, which completes the osseo-fibrous case in which the Supraspinatus muscle is contained; affording attachment, by its deep surface, to some of the fibres of the muscle. It is thick internally, but thinner externally under the coraco-acromial ligament. When this fascia is removed, the Supraspinatus muscle is exposed.

The **Supraspinatus muscle** occupies the whole of the supraspinous fossa, arising from its internal two-thirds, and from the strong fascia which covers its surface. The muscular fibres converge to a tendon, which passes across the upper part of the capsular ligament of the shoulder-joint, to which it is intimately adherent, and is inserted into the highest of the three impressions on the great tuberosity of the humerus.

Relations.—By its *upper surface*, with the Trapezius, the clavicle, the acromion, the coraco-acromial ligament, and the Deltoid. By its *under surface*, with the scapula, the suprascapular vessels and nerve, and upper part of the shoulder-joint.

The **infraspinous fascia** is a dense fibrous membrane, covering in the Infraspinatus muscle and fixed to the circumference of the infraspinous fossa; it affords attachment, by its inner surface, to some fibres of that muscle. At the

FIG. 424.—Muscles on the dorsum of the scapula and the Triceps.

point where the Infraspinatus commences to be covered by the Deltoid, this fascia divides into two layers: one layer passes over the Deltoid muscle, helping to form the Deltoid fascia already described; the other passes beneath the Deltoid to the shoulder-joint.

The **Infraspinatus** is a thick triangular muscle, which occupies the chief part of the infraspinous fossa, arising by fleshy fibres from its internal two-thirds; and by tendinous fibres from the ridges on its surface: it also arises from a strong fascia which covers it externally, and separates it from the Teres major and minor. The fibres converge to a tendon, which glides over the external border of the spine of the scapula, and, passing across the posterior part of the capsular ligament of the shoulder-joint, is inserted into the middle impression on the great tuberosity of the humerus. The tendon of this muscle is sometimes separated from the capsule of the shoulder-joint by a synovial bursa, which may communicate with the joint cavity.

Relations.—By its *posterior surface*, with the Deltoid, the Trapezius, Latissimus dorsi, and the integument. By its *anterior surface*, with the scapula, the suprascapular nerve, the suprascapular and dorsalis scapulæ vessels, and the capsular ligament of the shoulder-joint. Its *lower border* is in contact with the Teres major and minor, and is occasionally united with the latter.

The **Teres minor** is a narrow, elongated muscle, which arises from the dorsal surface of the axillary border of the scapula for the upper two-thirds of its extent, and from two aponeurotic laminæ, one of which separates this muscle from the Infraspinatus, the other from the Teres major; its fibres pass obliquely upwards and outwards, and terminate in a tendon, which is inserted into the lowest of the three impressions on the great tuberosity of the humerus, and, by fleshy fibres, into the humerus immediately below it. The tendon of this muscle passes across, and is united with, the posterior part of the capsular ligament of the shoulder-joint.

Relations.—By its *posterior surface*, with the Deltoid, and the integument. By its *anterior surface*, with the scapula, the dorsal branch of the subscapular artery, the long head of the Triceps, and the shoulder-joint. By its *upper border*, with the Infraspinatus. By its *lower border*, with the Teres major, from which it is separated anteriorly by the long head of the Triceps.

The **Teres major** is a thick but somewhat flattened muscle, which arises from the oval surface on the dorsal aspect of the inferior angle of the scapula, and from the fibrous septa interposed between it and the Teres minor and Infraspinatus; the fibres are directed upwards and outwards, and terminate in a flat tendon, about two inches in length, which is inserted into the inner bicipital ridge of the humerus. The tendon of this muscle, at its insertion into the humerus, lies behind that of the Latissimus dorsi, from which it is separated by a synovial bursa, the two tendons being, however, united along their lower borders for a short distance.

Relations.—By its *posterior surface*, with the Latissimus dorsi below, and the long head of the Triceps above. By its *anterior surface*, with the Subscapularis, Latissimus dorsi, Coraco-brachialis, short head of the Biceps, the axillary vessels, and brachial plexus of nerves. Its *upper border* is at first in relation with the Teres minor, from which it is afterwards separated by the long head of the Triceps. Its *lower border* forms, in conjunction with the Latissimus dorsi, part of the posterior boundary of the axilla. The Latissimus dorsi at first covers the origin of the Teres major, then wraps itself obliquely round its lower border, so that its tendon ultimately comes to lie in front of that of the Teres major.

Nerves.—The Supra- and Infra-spinatus muscles are supplied by the fifth and sixth cervical nerves through the suprascapular nerve; the Teres minor, by the fifth cervical, through the circumflex; and the Teres major, by the fifth and sixth cervical, through the lower subscapular.

Actions.—The Supraspinatus assists the Deltoid in raising the arm from the side, and fixes the head of the humerus in the glenoid cavity. The Infraspinatus and Teres minor rotate the head of the humerus outwards: they also assist in carrying the arm backwards. One of the most important uses of these three muscles is the great protection they afford to the shoulder-joint, the Supraspinatus supporting it above, and preventing displacement of the head of the humerus upwards, while the Infraspinatus and Teres minor protect it behind, and prevent dislocation backwards. The Teres major assists the Latissimus dorsi in drawing the humerus downwards and backwards, when previously raised, and rotating it inwards; when the arm is fixed it may assist the Pectoral and Latissimus dorsi muscles in drawing the trunk forwards.

6. *Anterior Humeral Region* (fig. 422)

Coraco-brachialis. Biceps. Brachialis anticus.

Dissection.—The arm being placed on the table, with the front surface uppermost, make a vertical incision through the integument along the middle line, from the outer extremity of the anterior fold of the axilla, to about two inches below the elbow-joint, where it should be joined by a transverse incision, extending from the inner to the outer side of the forearm; the two flaps being reflected on either side, the fascia should be examined (fig. 420).

The **deep fascia** of the arm is continuous with that covering the Deltoid and the great Pectoral muscle, by means of which it is attached, above, to the clavicle, acromion, and spine of the scapula ; it forms a thin, loose, membranous sheath investing the muscles of the arm, and sends inwards septa between them ; it is composed of fibres disposed in a circular or spiral direction, and connected together by vertical and oblique fibres. It differs in thickness at different parts, being thin over the Biceps, but thicker where it covers the Triceps, and over the condyles of the humerus : it is strengthened by fibrous aponeuroses, derived from the Pectoralis major and Latissimus dorsi on the inner side, and from the Deltoid externally. On either side it gives off a strong intermuscular septum, which is attached to the corresponding supracondylar ridge and condyle of the humerus. These septa serve to separate the muscles of the anterior from those of the posterior brachial region. The *external intermuscular septum* extends from the lower part of the anterior bicipital ridge, along the external supracondylar ridge, to the outer epicondyle ; it is blended with the tendon of the Deltoid, gives attachment to the Triceps behind, to the Brachialis anticus, Supinator longus, and Extensor carpi radialis longior, in front ; and is perforated by the musculo-spiral nerve and superior profunda artery. The *internal intermuscular septum*, thicker than the preceding, extends from the lower part of the posterior lip of the bicipital groove below the Teres major, along the internal supracondylar ridge to the inner epicondyle ; it is blended with the tendon of the Coraco-brachialis, and affords attachment to the Triceps behind and the Brachialis anticus in front. It is perforated by the ulnar nerve, the inferior profunda artery, and the posterior branch of the anastomotic artery. At the elbow, the deep fascia is attached to all the prominent points round the joint, viz. the epicondyles of the humerus and the olecranon process of the ulna, and is continuous with the deep fascia of the forearm. Just below the middle of the arm, on its inner side, in front of the internal intermuscular septum, is an oval opening in the deep fascia, which transmits the basilic vein and some lymphatic vessels. On the removal of this fascia, the muscles, vessels, and nerves of the anterior humeral region are exposed.

The **Coraco-brachialis**, the smallest of the three muscles in this region, is situated at the upper and inner part of the arm. It arises by fleshy fibres from the apex of the coracoid process, in common with the short head of the Biceps, and from the intermuscular septum, between the two muscles ; the fibres pass downwards, backwards, and a little outwards, to be inserted by means of a flat tendon into an impression at the middle of the inner surface and internal border of the shaft of the humerus between the origins of the Triceps and Brachialis anticus. It is perforated by the musculo-cutaneous nerve. The inner border of the muscle forms a guide to the position of the terminal portion of the axillary and upper part of the brachial arteries.

Relations.—By its *anterior surface*, with the Pectoralis major above, and at its insertion with the brachial vessels and median nerve which cross it. By its *posterior surface*, with the tendons of the Subscapularis, Latissimus dorsi, and Teres major, the inner head of the Triceps, the humerus, and the anterior circumflex vessels. By its *inner border*, with the brachial artery and the median and musculo-cutaneous nerves. By its *outer border*, with the short head of the Biceps and Brachialis anticus.

The **Biceps** (*Biceps flexor cubiti*) is a long fusiform muscle, occupying the whole of the anterior surface of the arm, and divided above into two portions or heads, from which circumstance it has received its name. The short head arises by a thick flattened tendon from the apex of the coracoid process, in common with the Coraco-brachialis. The long head arises from the supraglenoid tubercle at the upper margin of the glenoid cavity, and is continuous with the glenoid ligament. This tendon arches over the head of the humerus, being enclosed in a special sheath of the synovial membrane of the shoulder-joint ; it then passes through an opening in the capsular ligament at its attachment to the humerus, and descends in the bicipital groove, in which it is retained by the transverse humeral ligament and by a fibrous prolongation from the tendon of the Pectoralis major. Each tendon is succeeded by an elongated muscular belly, and the two bellies, although closely applied to each other, can readily be separated until within about three inches of the elbow-joint. Here they end in a flattened tendon, which is inserted into the rough posterior portion of the tuberosity of the radius,

a synovial bursa being interposed between the tendon and the front part of the tuberosity. As the tendon of the muscle approaches the radius it is twisted upon itself, so that its anterior surface becomes external and is applied to the tuberosity of the radius at its insertion: opposite the bend of the elbow the tendon gives off, from its inner side, a broad aponeurosis, the *bicipital fascia* (*semilunar fascia*), which passes obliquely downwards and inwards across the brachial artery, and is continuous with the deep fascia covering the origins of the Flexor muscles of the forearm (fig. 421). The inner border of this muscle forms a guide to the position of the brachial artery, in tying the vessel in the middle of the arm.*

Relations.—Its *anterior surface* is overlapped above by the Pectoralis major and Deltoid; in the rest of its extent it is covered by the superficial and deep fasciæ and the integument. Its *posterior surface* rests above on the shoulder-joint and upper part of the humerus; below, it lies on the Brachialis anticus, with the musculo-cutaneous nerve intervening between the two, and on the Supinator brevis. Its *inner border* is in relation with the Coraco-brachialis, and overlaps the brachial vessels, and median nerve; its *outer border*, with the Deltoid and Supinator longus.

The **Brachialis anticus** is a broad muscle, which covers the elbow-joint and the lower half of the front of the humerus. It is somewhat compressed from before backwards, and is broader in the middle than at either extremity. It arises from the lower half of the front of the humerus; and commences above at the insertion of the Deltoid, which it embraces by two angular processes. Its origin extends below, to within an inch of the margin of the articular surface. It also arises from the intermuscular septa, but more extensively from the inner than the outer, from which it is separated below by the Brachio-radialis (Supinator longus) and Extensor carpi radialis longior. Its fibres converge to a thick tendon, which is inserted into a rough depression on the anterior surface of the coronoid process of the ulna, being received into an interval between two fleshy slips of the Flexor profundus digitorum.

Relations.—By its *anterior surface*, with the Biceps, the brachial vessels, musculo-cutaneous and median nerves. By its *posterior surface*, with the humerus and front of the elbow-joint. By its *inner border*, with the Triceps, ulnar nerve, and Pronator radii teres, from which it is separated by the intermuscular septum. By its *outer border*, with the musculo-spiral nerve, radial recurrent artery, the Brachio-radialis, and Extensor carpi radialis longior.

Nerves.—The muscles of this group are supplied by the musculo-cutaneous nerve. The Brachialis anticus usually receives an additional filament from the musculo-spiral. The Coraco-brachialis receives its supply primarily from the seventh cervical, the Biceps and Brachialis anticus from the fifth and sixth cervical nerves.

Actions.—The Coraco-brachialis draws the humerus forwards and inwards, and at the same time assists in elevating it towards the scapula. The Biceps is a flexor of the forearm: it is also a powerful supinator, and serves to render tense the deep fascia of the forearm by means of the bicipital fascia given off from its tendon. The Brachialis anticus is a flexor of the forearm, and forms an important defence to the elbow-joint. When the forearm is fixed, the Biceps and Brachialis anticus flex the arm upon the forearm, as is seen in efforts of climbing.

Surgical Anatomy.—The long tendon of the Biceps is sometimes dislocated from the Bicipital groove. When this takes place, the arm becomes fixed in a position of abduction, but the head of the humerus can be felt in its proper position. It can generally be replaced by flexing the forearm on the arm and rotating the limb. Rupture of the long tendon of the Biceps may also take place.

* A third head to the Biceps is occasionally found (Theile says as often as once in eight or nine subjects), arising at the upper and inner part of the Brachialis anticus, with the fibres of which it is continuous, and inserted into the bicipital fascia and inner side of the tendon of the Biceps. In most cases this additional slip passes behind the brachial artery in its course down the arm. In some instances the third head consists of two slips, which pass down, one in front, the other behind the artery, concealing the vessel in the lower half of the arm.

7. *Posterior Humeral Region*

Triceps. Subanconeus.

The **Triceps** (*Triceps extensor cubiti*) (fig. 424) is situated on the back of the arm, extending the entire length of the posterior surface of the humerus. It is of large size, and divided above into three parts: hence its name. These three portions have been named (1) the middle, scapular, or long head; (2) the external, or long humeral head; and (3) the internal, or short humeral head.

The *middle* or *scapular head* arises, by a flattened tendon, from a rough triangular depression on the scapula, immediately below the glenoid cavity, being blended at its upper part with the capsular ligament; the muscular fibres pass downwards between the two other portions of the muscle, and join with them in the common tendon of insertion.

The *external head* arises from the posterior surface of the shaft of the humerus, between the insertion of the Teres minor and the upper part of the musculo-spiral groove; from the external border of the humerus and the external intermuscular septum: the fibres from this origin converge towards the common tendon of insertion.

The *internal head* arises from the posterior surface of the shaft of the humerus, below the musculo-spiral groove: it is narrow and pointed above, and extends below the insertion of the Teres major to within an inch of the trochlear surface: it also arises from the internal border of the humerus and from the back of the whole length of the internal and lower part of the external intermuscular septa. The fibres of this portion of the muscle are directed, some downwards to the olecranon, while others converge to the common tendon of insertion.

The *common tendon* of the Triceps commences about the middle of the back part of the muscle: it consists of two aponeurotic laminæ, one of which is subcutaneous and covers the posterior surface of the muscle for the lower half of its extent; the other is more deeply seated in the substance of the muscle; after receiving the attachment of the muscular fibres, they join together above the elbow, and are inserted, for the most part, into the posterior portion of the upper surface of the olecranon process; a band of fibres is, however, continued downwards, on the outer side, over the Anconeus, to blend with the deep fascia of the forearm.

The long head of the Triceps descends between the Teres minor and Teres major, dividing the triangular space between these two muscles and the humerus into two smaller spaces, one triangular, the other quadrangular (fig. 424). The triangular space contains the dorsalis scapulæ vessels; it is bounded by the Teres minor above, the Teres major below, and the scapular head of the Triceps externally: the quadrangular space transmits the posterior circumflex vessels and the circumflex nerve; it is bounded by the Teres minor above, the Teres major below, the scapular head of the Triceps internally, and the humerus externally.

Relations.—By its *posterior surface*, with the Deltoid above: in the rest of its extent it is subcutaneous. By its *anterior surface*, with the humerus, musculo-spiral nerve, superior profunda vessels, and back part of the elbow-joint. Its *middle* or *long head* is in relation, behind, with the Deltoid and Teres minor; in front, with the Subscapularis, Latissimus dorsi, and Teres major.

The **Subanconeus** is a name given to a few fibres from the under surface of the lower part of the Triceps muscle, which are inserted into the posterior ligament and synovial membrane of the elbow-joint. By some authors it is regarded as the analogue of the Subcrureus in the lower limb, but it is not a separate muscle.

Nerves.—The Triceps is supplied by the seventh and eighth cervical nerves through the musculo-spiral nerve.

Actions.—The Triceps is the great extensor muscle of the forearm, serving, when the forearm is flexed, to extend the elbow-joint. It is the direct antagonist of the Biceps and Brachialis anticus. When the arm is extended, the long head of the muscle may assist the Teres major and Latissimus dorsi in drawing the humerus backwards and in adducting it to the thorax. The long head of the Triceps protects the under part of the shoulder-joint, and prevents displacement of the head of the humerus downwards and backwards. The Subanconeus draws up the posterior ligament during extension of the forearm.

Surgical Anatomy.—The existence of the band of fibres from the Triceps to the fascia of the forearm is of importance in excision of the elbow, and should always be carefully preserved from injury by the operator, as by means of these fibres the patient is enabled to extend the forearm, a movement which would otherwise mainly be accomplished by gravity—that is to say, by allowing the forearm to drop from its own weight.

III. Muscles and Fasciæ of the Forearm

Dissection.—To dissect the forearm, place the limb in the position indicated in fig. 420, make a vertical incision along the middle line from the elbow to the wrist, and a transverse incision at the extremity of this; the superficial structures being removed, the deep fascia of the forearm is exposed.

The **deep fascia** of the forearm, continuous above with that enclosing the arm, is a dense, highly glistening aponeurotic investment, which forms a general sheath enclosing the muscles in this region; it is attached, behind, to the olecranon and posterior border of the ulna, and gives off from its deep surface numerous intermuscular septa, which enclose each muscle separately. Below, it is continuous in front with the anterior annular ligament of the wrist, and forms a sheath for the tendon of the Palmaris longus muscle, which passes over the annular ligament to be inserted into the palmar fascia. Behind, near the wrist-joint, it becomes much thickened by the addition of many transverse fibres, and forms the posterior annular ligament. It consists of circular and oblique fibres, connected together by numerous vertical fibres. It is much thicker on the posterior than on the anterior surface, and at the lower than at the upper part of the forearm, and is strengthened above by tendinous fibres derived from the Biceps in front, and from the Triceps behind. Its deep surface gives origin to muscular fibres, especially at the upper part of the inner and outer sides of the forearm, and forms the boundaries of a series of conical-shaped cavities, in which the muscles are contained. Besides the vertical septa separating the individual muscles, transverse septa are given off both on the anterior and posterior surfaces of the forearm, separating the deep from the superficial layer of muscles. Numerous apertures exist in the fascia for the passage of vessels and nerves; one of these, of large size, situated at the front of the elbow, serves for the passage of a communicating branch between the superficial and deep veins. Near the wrist, it is perforated on its anterior surface by the ulnar artery and nerve.

The muscles of the forearm may be subdivided into groups corresponding to the region they occupy. One group occupies the inner and anterior aspect of the forearm, and comprises the Flexor and Pronator muscles. Another group occupies its outer side; and a third its posterior aspect. The two latter groups include all the Extensor and Supinator muscles.

8. *Anterior Radio-ulnar Region*

The muscles in this region are divided for convenience of description into two groups or layers, superficial and deep.

Superficial Layer

Pronator radii teres. Palmaris longus.
Flexor carpi radialis. Flexor carpi ulnaris.
Flexor sublimis digitorum.

These muscles take origin from the internal epicondyle of the humerus by a common tendon; they receive additional fibres from the deep fascia of the forearm near the elbow, and from the septa which pass inwards from this fascia between the individual muscles.

The **Pronator radii teres** has two heads of origin. One, the larger and more superficial, arises from the humerus, immediately above the internal epicondyle, and from the tendon common to the origin of the other muscles; also from the fascia of the forearm, and intermuscular septum between it and the Flexor carpi radialis. The other head is a thin fasciculus, which arises from the inner side of the coronoid process of the ulna, and joins the preceding at an acute angle. Between the two heads the median nerve enters the forearm. The muscle passes obliquely across the forearm from the inner to the outer side, and

terminates in a flat tendon, which turns over the outer margin of the radius, and is inserted into a rough impression at the middle of the outer surface of the shaft of that bone.

Relations.—By its *anterior surface* throughout the greater part of its extent with the deep fascia; at its insertion it is crossed by the radial vessels and nerve and covered by the Brachio-radialis. By its *posterior surface*, with the Brachialis anticus, Flexor sublimis digitorum, the median nerve, and ulnar artery: the small, or deep, head being interposed between the two latter structures. Its *outer border* forms the inner boundary of a triangular space (*antecubital fossa*), situated in front of the elbow-joint, which contains the brachial artery, median nerve, and tendon of the Biceps muscle. Its *inner border* is in contact with the Flexor carpi radialis.

Surgical Anatomy.—This muscle, when suddenly brought into very active use, as in the game of lawn tennis, is apt to be strained, producing slight swelling, tenderness, and pain on putting the muscle into action. This is known as 'lawn-tennis arm.'

The **Flexor carpi radialis** lies on the inner side of the preceding muscle. It arises from the internal epicondyle by the common tendon, from the fascia of the forearm, and from the intermuscular septa between it and the Pronator radii teres externally, the Palmaris longus internally, and the Flexor sublimis digitorum beneath. Slender and aponeurotic in structure at its commencement, it increases in size, and terminates in a tendon, which forms rather more than the lower half of its length. This tendon passes through a canal in the outer part of the annular ligament, runs through a groove in the os trapezium (which is converted into a canal by a fibrous sheath, and lined by a synovial membrane), and is inserted into the base of the metacarpal bone of the index finger, and by a slip into the base of the metacarpal bone of the middle finger. The radial artery, in the lower part of the forearm, lies between the tendon of this muscle and the Supinator longus, and may easily be tied in this situation.

Relations.—By its *superficial surface*, with the deep fascia and the integument. By its *deep surface*, with the Flexor sublimis digitorum, Flexor longus pollicis, and wrist-joint. By its *outer border*, with the Pronator radii teres and the radial vessels. By its *inner border*, with the Palmaris longus above, and the median nerve below.

The **Palmaris longus** is a slender, fusiform muscle, lying on the inner side of the preceding. It arises from the inner epicondyle of the humerus by the common tendon, from the deep fascia, and the intermuscular septa between it and the adjacent muscles. It terminates in a slender, flattened tendon, which passes over the upper part of the annular ligament, to end in the central part of the palmar fascia and lower part of the annular ligament, frequently sending a tendinous slip to the short muscles of the thumb. This muscle is often absent, and is subject to very considerable variations: it may be tendinous above and muscular below; or it may be muscular in the centre, with a tendon above and below; or it may present two muscular bundles with a central tendon; or finally it may consist simply of a mere tendinous band.

Relations.—By its *superficial surface*, with the deep fascia. By its *deep surface*, with the Flexor sublimis digitorum. *Internally*, with the Flexor carpi ulnaris. *Externally*, with the Flexor carpi radialis. Just above the wrist the median nerve lies close to the tendon, on its outer and posterior side.

The **Flexor carpi ulnaris** lies along the ulnar side of the forearm. It arises by two heads, connected by a tendinous arch, beneath which pass the ulnar nerve and posterior ulnar recurrent artery. One head arises from the inner epicondyle of the humerus by the common tendon; the other from the inner margin of the olecranon and from the upper two-thirds of the posterior border of the ulna by an aponeurosis, common to it and the Extensor carpi ulnaris and Flexor profundus digitorum; and from the intermuscular septum between it and the Flexor sublimis digitorum. The fibres terminate in a tendon, which occupies the anterior part of the lower half of the muscle, and is inserted into the pisiform bone, and is prolonged from this to the fifth metacarpal and unciform bones, by the piso-metacarpal and piso-unciform ligaments: it is also attached by a few fibres to the annular ligament. The ulnar artery lies on the outer side of the tendon of this muscle, in the lower two-thirds of the forearm; the tendon forming a guide in tying the vessel in this situation.

Relations.—By its *superficial surface*, with the deep fascia, with which it is intimately connected for a considerable extent. By its *deep surface*, with the Flexor sublimis digitorum, the Flexor profundus digitorum, the Pronator quadratus, and the ulnar vessels and nerve. By its *outer* or *radial border*, with the Palmaris longus above, and the ulnar vessels and nerve below.

The **Flexor sublimis digitorum** (*perforatus*) is placed beneath the preceding muscles, which therefore must be removed in order to bring its attachment into view. It is the largest of the muscles of the superficial layer, and arises by three heads. One head arises from the internal epicondyle of the humerus by the common tendon, from the internal lateral ligament of the elbow-joint, and from the intermuscular septum common to it and the preceding muscles. The second head arises from the inner side of the coronoid process of the ulna, above the ulnar origin of the Pronator radii teres (fig. 291, page 280). The third head arises from the oblique line of the radius, extending from the tubercle to the insertion of the Pronator radii teres. The fibres pass vertically downwards, forming a broad and thick muscle, which speedily separates into two planes of muscular fibres, superficial and deep: the superficial plane divides into two parts which end in tendons for the middle and ring fingers; the deep plane also divides into two parts, which end in tendons for the index and little fingers, but previously to having done so, it gives off a muscular slip, which joins that part of the superficial plane which is intended for the ring finger. As the four tendons thus formed pass beneath the annular ligament into the palm of the hand, they are arranged in pairs, the superficial pair corresponding to the middle and ring fingers, the deep pair to the index and little fingers. The tendons diverge from one another as they pass onwards. Opposite the bases of the first phalanges each tendon divides into two slips, to allow of the passage of the corresponding tendon of the Flexor profundus digitorum; the two portions of the tendon then unite and form a grooved channel for the reception of the accompanying deep Flexor tendon. Finally they subdivide a second time, to be inserted into the sides of the second phalanges about their middle. After leaving the palm, these tendons accompanied by the deep Flexor tendons lie in osseo-aponeurotic canals (fig. 426). The canals are formed by strong fibrous bands, which arch across the tendons, and are attached on each side to the margins of the phalanges. Opposite the middle of the proximal and second phalanges the sheath is very strong, and the fibres pass transversely; but opposite the joints it is much thinner, and the fibres pass obliquely. Each sheath is lined by a synovial membrane, which is reflected on the contained tendons.

Fig. 425.—Front of the left forearm. Superficial muscles.

Relations.—In the forearm, by its *superficial surface*, with the deep fascia and all the preceding superficial muscles; by its *deep surface*, with the Flexor profundus digitorum, Flexor longus pollicis, the ulnar vessels and nerve, and the median nerve. In the hand, its tendons are in relation, *in front*, with the palmar fascia, superficial palmar arch, and the branches of the median nerve; *behind* with the tendons of the deep Flexor and the Lumbricales.

Fig. 426.—Front of the left forearm. Deep muscles.

Deep Layer

Flexor profundus digitorum.
Flexor longus pollicis.
Pronator quadratus.

Dissection.—Divide each of the superficial muscles at its centre, and turn either end aside; the deep layer of muscles, together with the median nerve and ulnar vessels, will then be exposed.

The **Flexor profundus digitorum** (*perforans*) (fig. 426) is situated on the ulnar side of the forearm, immediately beneath the superficial Flexors. It arises from the upper three-fourths of the anterior and inner surfaces of the shaft of the ulna, embracing the insertion of the Brachialis anticus above, and extending, below, to within a short distance of the Pronator quadratus. It also arises from a depression on the inner side of the coronoid process; by an aponeurosis from the upper three-fourths of the posterior border of the ulna, in common with the Flexor and Extensor carpi ulnaris; and from the ulnar half of the interosseous membrane. The fibres form a fleshy belly of considerable size, which divides into four tendons: these pass under the annular ligament beneath the tendons of the Flexor sublimis digitorum. Opposite the first phalanges, the tendons pass through the openings in the tendons of the Flexor sublimis digitorum, and are finally inserted into the bases of the last phalanges. The portion of the muscle for the index finger is usually distinct throughout, but the tendons for the three inner fingers are connected together by cellular tissue and tendinous slips, as far as the palm of the hand. The tendons of this muscle and those of the Flexor sublimis digitorum, while contained in the osseo-aponeurotic canals of the fingers, are invested in a synovial sheath, and are connected to each other, and to the phalanges, by slender, tendinous filaments, called *vincula accessoria tendinum.* There are two sets of these: (*a*) the *ligamenta brevia*, which are two in number in each finger, and consist of triangular bands of fibres connecting the tendon of the Flexor sublimis digitorum to the front of

the first interphalangeal joint and head of the first phalanx, and the tendon of the Flexor profundus digitorum to the front of the second interphalangeal joint and head of the second phalanx; (*b*) the *ligamenta longa*, which connect the under surface of the tendons of the Flexor profundus digitorum to the subjacent Flexor sublimis after the tendons of the former have passed through the latter. The ligamentum breve of the deep Flexor tendons consists largely of yellow elastic tissue, and may assist in drawing down the tendon after flexion of the finger.*

Four small muscles, the Lumbricales, are connected with the tendons of the Flexor profundus in the palm. They will be described with the muscles of the hand.

Relations.—By its *superficial surface*, in the forearm, with the Flexor sublimis digitorum, the Flexor carpi ulnaris, the ulnar vessels and nerve, and the median nerve; and in the hand, with the tendons of the superficial Flexor. By its *deep surface*, in the forearm, with the ulna, the interosseous membrane, the Pronator quadratus; and in the hand, with the Interossei, Adductores pollicis, and deep palmar arch. By its *ulnar border*, with the Flexor carpi ulnaris. By its *radial border*, with the Flexor longus pollicis, the anterior interosseous vessels and nerve being interposed.

The **Flexor longus pollicis** is situated on the radial side of the forearm, lying on the same plane as the preceding. It arises from the grooved anterior surface of the shaft of the radius: commencing, above, immediately below the tuberosity and oblique line, and extending, below, to within a short distance of the Pronator quadratus. It also arises from the adjacent part of the interosseous membrane, and generally by a fleshy slip from the inner border of the coronoid process, or from the internal condyle of the humerus. The fibres proceed downwards, and terminate in a flattened tendon, which passes beneath the annular ligament, is then lodged in the interspace between the outer head of the Flexor brevis pollicis and the Adductor obliquus pollicis, and, entering an osseo-aponeurotic canal similar to those for the other Flexor tendons, is inserted into the base of the last phalanx of the thumb.

Relations.—By its *superficial surface*, with the Flexor sublimis digitorum, Flexor carpi radialis, Brachio-radialis, and radial vessels. By its *deep surface*, with the radius, interosseous membrane, and Pronator quadratus. By its *ulnar border*, with the Flexor profundus digitorum, from which it is separated by the anterior interosseous vessels and nerve.

The **Pronator quadratus** is a small, flat, quadrilateral muscle, extending transversely across the front of the radius and ulna, above their carpal extremities. It arises from the pronator ridge on the lower part of the anterior surface of the shaft of the ulna; from the inner part of the anterior surface of the lower fourth of the ulna; and from a strong aponeurosis which covers the inner third of the muscle. The fibres pass outwards and slightly downwards, to be inserted into the lower fourth of the outer border and the anterior surface of the shaft of the radius. The deeper fibres of the muscle are inserted into the triangular area above the sigmoid cavity of the radius—an attachment comparable with the ulnar origin of the Supinator brevis from the triangular area below the lesser sigmoid cavity of that bone.

Relations.—By its *superficial surface*, with the Flexor profundus digitorum, the Flexor longus pollicis, Flexor carpi radialis, and the radial vessels. By its *deep surface*, with the radius, ulna, and interosseous membrane.

Nerves.—All the muscles of the superficial layer are supplied by the median nerve, excepting the Flexor carpi ulnaris, which is supplied by the ulnar. The Pronator radii teres, the Flexor carpi radialis, and the Palmaris longus derive their supply primarily from the sixth cervical; the Flexor sublimis digitorum from the seventh and eighth cervical and first dorsal, and the Flexor carpi ulnaris from the eighth cervical and first dorsal nerves. Of the deep layer, the Flexor profundus digitorum is supplied by the eighth cervical and first dorsal through the ulnar and anterior interosseous branch of the median. The remaining two muscles, Flexor longus pollicis and Pronator quadratus, are also supplied by the eighth cervical and first dorsal through the anterior interosseous branch of the median.

Actions.—These muscles act upon the forearm, the wrist, and hand. The

* Marshall, *Brit. and For. Med.-Chir. Rev.* 1853.

Pronator radii teres helps to rotate the radius upon the ulna, rendering the hand prone; when the radius is fixed, it assists the other muscles in flexing the forearm. The Flexor carpi radialis is one of the flexors of the wrist; when acting alone, it flexes the wrist, inclining it to the radial side. It can also assist in pronating the forearm and hand, and, by continuing its action, in bending the elbow. The Flexor carpi ulnaris is one of the flexors of the wrist; when acting alone, it flexes the wrist, inclining it to the ulnar side; and by continuing to contract, it bends the elbow. The Palmaris longus is a tensor of the palmar fascia. It also assists in flexing the wrist and elbow. The Flexor sublimis digitorum flexes first the middle, and then the proximal phalanx. It assists in flexing the wrist and elbow. The Flexor profundus digitorum is one of the flexors of the phalanges. After the Flexor sublimis has bent the second phalanx, the Flexor profundus flexes the terminal one; but it cannot do so until after the contraction of the superficial muscle. It also assists in flexing the wrist. The Flexor longus pollicis is a flexor of the phalanges of the thumb. When the thumb is fixed, it also assists in flexing the wrist. The Pronator quadratus helps to rotate the radius upon the ulna, rendering the hand prone.

9. *Radial Region* (fig. 427)

Brachio-radialis (Supinator longus). Extensor carpi radialis longior.
Extensor carpi radialis brevior.

Dissection.—Divide the integument in the same manner as in the dissection of the anterior brachial region; and, after having examined the cutaneous vessels and nerves and deep fascia, remove all these structures. The muscles will then be exposed. The removal of the fascia will be considerably facilitated by detaching it from below upwards. Great care should be taken to avoid cutting across the tendons of the muscles of the thumb, which cross obliquely the larger tendons running down the back of the radius.

The **Brachio-radialis** (Supinator longus) is the most superficial muscle on the radial side of the forearm: it is fleshy for the upper two-thirds of its extent, tendinous below. It arises from the upper two-thirds of the external supracondylar ridge of the humerus, and from the external intermuscular septum, being limited above by the musculo-spiral groove. The fibres terminate above the middle of the forearm in a flat tendon, which is inserted into the outer side of the base of the styloid process of the radius.

Relations.—By its *superficial surface*, with the integument and fascia for the greater part of its extent; near its insertion it is crossed by the Extensor ossis metacarpi pollicis and the Extensor brevis pollicis. By its *deep surface*, with the humerus, the Extensor carpi radialis longior and brevior, the insertion of the Pronator radii teres, and the Supinator brevis. By its *inner border*, above the elbow, with the Brachialis anticus, the musculo-spiral nerve, and radial recurrent artery; and in the forearm with the radial vessels and nerve.

The **Extensor carpi radialis longior** is placed partly beneath the preceding muscle. It arises from the lower third of the external supracondylar ridge of the humerus, from the external intermuscular septum, and by a few fibres from the common tendon of origin of the Extensor muscles of the forearm. The fibres terminate at the upper third of the forearm in a flat tendon, which runs along the outer border of the radius, beneath the Extensor tendons of the thumb; it then passes beneath the posterior annular ligament of the wrist, where it lies in a groove on the back of the radius common to it and the Extensor carpi radialis brevior, immediately behind the styloid process, and is inserted into the posterior surface of the base of the metacarpal bone of the index finger, on its radial side.

Relations.—By its *superficial surface*, with the Supinator longus, and fascia of the forearm. Its *outer side* is crossed obliquely by the Extensor tendons of the thumb. By its *deep surface*, with the elbow-joint, the Extensor carpi radialis brevior, and back part of the wrist.

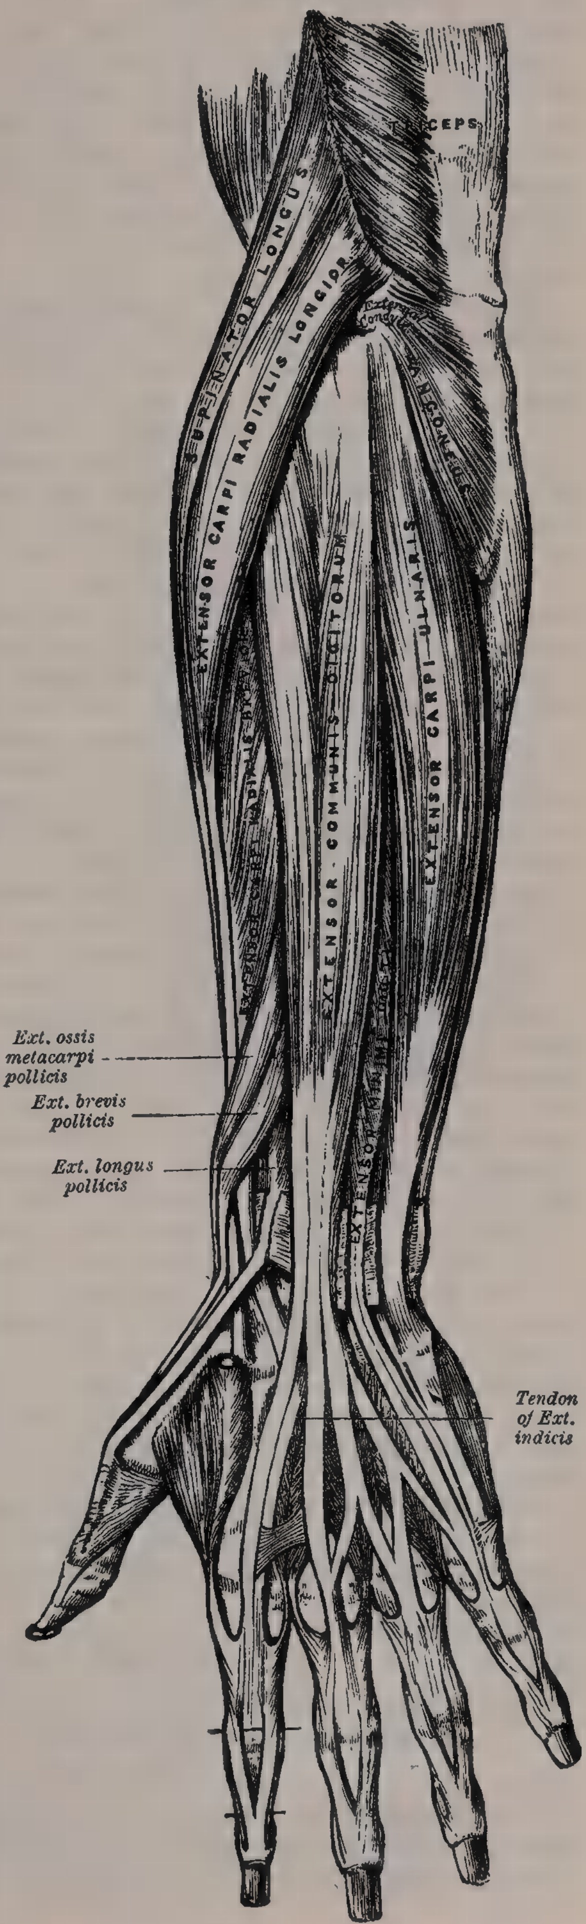
The **Extensor carpi radialis brevior** is shorter, as its name implies, and thicker than the preceding muscle, beneath which it is placed. It arises from the external epicondyle of the humerus, by a tendon common to it and the three following muscles: from the external lateral ligament of the elbow-joint; from a strong aponeurosis which covers its surface; and from the intermuscular

septa between it and the adjacent muscles. The fibres terminate about the middle of the forearm in a flat tendon, which is closely connected with that of the preceding muscle, and accompanies it to the wrist; it passes beneath the Extensor tendons of the thumb, then beneath the annular ligament, and, diverging somewhat from its fellow, is inserted into the posterior surface of the base of the metacarpal bone of the middle finger, on its radial side. Under the posterior annular ligament of the wrist the tendon lies in a shallow groove on the back of the radius, to the ulnar side of the groove which lodges the tendon of the Extensor carpi radialis longior, and separated from it by an indistinct ridge.

The tendons of the two preceding muscles pass through the same compartment of the annular ligament, and are lubricated by a single synovial membrane.

Relations. — By its *superficial surface*, with the Extensor carpi radialis longior, and with the Extensor muscles of the thumb which cross it. By its *deep surface*, with the Supinator brevis, tendon of the Pronator radii teres, radius, and wrist-joint. By its *ulnar border*, with the Extensor communis digitorum.

FIG. 427.—Posterior surface of the forearm. Superficial muscles.



10. *Posterior Radio-ulnar Region* (fig. 427)

The muscles in this region are divided for purposes of description into two groups or layers, superficial and deep.

Superficial Layer

Extensor communis digitorum.
Extensor minimi digiti.
Extensor carpi ulnaris.
Anconeus.

The **Extensor communis digitorum** is situated at the back part of the forearm. It arises from the external epicondyle of the humerus, by the common tendon; from the deep fascia, and the intermuscular septa between it and the adjacent muscles. It divides below into four tendons, which pass, together with that of the Extensor indicis,

through a separate compartment of the annular ligament, lubricated by a synovial membrane. The tendons then diverge, and, after passing across the back of the hand, are inserted into the second and third phalanges of the fingers in the following manner: Opposite the metacarpo-phalangeal articulation each tendon is bound by fasciculi to the lateral ligaments and serves as the posterior ligament; after having passed the joint, it spreads out into a broad aponeurosis, which covers the dorsal surface of the first phalanx and is reinforced, in this situation, by the tendons of the Interossei and Lumbricales. Opposite the first phalangeal joint this aponeurosis divides into three slips, a middle and two lateral: the former is inserted into the base of the second phalanx; and the two lateral, which are continued onwards along the sides of the second phalanx, unite by their contiguous margins, and are inserted into the dorsal surface of the last phalanx. As the tendons cross the phalangeal joints, they furnish them with posterior ligaments. The tendon to the index finger is accompanied by the Extensor indicis, which lies on its inner side. On the back of the hand, the three inner tendons—those to the middle, ring, and little fingers—are connected by two obliquely placed bands, one from the third tendon passing downwards and outwards to the second tendon, and the other passing from the same tendon downwards and inwards to the fourth. Occasionally the first tendon is connected to the second by a thin transverse band.

Relations.—By its *superficial surface*, with the fascia of the forearm and hand, the posterior annular ligament, and integument. By its *deep surface*, with the Supinator brevis, the Extensor muscles of the thumb and index finger, the posterior interosseous vessels and nerve, the wrist-joint, carpus, metacarpus, and phalanges. By its *radial border*, with the Extensor carpi radialis brevior. By its *ulnar border*, with the Extensor minimi digiti and Extensor carpi ulnaris.

The **Extensor minimi digiti** is a slender muscle placed on the inner side of the Extensor communis, with which it is generally connected. It arises from the common Extensor tendon by a thin, tendinous slip; and from the intermuscular septa between it and the adjacent muscles. Its tendon runs through a separate compartment in the annular ligament behind the inferior radio-ulnar joint, then divides into two as it crosses the hand, and is finally inserted into the expansion of the Extensor tendon on the dorsum of the first phalanx of the little finger.

The **Extensor carpi ulnaris** is the most superficial muscle on the ulnar side of the forearm. It arises from the external epicondyle of the humerus, by the common tendon; by an aponeurosis from the posterior border of the ulna in common with the Flexor carpi ulnaris and the Flexor profundus digitorum; and from the deep fascia of the forearm. This muscle terminates in a tendon, which runs through a groove behind the styloid process of the ulna, passing through a separate compartment in the annular ligament, and is inserted into the prominent tubercle on the ulnar side of the base of the metacarpal bone of the little finger.

Relations.—By its *superficial surface*, with the deep fascia of the forearm. By its *deep surface*, with the ulna, and the muscles of the deep layer.

The **Anconeus** is a small, triangular muscle, placed behind and below the elbow-joint, and appears to be a continuation of the external portion of the Triceps. It arises by a separate tendon from the back part of the external epicondyle of the humerus, and is inserted into the side of the olecranon, and upper fourth of the posterior surface of the shaft of the ulna; its fibres diverge from their origin, the upper ones being directed transversely, the lower obliquely inwards.

Relations.—By its *superficial surface*, with a strong fascia derived from the Triceps. By its *deep surface*, with the elbow-joint, the orbicular ligament, the ulna, a small portion of the Supinator brevis, and the posterior interosseous recurrent artery.

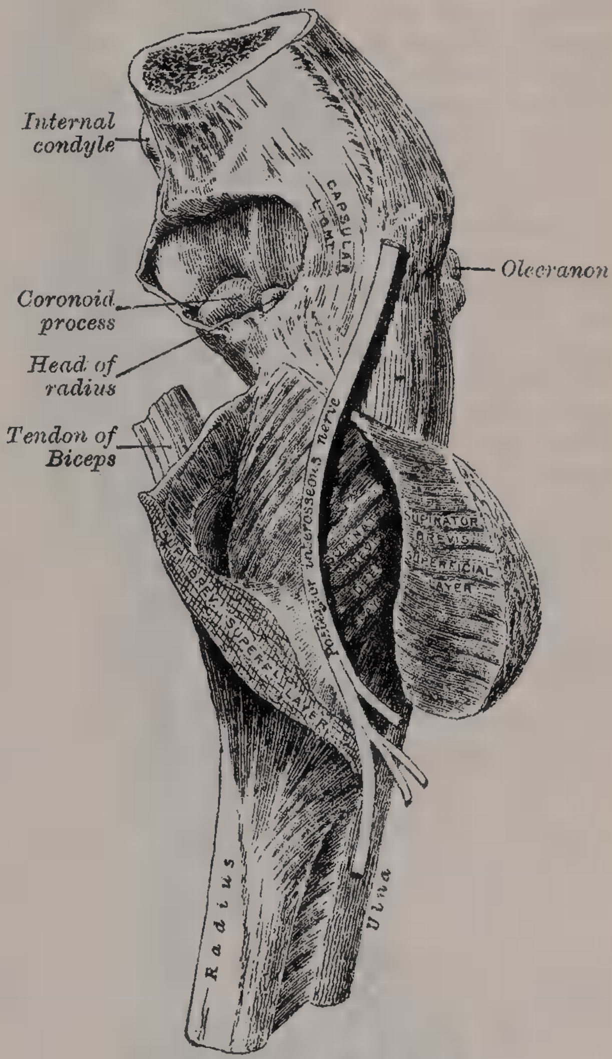
Deep Layer (fig. 429)

Supinator brevis. Extensor brevis pollicis.
Extensor ossis metacarpi pollicis. Extensor longus pollicis.
Extensor indicis.

The **Supinator brevis** (fig. 428) is a broad muscle, of a hollow cylindrical form, curved round the upper third of the radius. It consists of two distinct planes of muscular fibres, between which lies the posterior interosseous nerve.

The two planes arise in common: the superficial one by tendinous, and the deeper by muscular fibres from the external epicondyle of the humerus; from the external lateral ligament of the elbow-joint, and the orbicular ligament of the radius; from the ridge on the ulna, which runs obliquely downwards from the posterior extremity of the lesser sigmoid cavity; from the triangular depression below that cavity; and from a tendinous expansion which covers the surface of the muscle. The superficial fibres surround the upper part of the radius, and are inserted into the outer edge of the bicipital tuberosity and to the oblique line of the radius, as low down as the insertion of the Pronator radii teres. The upper fibres of the deeper plane form a sling-like fasciculus, which encircles the neck of the radius above the tuberosity and is attached to the back part of its inner surface: the greater part of this portion of the muscle is inserted into the posterior and external surface of the shaft, midway between the oblique line and the head of the bone. Between the insertion of the two planes, the posterior interosseous nerve passes to the back of the forearm.

Fig. 428.—Supinator brevis. (From a preparation in the Museum of the Royal College of Surgeons of England.)



Relations.—By its *superficial surface,* with the superficial Extensors and the Brachio-radialis, and the radial vessels and nerve. By its *deep surface,* with the elbow-joint, the interosseous membrane, and the radius.

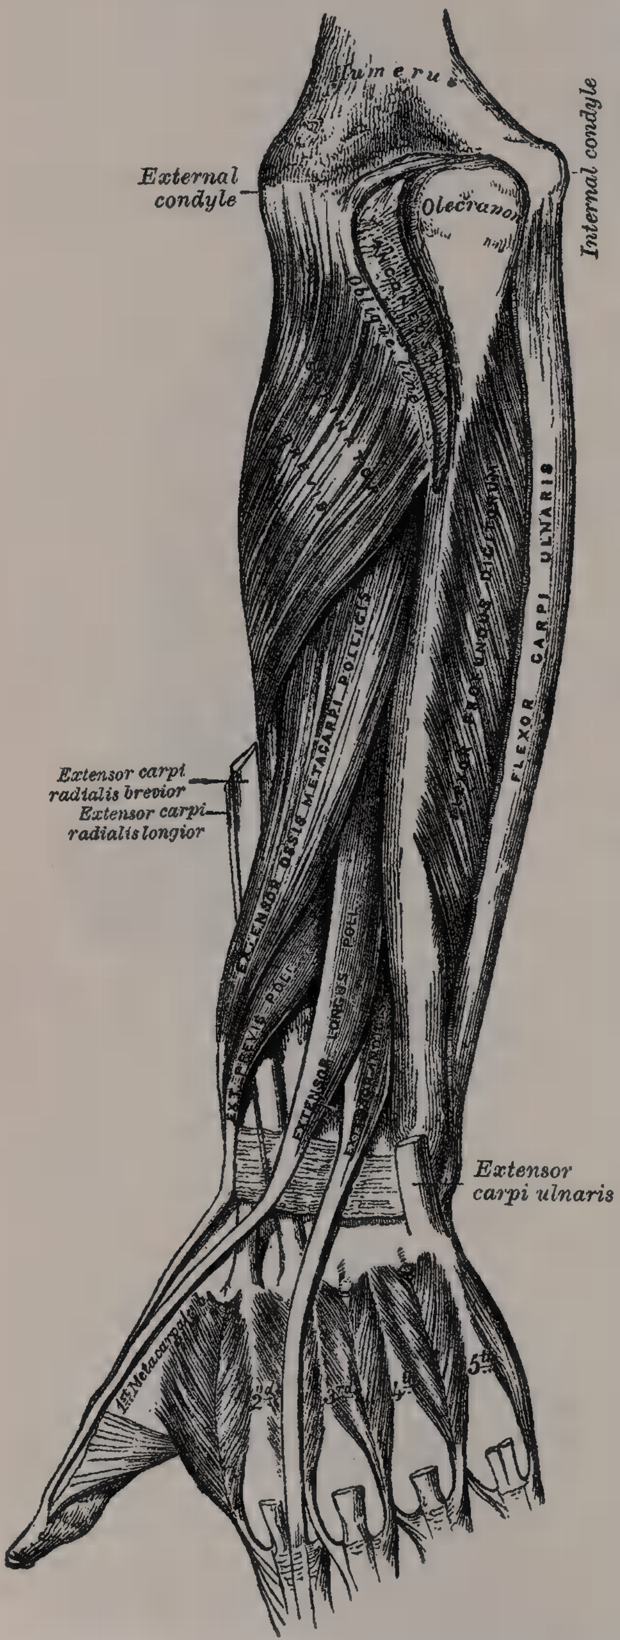
The **Extensor ossis metacarpi pollicis** is the most external and the largest of the deep Extensor muscles; it lies immediately below the Supinator brevis, with which it is sometimes united. It arises from the outer part of the posterior surface of the shaft of the ulna below the insertion of the Anconeus, from the interosseous membrane, and from the middle third of the posterior surface of the shaft of the radius. Passing obliquely downwards and outwards, it terminates in a tendon, which runs through a groove on the outer side of the lower end of the radius, accompanied by the tendon of the Extensor brevis pollicis, and is inserted into the outer side of the base of the metacarpal bone of the thumb. It occasionally gives off two slips, near its insertion: one to the Trapezium, and the other to blend with the origin of the Abductor pollicis.

Relations.—By its *superficial surface,* with the Extensor communis digitorum, Extensor minimi digiti, and fascia of the forearm; and with the branches of the posterior interosseous artery and nerve which cross it. By its *deep surface,* with the ulna, interosseous membrane, radius, the tendons of the Extensor carpi radialis longior and brevior, which it crosses obliquely; and, at the outer side of the wrist, with the radial vessels. By its *upper border,* with the Supinator brevis. By its *lower border,* with the Extensor brevis pollicis.

The **Extensor brevis pollicis** (*Extensor primi internodii pollicis*), the smallest muscle of this group, lies on the inner side of the preceding It arises from the posterior surface of the shaft of the radius, below the Extensor ossis metacarpi pollicis and from the interosseous membrane. Its direction is similar to that of

the Extensor ossis metacarpi pollicis, its tendon passing through the same groove on the outer side of the lower end of the radius, to be inserted into the base of the first phalanx of the thumb. It is closely connected with the Extensor ossis metacarpi pollicis, of which it is usually regarded as a segmentation.

Fig. 429.—Posterior surface of the forearm. Deep muscles.



Relations. — The same as those of the Extensor ossis metacarpi pollicis.

The **Extensor longus pollicis** (*Extensor secundi internodii pollicis*) is much larger than the preceding muscle, the origin of which it partly covers. It arises from the outer part of the posterior surface of the middle third of the shaft of the ulna, below the origin of the Extensor ossis metacarpi pollicis, and from the interosseous membrane. It terminates in a tendon, which passes through a separate compartment in the annular ligament, lying in a narrow, oblique groove at the back part of the lower end of the radius. It then crosses obliquely the tendons of the Extensor carpi radialis longior and brevior, being separated from the other Extensor tendons of the thumb by a triangular interval, in which the radial artery is found; and is finally inserted into the base of the last phalanx of the thumb.

Relations.—By its *superficial surface*, with the same parts as the Extensor ossis metacarpi pollicis. By its *deep surface*, with the ulna, interosseous membrane, the posterior interosseous nerve, radius, the wrist, the radial vessels, and metacarpal bone of the thumb.

The **Extensor indicis** is a narrow, elongated muscle, placed on the inner side of, and parallel with, the preceding. It arises from the posterior surface of the shaft of the ulna, below the origin of the Extensor longus pollicis and from the interosseous membrane. Its tendon passes under the annular ligament in the same compartment as that which transmits the Extensor communis digitorum, and subsequently joins the ulnar side of the tendon of the Extensor communis which belongs to the index finger, opposite the lower end of the corresponding metacarpal bone.

Relations.—The relations are similar to those of the preceding muscles.

Nerves.—The Brachio-radialis is supplied by the fifth and sixth, the Extensor carpi radialis longior and brevior by the sixth and seventh, and the Anconeus by the seventh and eighth cervical nerves, all through the musculo-spiral nerve; the remaining muscles are enervated through the posterior interosseous nerve, the Supinator brevis being supplied by the sixth cervical, and all the other muscles by the seventh cervical.

Actions.—The muscles of the radial and posterior aspects of the forearm, which comprise all the Extensor and Supinator muscles, act upon the forearm, wrist, and hand; they are the direct antagonists of the Pronator and Flexor muscles. The Anconeus assists the Triceps in extending the forearm. The chief action of the Brachio-radialis is that of a flexor of the elbow-joint, but in addition to this it may act both as a supinator and as a pronator: that is to say, if the forearm is forcibly pronated, it will act as a supinator, and bring the bones into a position midway between supination and pronation; and, *vice versâ*, if the arm is forcibly supinated, it will act as a pronator, and bring the bones into the same position, midway between supination and pronation. The action of the muscle is therefore to throw the forearm and hand into the position they naturally occupy when placed across the chest. The Supinator brevis is a supinator: that is to say, when the radius has been carried across the ulna in pronation, and the back of the hand is directed forwards, this muscle carries the radius back again to its normal position on the outer side of the ulna, and the palm of the hand is again directed forwards. The Extensor carpi radialis longior extends the wrist and abducts the hand. It may also assist in bending the elbow-joint; at all events it serves to fix or steady this articulation. The Extensor carpi radialis brevior assists the Extensor carpi radialis longior in extending the wrist, and may also act slightly as an abductor of the hand. The Extensor carpi ulnaris helps to extend the hand, but when acting alone inclines it towards the ulnar side: by its continued action it extends the elbow-joint. The Extensor communis digitorum extends the phalanges, then the wrist, and finally the elbow. It acts principally on the proximal phalanges, the middle and terminal phalanges being acted upon mainly by the Interossei and Lumbricales. It has also a tendency to separate the fingers as it extends them. The Extensor minimi digiti extends the little finger, and by its continued action assists in extending the wrist. It is owing to this muscle that the little finger can be extended or pointed while the others are flexed. The chief action of the Extensor ossis metacarpi pollicis is to carry the thumb outwards and backwards from the palm of the hand, and hence it has been called the *Abductor pollicis longus*. By its continued action it helps to extend and abduct the wrist. The Extensor brevis pollicis extends the proximal phalanx of the thumb. By its continued action it helps to extend and abduct the wrist. The Extensor longus pollicis extends the terminal phalanx of the thumb. By its continued action it helps to extend and abduct the wrist. The Extensor indicis extends the index finger, and by its continued action assists in extending the wrist. It is owing to this muscle that the index finger can be extended or pointed while the others are flexed.

Surgical Anatomy.—The tendons of the Extensor muscles of the thumb are liable to become strained, and their sheaths inflamed, after excessive exercise, producing a sausage-shaped swelling along the course of the tendons and giving a peculiar creaking sensation to the finger when the muscles act. In consequence of its often being caused by such movements as wringing clothes, it is known as 'washerwoman's sprain.'

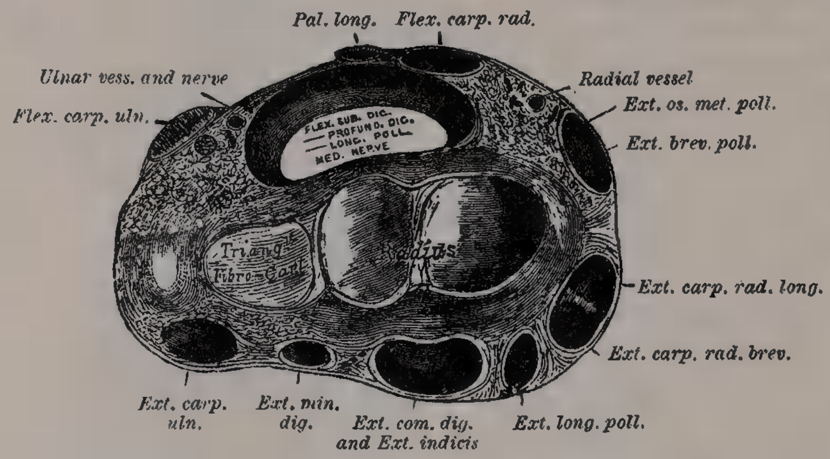
IV. Muscles and Fasciæ of the Hand

The **Muscles of the Hand** are subdivided into three groups: 1. Those of the thumb, which occupy the radial side and produce the *thenar* eminence; 2. Those of the little finger, which occupy the ulnar side and give rise to the *hypothenar* eminence; 3. Those in the middle of the palm and within the interosseous spaces.

Dissection (fig. 420).—Make a transverse incision across the front of the wrist, and a second across the heads of the metacarpal bones: connect the two by a vertical incision in the middle line, and continue it through the centre of the middle finger. The anterior and posterior annular ligaments, and the palmar fascia, should then be dissected.

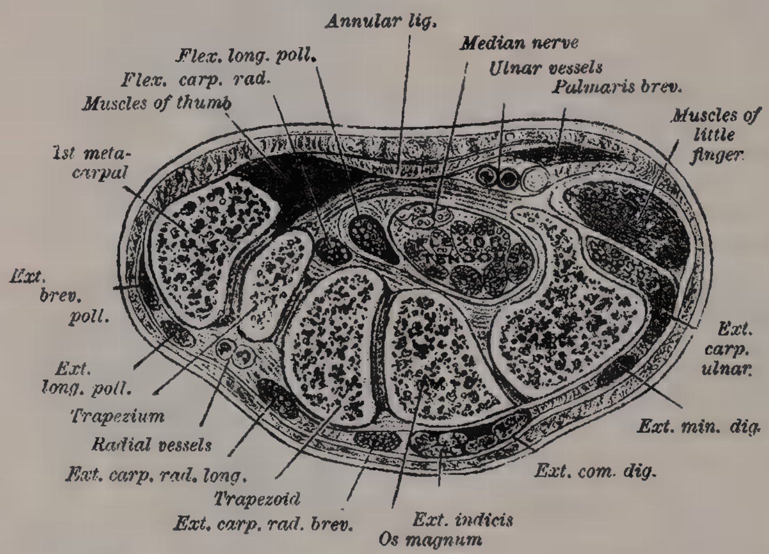
The **Anterior Annular Ligament** is a strong, fibrous band, which arches over the carpus, converting the deep groove on the front of the carpal bones into a canal, beneath which pass the Flexor tendons of the digits. It is attached, internally, to the pisiform bone and the hook of the unciform bone; and externally, to the tuberosity of the scaphoid, and to the inner part of the anterior surface and the ridge on the trapezium. It is continuous, above, with the deep fascia of the forearm, of which it may be regarded as a thickened portion; and

Fig. 430.—Transverse section through the wrist, showing the annular ligaments and the canals for the passage of the tendons.



below, with the palmar fascia. It is crossed by the ulnar vessels and nerve, and the cutaneous branches of the median and ulnar nerves. At its outer extremity is the tendon of the Flexor carpi radialis, which lies in the groove on the trapezium between the attachments of the annular ligament to the bone. It has inserted into its anterior surface a part of the tendon of the Palmaris longus and part of the tendon of the Flexor carpi ulnaris, and has arising from

Fig. 431.—Transverse section through the carpus, showing the relative positions of the tendons, vessels, and nerves. (Henle.)



it, below, the small muscles of the thumb and little finger. Beneath it pass the tendons of the Flexor sublimis and profundus digitorum, the tendon of the Flexor longus pollicis, and the median nerve.

The Synovial Membranes of the Flexor Tendons at the Wrist.—There are two synovial membranes which enclose all the tendons as they pass beneath this ligament, one for the Flexor sublimis and profundus digitorum, the other for the Flexor longus pollicis. They extend up into the forearm for about an inch above the annular ligament, and occasionally communicate with each other under the

ligament. The sheath which surrounds the Flexor tendons of the fingers extends downwards about halfway along the metacarpal bones, where it terminates in blind diverticula around the tendons to the index, middle, and ring fingers. In the case of the little finger, it is prolonged on its tendons, and usually communicates with the synovial sheath of that digit. The sheath which envelops the tendon of the Flexor longus pollicis is continued along the thumb as far as the insertion of the tendon.

The **Posterior Annular Ligament** is a strong, fibrous band, extending obliquely downwards and inwards across the back of the wrist, and consisting of the deep fascia of the back of the forearm, strengthened by the addition of some transverse fibres. It binds down the Extensor tendons in their passage to the fingers, being attached, internally, to the styloid process of the ulna, the cuneiform and pisiform bones; externally, to the outer margin of the radius; and, in its passage across the wrist, to the elevated ridges on the posterior surface of the radius. Between it and the bones are formed six compartments for the passage of tendons, each of which is lined by a separate synovial membrane. These are, from without inwards: 1. On the outer side of the styloid process, for the tendons of the Extensor ossis metacarpi and Extensor brevis pollicis. 2. Behind the styloid process, for the tendons of the Extensor carpi radialis longior and brevior. 3. About the middle of the posterior surface of the radius, for the tendon of the Extensor longus pollicis. 4. To the inner side of the latter, for the tendons of the Extensor communis digitorum and Extensor indicis. 5. Opposite the interval between the radius and ulna, for the Extensor minimi digiti. 6. Grooving the back of the ulna, for the tendon of the Extensor carpi ulnaris. The synovial membranes lining these sheaths are usually very extensive, reaching from above the annular ligament, down upon the tendons for a variable distance on the back of the hand.

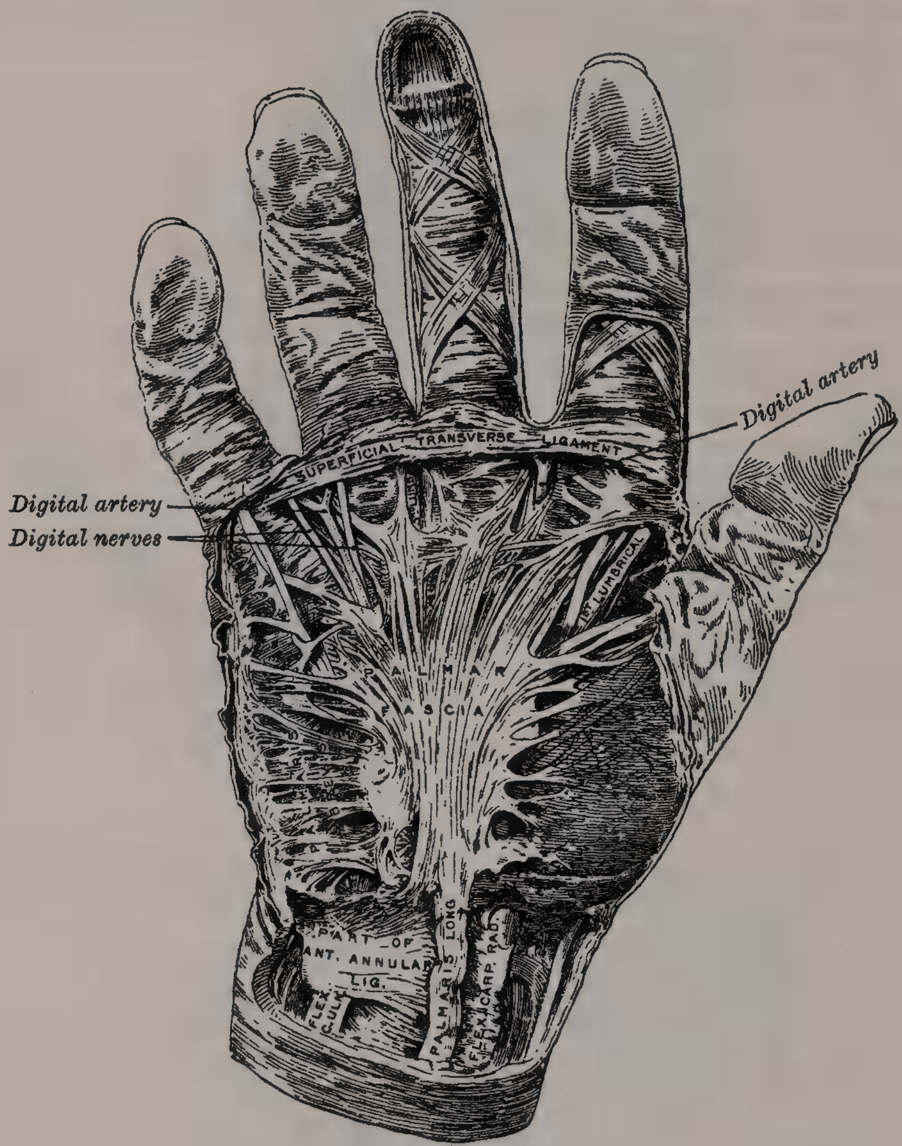
Fig. 432.—Diagram showing the arrangement of the synovial sheaths of the palm and fingers.

The **deep palmar fascia** (fig. 433) forms a common sheath which invests the muscles of the hand. It consists of a central and two lateral portions.

The *central portion* occupies the middle of the palm, is triangular in shape, of great strength and thickness, and binds down the tendons and protects the vessels and nerves in this situation. It is narrow above, where it is attached to the lower margin of the annular ligament, and receives the expanded tendon of the Palmaris longus muscle. Below, it is broad and expanded, and divides into four slips, one for each finger. Each slip gives off superficial fibres, which are inserted into the skin of the palm and finger, those to the palm joining the skin at the furrow corresponding to the metacarpo-phalangeal articulation, and those to the fingers passing into the skin at the transverse fold at the base of the fingers. The deeper part of each slip subdivides into two processes, which are inserted into the fibrous sheaths which confine the Flexor tendons. From the sides of these processes, offsets are sent backwards, to be attached to the transverse metacarpal ligament. By this arrangement short channels are formed on the front of the lower ends of the metacarpal bones, through which the Flexor tendons pass. Between the two processes into which each slip divides is attached the *digital sheath*. The intervals left in the fascia, between the four fibrous slips, transmit the digital vessels and nerves, and the tendons of the Lumbricales. At the points of division of the palmar fascia into the slips above mentioned,

numerous strong, transverse fibres bind the separate processes together and form the *superficial transverse metacarpal ligament.* The palmar fascia is intimately adherent to the integument by dense fibro-areolar tissue forming the superficial palmar fascia, and gives origin by its inner margin to the Palmaris brevis; it covers the superficial palmar arch, the tendons of the Flexor muscles, and the branches of the median and ulnar nerves; and on each side it gives off a vertical septum, which is continuous with the interosseous aponeurosis, and separates the lateral from the middle palmar group of muscles.

Fig. 433.—Palmar fascia.
(From a preparation in the Museum of the Royal College of Surgeons of England.)



The *lateral portions* of the palmar fascia are thin, fibrous layers, which cover, on the radial side, the muscles of the ball of the thumb, and, on the ulnar side, the muscles of the little finger: they are continuous with the dorsal fascia, and in the palm with the central portion of the palmar fascia.

The **Superficial Transverse Ligament of the Fingers** is a thin, fibrous band, which stretches across the roots of the four fingers, and is closely attached to the skin of the clefts, and internally to the fifth metacarpal bone, forming a sort of rudimentary web. Beneath it the digital vessels and nerves pass onwards to their destination.

Surgical Anatomy.—The palmar fascia is liable to undergo contraction, producing a very inconvenient deformity, known as 'Dupuytren's contraction.' The ring and little fingers are most frequently implicated, but the middle, the index, and the thumb may be

involved. The proximal phalanx is drawn down and cannot be straightened, and the two distal phalanges become similarly flexed as the disease advances.

Owing to their constant exposure to injury and septic influences, the fingers are very liable to become the seat of serious inflammatory mischief. To this inflammation the term *paronychia* is given, and this affection may assume various degrees of severity. In the mildest cases the disease is confined to the superficial layer of the skin, and suppuration takes place beneath it. This is known as *subcuticular paronychia*, and is a comparatively simple condition, and an incision through the epidermis will at once relieve it. The only complication is that the pus may burrow under the nail, causing increased pain. A more severe condition is the *paronychia cellulosa*, in which the pulp of the end of the finger is involved. This is attended with intense throbbing pain, owing to the fact that the inflamed area is covered by thick and often horny epithelium, when the disease occurs in the labouring classes, as it so frequently does. In these cases, unless a timely incision is made, the inflammation is liable to involve the periosteum covering the phalanx, as there is least resistance in this direction; and *subperiosteal paronychia* is set up, which is followed by necrosis of a part or the whole of the ungual phalanx. In other cases, the inflammation may involve the theca of the Flexor tendons, and a *thecal paronychia* may be set up. The inflammation then rapidly spreads up the sheath; but the extent will depend upon the particular digit involved. From the description of the Flexor sheaths given above (page 527), it will be evident that inflammation of the sheath of the thumb and little finger may prove a far more formidable affection than that of the other three digits, because the sheaths of these two digits communicate with the large synovial sheaths which surround the Flexor tendons, and the inflammation may extend into the palm of the hand and beneath the annular ligament into the forearm.

In order to relieve these conditions, free and early incisions are necessary, and must be made with discrimination, in order to avoid wounding important structures. In the pulp of the finger—i.e. over the distal phalanx—the incision should be made in the middle line and down to the bone. In the rest of the finger, the incision should be made in the middle line over the phalanges, and not over the interphalangeal joints. In the palm of the hand, incisions may be made either on the distal or proximal side of the superficial palmar arch. On the distal sides, the incisions should be made over the metacarpal bones, preferably those of the index and middle finger. On the proximal side, the safest line of incision is along the radial side of the hypothenar eminence, between the ulnar artery and nerve internally, and the median nerve externally. When suppuration has extended under the annular ligament, and incisions are required in the forearm, the positions in which they should be made are over the tendons of the Flexor sublimis digitorum, between the median nerve and the ulnar artery, and over the tendon of the Flexor longus pollicis, between the radial artery and the tendon of the Flexor carpi radialis muscle.

Chronic inflammation of the Flexor tendons of the fingers, probably tuberculous, is occasionally met with, constituting a disease known as 'compound palmar ganglion:' it presents an hourglass outline, with a swelling in front of the wrist and in the palm of the hand, and a constriction, corresponding to the annular ligament, between the two. The fluid can be forced from the one swelling to the other under the ligament, and when this is done, a crackling sensation is sometimes perceived, from the presence of 'melon-seed' bodies in the interior of the ganglion.

11. *Radial Region* (figs. 434, 435)

Abductor pollicis.	Flexor brevis pollicis.
Opponens pollicis.	Adductor obliquus pollicis.

Adductor transversus pollicis.

The **Abductor pollicis** is a thin, flat muscle, placed immediately beneath the integument. It arises from the annular ligament, the tuberosity of the scaphoid, and the ridge of the trapezium, frequently by two distinct slips; and, passing outwards and downwards, is inserted by a thin, flat tendon into the radial side of the base of the first phalanx of the thumb and the capsule of the metacarpo-phalangeal articulation.

Relations.—By its *superficial surface*, with the palmar fascia and superficialis volæ artery, which frequently perforates it. By its *deep surface*, with the Opponens pollicis, from which it is separated by a thin aponeurosis. Between its *inner border* and the Flexor brevis pollicis is a narrow cellular interval.

The **Opponens pollicis** is a small, triangular muscle, placed beneath the preceding. It arises from the palmar surface of the ridge on the trapezium and from the annular ligament, passes downwards and outwards, and is inserted into the whole length of the metacarpal bone of the thumb on its radial side.

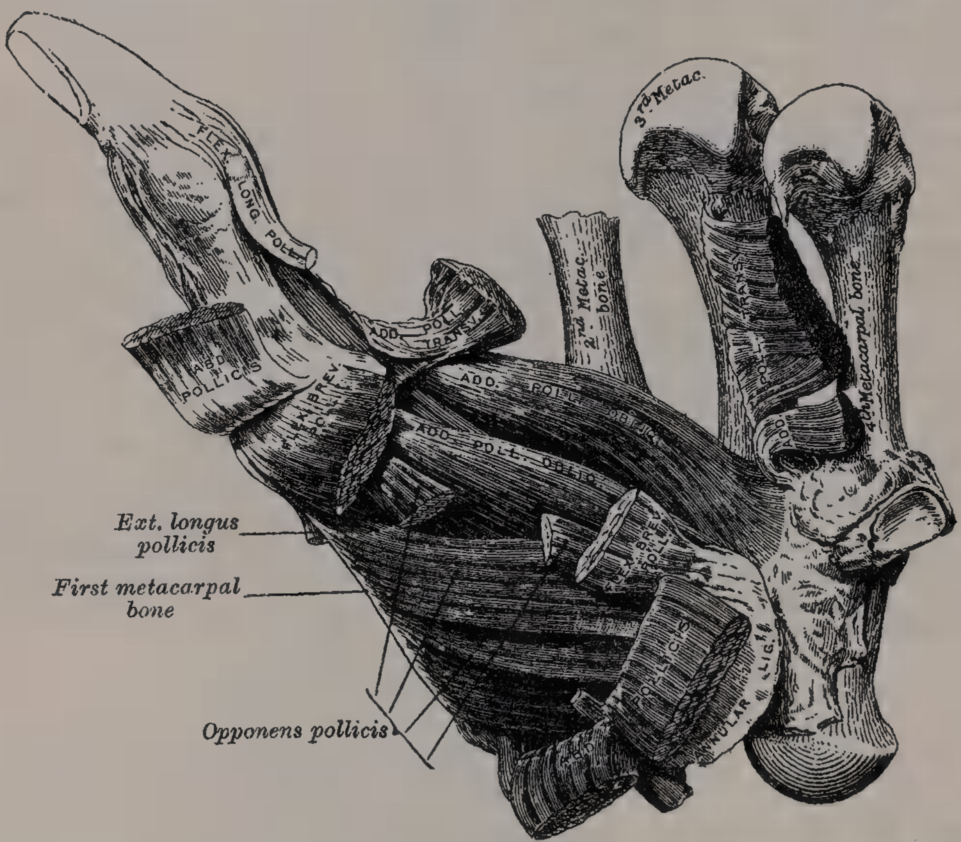
Relations.—By its *superficial surface*, with the Abductor and Flexor brevis pollicis. By its *deep surface*, with the trapezio-metacarpal articulation. By its *inner border*, with the Adductor obliquus pollicis.

The **Flexor brevis pollicis** consists of two portions, outer and inner. The *outer and more superficial portion* arises from the outer two-thirds of the lower border of the annular ligament and the lower part of the ridge on the trapezium; it passes along the outer side of the tendon of the Flexor longus pollicis, and, becoming tendinous, has a sesamoid bone developed in its tendon, and is inserted into the outer side of the base of the first phalanx of the thumb. The *inner and deeper portion* of the muscle is very small, and arises from the ulnar side of the first metacarpal bone between the Adductor obliquus pollicis and the outer head of the First dorsal interosseous, and is inserted into the inner side of the base of the first phalanx with the Adductor obliquus pollicis.

Relations.—By its *superficial surface*, with the palmar fascia. By its *deep surface*, with the tendon of the Flexor longus pollicis. By its *external surface*, with the Opponens pollicis. *Behind*, with the Adductor obliquus pollicis.

The **Adductor obliquus pollicis** arises by several slips from the os magnum, the bases of the second and third metacarpal bones, the anterior carpal ligaments,

FIG. 434.—Muscles of the thumb.
(From a preparation in the Museum of the Royal College of Surgeons of England.)



and the sheath of the tendon of the Flexor carpi radialis. From this origin the greater number of fibres pass obliquely downwards and converge to a tendon, which, uniting with the tendons of the deeper portion of the Flexor brevis pollicis and the Adductor transversus, is inserted into the inner side of the base of the first phalanx of the thumb, a sesamoid bone being developed in the tendon of insertion. A considerable fasciculus, however, passes more obliquely outwards beneath the tendon of the long flexor to join the superficial portion of the short flexor and the Abductor pollicis.

Relations.—By its *superficial surface*, with the Flexor longus pollicis and the outer head of the Flexor brevis pollicis. Its *deep surface* is in relation with the deep palmar arch, which passes between the two adductors.

The **Adductor transversus pollicis** (fig. 434) is the most deeply seated of this group of muscles. It is of a triangular form, arising by its broad base from the lower two-thirds of the metacarpal bone of the middle finger on its palmar surface; the fibres, proceeding outwards, converge, to be inserted, with the inner

part of the Flexor brevis pollicis, and the Adductor obliquus pollicis, into the ulnar side of the base of the first phalanx of the thumb.

Relations.—By its *superficial surface*, with the Adductor obliquus pollicis, the tendons of the Flexor profundus, and the Lumbricales. Its *deep surface* covers the first two interosseous spaces, from which it is separated by a strong aponeurosis.

Nerves.—The Abductor, Opponens, and outer head of the Flexor brevis pollicis are supplied by the sixth cervical through the median nerve; the inner head of the Flexor brevis, and the Adductors, by the eighth cervical through the ulnar nerve.

Actions.—The actions of the muscles of the thumb are almost sufficiently indicated by their names. This segment of the hand is provided with three extensors—an extensor of the metacarpal bone, an extensor of the first, and an extensor of the second phalanx; these occupy the dorsal surface of the forearm and hand. There are also three flexors on the palmar surface—a flexor of the metacarpal bone, a flexor of the proximal, and a flexor of the terminal phalanx; there is also an abductor and two adductors. The Abductor pollicis moves the metacarpal bone of the thumb outwards: that is, away from the index finger. The Opponens pollicis flexes the metacarpal bone: that is, draws it inwards over the palm, and at the same time rotates the bone, so as to turn the ball of the thumb towards the fingers, thus producing the movement of opposition. The Flexor brevis pollicis flexes and adducts the proximal phalanx of the thumb. The Adductores pollicis move the metacarpal bone of the thumb inwards: that is, towards the index finger. These muscles give to the thumb its extensive range of motion. It will be noticed, however, that in consequence of the position of the first metacarpal bone, these movements differ from the corresponding movements of the metacarpal bones of the other fingers. Thus extension of the thumb more nearly corresponds to the motion of abduction in the other fingers, and flexion to adduction.

12. *Ulnar Region* (fig. 435)

Palmaris brevis.	Flexor brevis minimi digiti.
Abductor minimi digiti.	Opponens minimi digiti.

The **Palmaris brevis** is a thin quadrilateral muscle, placed beneath the integument on the ulnar side of the hand. It arises, by tendinous fasciculi, from the annular ligament and palmar fascia; the fleshy fibres pass inwards, to be inserted into the skin on the inner border of the palm of the hand.

Relations.—By its *superficial surface*, with the integument, to which it is intimately adherent, especially by its inner border. By its *deep surface*, with the inner portion of the palmar fascia, which separates it from the ulnar vessels and nerve, and from the muscles of the ulnar side of the hand.

The **Abductor minimi digiti** is situated on the ulnar border of the palm of the hand. It arises from the pisiform bone and from the tendon of the Flexor carpi ulnaris, and terminates in a flat tendon, which divides into two slips; one is inserted into the ulnar side of the base of the first phalanx of the little finger. The other slip is inserted into the ulnar border of the aponeurosis of the Extensor minimi digiti.

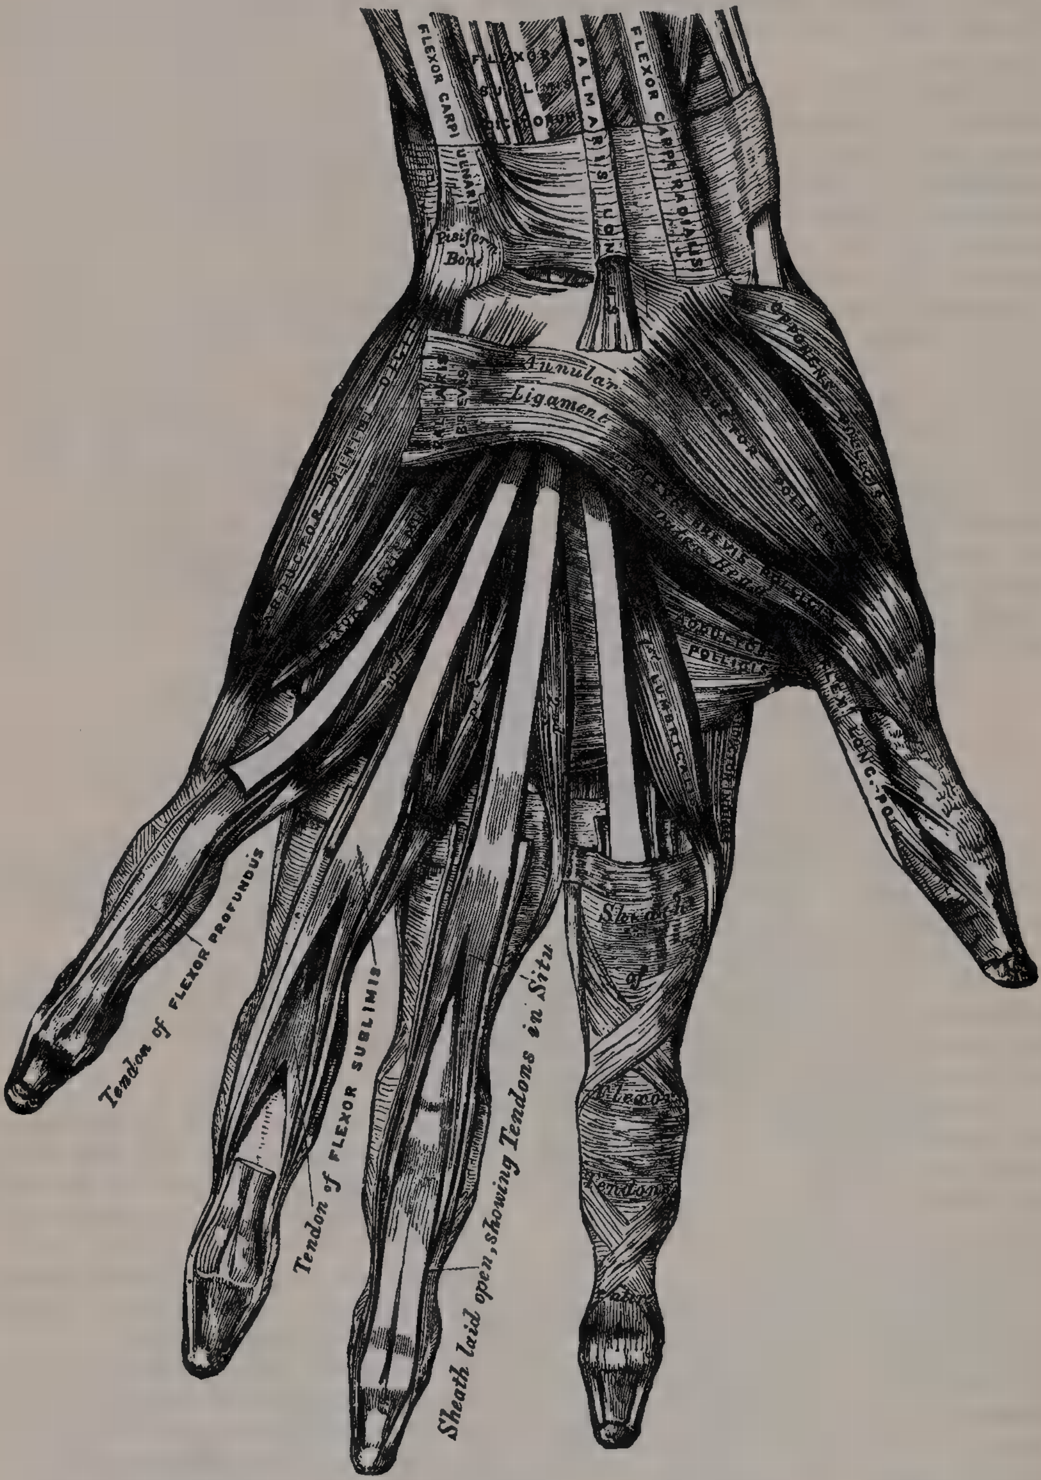
Relations.—By its *superficial surface*, with the inner portion of the palmar fascia, and the Palmaris brevis. By its *deep surface*, with the Opponens minimi digiti. By its *outer border*, with the Flexor brevis minimi digiti.

The **Flexor brevis minimi digiti** lies on the same plane as the preceding muscle, on its radial side. It arises from the convex aspect of the hook of the unciform bone, and anterior surface of the annular ligament, and is inserted into the inner side of the base of the first phalanx of the little finger. It is separated from the Abductor at its origin, by the deep branches of the ulnar artery and nerve. This muscle is sometimes wanting; the Abductor is then, usually, of large size.

Relations.—By its *superficial surface*, with the internal portion of the palmar fascia, and the Palmaris brevis. By its *deep surface*, with the Opponens. The deep branch of the ulnar artery and the corresponding branch of the ulnar nerve pass between the Abductor and Flexor brevis minimi digiti muscles.

The **Opponens minimi digiti** (fig. 426) is of a triangular form, and placed immediately beneath the preceding muscles. It arises from the convexity of the hook of the unciform bone, and contiguous portion of the annular ligament; its fibres pass downwards and inwards, to be inserted into the whole length of the metacarpal bone of the little finger, along its ulnar margin.

FIG. 435.—Muscles of the left hand. Palmar surface.



Relations.—By its *superficial surface*, with the Flexor brevis, and Abductor minimi digiti. By its *deep surface*, with the Interossei muscles in the fourth metacarpal space, the metacarpal bone, and the Flexor tendons of the little finger.

Nerves.—All the muscles of this group are supplied by the eighth cervical nerve through the ulnar nerve.

Actions.—The Abductor minimi digiti abducts the little finger from the ring finger. It corresponds to a dorsal interosseous muscle. It also assists in flexing the proximal phalanx. The Flexor brevis minimi digiti abducts the little finger from the middle line of the hand. It also assists in flexing the proximal phalanx. The Opponens minimi digiti draws forwards the fifth metacarpal bone, so as to deepen the hollow of the palm. The Palmaris brevis corrugates the skin on the inner side of the palm of the hand.

13. *Middle Palmar Region*

Lumbricales. Interossei dorsales.
Interossei palmares.

The **Lumbricales** (fig. 435) are four small fleshy fasciculi, accessories to the Flexor profundus digitorum muscle. They arise from the tendons of the deep Flexor: the first and second, from the radial side and palmar surface of the tendons of the index and middle fingers respectively; the third, from the contiguous sides of the tendons of the middle and ring fingers; and the fourth,

Fig. 436.—The Dorsal interossei of left hand.

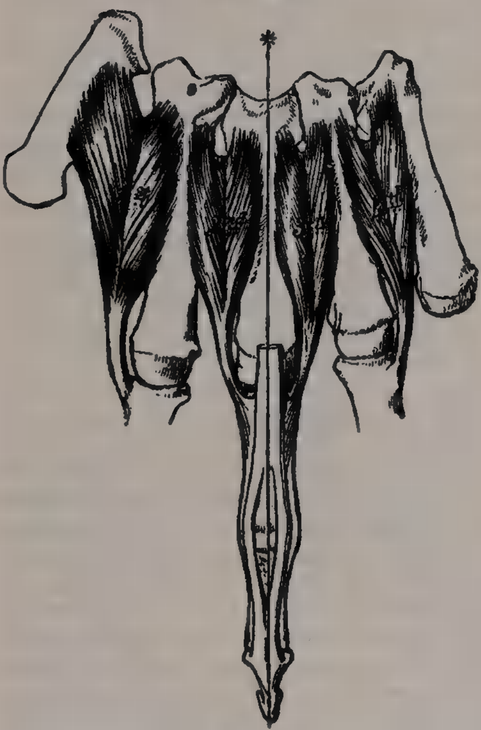


Fig. 437.—The Palmar interossei of left hand.

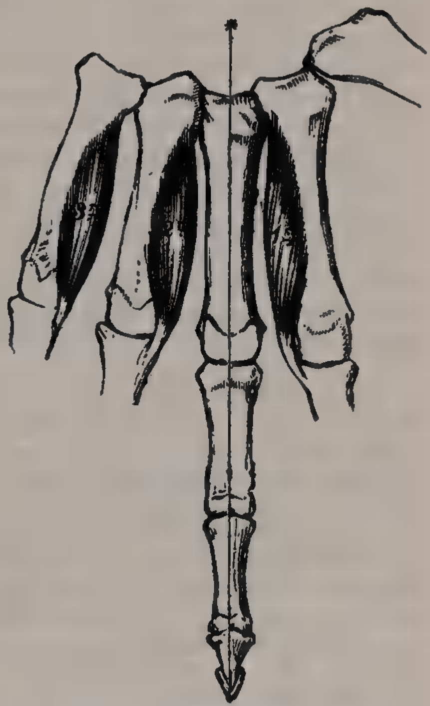


from the contiguous sides of the tendons of the ring and little fingers. They pass to the radial side of the corresponding fingers, and opposite the metacarpo-phalangeal articulation each tendon is inserted into the tendinous expansion of the Extensor communis digitorum, covering the dorsal aspect of each finger.

The **Interossei muscles** (figs. 436, 437) are so named from occupying the intervals between the metacarpal bones, and are divided into two sets, a dorsal and palmar.

The **Dorsal interossei** are four in number, larger than the palmar, and occupy the intervals between the metacarpal bones. They are bipenniform muscles, arising by two heads from the adjacent sides of the metacarpal bones, but more extensively from the metacarpal bone of the finger into which the muscle is inserted. They are inserted into the bases of the first phalanges and into the aponeurosis of the common Extensor tendon. Between the double origin of each of these muscles is a narrow triangular interval, through the first of which the radial artery passes; through each of the other three a perforating branch from the deep palmar arch is transmitted.

The *First dorsal interosseous muscle*, or *Abductor indicis*, is larger than the others. It is flat, triangular in form, and arises by two heads, separated by a fibrous arch, for the passage of the radial artery from the dorsum to the palm of

the hand. The outer head arises from the upper half of the ulnar border of the first metacarpal bone; the inner head, from almost the entire length of the radial border of the second metacarpal bone; the tendon is inserted into the radial side of the index finger. The *second* and *third dorsal interossei* are inserted into the middle finger, the former into its radial, the latter into its ulnar side. The *fourth* is inserted into the ulnar side of the ring finger.

The **Palmar interossei**, three in number, are smaller than the Dorsal, and placed upon the palmar surface of the metacarpal bones, rather than between them. They arise from the entire length of the metacarpal bone of one finger, and are inserted into the side of the base of the first phalanx and aponeurotic expansion of the common Extensor tendon of the same finger.

The *first* arises from the ulnar side of the second metacarpal bone, and is inserted into the same side of the first phalanx of the index finger. The *second* arises from the radial side of the fourth metacarpal bone, and is inserted into the same side of the ring finger. The *third* arises from the radial side of the fifth metacarpal bone, and is inserted into the same side of the little finger. From this account it may be seen that each finger is provided with two Interossei muscles, with the exception of the little finger, in which the Abductor muscle takes the place of one of the pair.

Nerves.—The two outer Lumbricales are supplied by the sixth cervical nerve, through the third and fourth digital branches of the median nerve: the two inner Lumbricales and all the Interossei are supplied by the eighth cervical nerve, through the deep palmar branch of the ulnar nerve. Brooks states that the third lumbrical received a twig from the median in twelve out of twenty-one cases.

Actions.—The Palmar interossei muscles adduct the fingers to an imaginary line drawn longitudinally through the centre of the middle finger; and the Dorsal interossei abduct the fingers from that line. In addition to this the Interossei, in conjunction with the Lumbricales, flex the first phalanges at the metacarpo-phalangeal joints, and extend the second and third phalanges in consequence of their insertion into the expansion of the Extensor tendons. The Extensor communis digitorum is believed to act almost entirely on the first phalanges.

Surface Form.—The *Pectoralis major* largely influences surface form and conceals a considerable part of the thoracic wall in front. Its sternal origin presents a festooned border, which bounds and determines the width of the sternal furrow Its clavicular origin is somewhat depressed and flattened, and between the two portions of the muscle is often an oblique depression, which differentiates the one from the other. The outer margin of the muscle is generally well marked above, and bounds the infraclavicular fossa, a triangular interval which separates the Pectoralis major from the Deltoid. It gradually becomes less marked as it approaches the tendon of insertion, and is more closely blended with the Deltoid muscle. The lower border of the Pectoralis major forms the rounded anterior axillary fold, and corresponds with the direction of the fifth rib. The *Pectoralis minor* influences surface form. When the arm is raised, its lowest slip of origin produces a local fulness just below the border of the anterior fold of the axilla, and so serves to break the sharp line of the lower border of the Pectoralis major muscle which is produced when the arm is in this position. The origin of the *Serratus magnus* causes a very characteristic surface marking. When the arm is raised from the side, in a well-developed subject, the five or six lower serrations are plainly discernible, forming a zigzag line, caused by the series of digitations, which diminish in size from above downwards, and have their apices arranged in the form of a curve. When the arm is lying by the side, the first serration to appear, at the lower margin of the Pectoralis major, is the one attached to the fifth rib. The *Deltoid*, with the prominence of the upper extremity of the humerus, produces the rounded outline of the shoulder. It is rounder and fuller in front than behind, where it presents a somewhat flattened form. Above, its anterior border presents a rounded, slightly curved eminence, which bounds externally the infraclavicular fossa; below, it is closely united with the Pectoralis major. Its posterior border is thin, flattened, and scarcely marked above; below, it is thicker and more prominent. When the muscle is in action, the middle portion becomes irregular, presenting alternate longitudinal elevations and depressions: the elevations corresponding to the fleshy portions; the depressions, to the tendinous intersections of the muscle. The insertion of the Deltoid is marked by a depression on the outer side of the middle of the arm. Of the scapular muscles, the only one which materially influences surface form is the *Teres major*, which assists the Latissimus dorsi in forming the thick, rounded, posterior fold of the axilla. When the arm is raised, the Coraco-brachialis reveals itself as a long, narrow elevation, which

emerges from under cover of the anterior fold of the axilla and runs downwards, internal to the shaft of the humerus. When the arm is hanging by the side, its front and inner part presents the prominence of the Biceps, bounded on either side by an intermuscular depression. This muscle determines the contour of the front of the arm, and extends from the anterior margin of the axilla to the bend of the elbow. Its upper tendons are concealed by the Pectoralis major and the Deltoid, and its lower tendon sinks into the space at the bend of the elbow. When the muscle is in a state of complete contraction—that is to say, when the forearm has been flexed and supinated—it presents a rounded convex form, bulged out laterally, and its length is diminished. On each side of the Biceps, at the lower part of the arm, the *Brachialis anticus* is discernible. On the outer side it forms a narrow eminence, which extends some distance up the arm along the border of the Biceps. On the inner side it shows itself only as a little fulness just above the elbow. On the back of the arm the long head of the *Triceps* may be seen as a longitudinal eminence emerging from under cover of the Deltoid, and gradually merging into the longitudinal flattened plane of the tendon of the muscle on the lower part of the back of the arm. The tendon of insertion of the muscle extends about halfway up the back of the arm, where it forms an elongated flattened plane when the muscle is in action. Under similar conditions the surface forms produced by the three heads of the muscle are well seen. On the anterior aspect of the elbow are to be seen two muscular elevations, one on each side, separated above, and converging below so as to form a triangular space. Of these, the inner elevation, consisting of the flexors and pronator, forms the prominence along the inner side and front of the forearm. It is a fusiform mass, pointed above at the internal condyle, and gradually tapering off below. The *Pronator radii teres*, the innermost muscle of the group, forms the boundary of the triangular space at the bend of the elbow. It is shorter, less prominent, and more oblique than the outer boundary. The most prominent part of the eminence is produced by the *Flexor carpi radialis*, the muscle next in order on the inner side of the preceding one. It forms a rounded prominence above, and may be traced downwards to its tendon, which can be felt lying on the front of the wrist, nearer to the radial than to the ulnar border and to the inner side of the radial artery. The *Palmaris longus* presents no surface marking above, but, below, is the most prominent tendon on the front of the wrist, standing out, when the muscle is in action, as a sharp tense cord beneath the skin. The *Flexor sublimis digitorum* does not directly influence surface form. The position of its four tendons on the front of the lower part of the forearm is indicated by an elongated depression between the tendons of the Palmaris longus and the Flexor carpi ulnaris. The *Flexor carpi ulnaris* occupies a small part of the posterior surface of the forearm, and is separated from the extensor and supinator group, which occupies the greater part of this surface, by the ulnar furrow, produced by the subcutaneous posterior border of the ulna. Its tendon can be perceived along the ulnar border of the front of the forearm, and is most marked when the hand is flexed and adducted. The deep muscles of the front of the forearm have no direct influence on surface form. The external group of muscles of the forearm, consisting of the extensors and supinators, occupy the outer, and a considerable portion of the posterior, surface of this region. It has a fusiform outline, which is altogether on a higher level than the pronato-flexor group. Its apex emerges from between the Triceps and Brachialis anticus muscles some distance above the elbow-joint, and acquires its greatest breadth opposite the external condyle, and thence gradually shades off into a flattened surface. About the middle of the forearm it divides into two longitudinal eminences which diverge from each other, leaving a triangular interval between them. The outer of these two groups of muscles consists of the Supinator longus and the Extensor carpi radialis longior and brevior, which forms a longitudinal eminence descending from the external condylar ridge in the direction of the styloid process of the radius. The other and more posterior group consists of the Extensor communis digitorum, the Extensor minimi digiti, and the Extensor carpi ulnaris. It commences above as a tapering form at the external condyle of the humerus, and is separated behind at its upper part from the Anconeus by a well-marked furrow; and below, from the pronato-flexor mass, by the ulnar furrow. In the triangular interval left between these two groups, the Extensor muscles of the thumb and index finger are seen. The only two muscles of this region which require special mention, as independently influencing surface form, are the Supinator longus and the Anconeus. The inner border of the *Supinator longus* forms the outer boundary of the triangular space at the bend of the elbow. It commences as a rounded border above the condyle, and is longer, less oblique, and more prominent than the inner boundary. Lower down, the muscle forms a full fleshy mass on the outer side of the upper part of the forearm, and below tapers into a tendon, which may be traced down to the styloid process of the radius. The *Anconeus* presents a distinct and characteristic surface form in the shape of a triangular, slightly elevated surface, immediately external to the subcutaneous posterior surface of the olecranon, and differentiated from the common extensor group by a well-marked oblique longitudinal depression. The upper angle of the triangle corresponds to the external condyle, and is marked by a depression or dimple in this situation. In the interval, caused by the divergence from each other or the two groups of muscles into which the extensor and supinator group is divided at the

lower part of the forearm, an oblique elongated eminence is seen, caused by the emergence of two of the extensors of the thumb from their deep origin at the back of the forearm, This eminence, full above, and becoming flattened out and partially subdivided below, runs downwards and outwards over the back and outer surface of the radius to the outer side of the wrist-joint, where it forms a ridge, especially marked when the thumb is extended, which passes onwards to the posterior aspect of the thumb. The tendons of most of the Extensor muscles are to be seen and felt at the level of the wrist-joint. Most externally are the tendons of the Extensor ossis metacarpi pollicis and the Extensor brevis pollicis, forming a vertical ridge over the outer side of the joint from the styloid process of the radius to the thumb. Internal to this is the oblique ridge produced by the tendon of the Extensor longus pollicis, very noticeable when the muscle is in action. The Extensor carpi radialis longior is scarcely to be felt, but the Extensor carpi radialis brevior can be distinctly perceived, as a vertical ridge emerging from under the ulnar border of the tendon of the Extensor longus pollicis, when the hand is forcibly extended at the wrist. Internal to this, again, can be felt the tendons of the Extensor indicis, Extensor communis digitorum, and Extensor minimi digiti; the latter tendon being separated from those of the common extensor by a slight furrow. The muscles of the hand are principally concerned, as far as regards surface form, in producing the thenar and hypothenar eminences, and individually are not to be distinguished, on the surface, from each other. The *Adductor transversus pollicis* is, however, an exception to this; its anterior border gives rise to a ridge across the web of skin connecting the thumb to the rest of the hand. The thenar eminence is much larger and rounder than the hypothenar one, which presents a longer and narrower eminence along the ulnar side of the hand. When the *Palmaris brevis* is in action it produces a wrinkling of the skin over the hypothenar eminence, and a deep dimple on the ulnar border of the hand. On the back of the hand the *Dorsal interossei* produce elongated swellings between the metacarpal bones. When the thumb is closely adducted to the hand, the first dorsal interosseous (Abductor indicis) forms a prominent fusiform bulging; the other interossei are not so marked.

The skin over the inner side and front of the forearm is thin, smooth and sensitive; it contains few hairs and many sweat-glands. Over the outer side and back of the arm and forearm it is thicker, denser, not so sensitive, and contains more hairs and fewer sweat-glands. Over the olecranon the cuticle is thick and rough; the skin loosely connected to the underlying tissues, and transversely wrinkled when the forearm is extended. At the front of the wrist, the skin presents three transverse wrinkles, which correspond to the position of the styloid process of the ulna, the wrist-joint, and the mid-carpal joint respectively. The skin of the palm of the hand differs considerably from that of the forearm. At the wrist, it suddenly becomes hard and dense and covered with a thick layer of cuticle. The skin in the thenar region presents these characteristics less than elsewhere. In spite of this hardness and density, the skin of the palm is exceedingly sensitive and very vascular. It is destitute of hair, and contains no sebaceous follicles. The skin of the palm is tied down by fibrous bands along the lines of flexion, producing certain furrows of a permanent character. One of these (*linea vitalis*), starting from about the tubercle of the scaphoid, extends downwards and inwards, and then downwards and outwards, curving round the thenar eminence, and terminates on the radial border of the hand, a little above the metacarpo-phalangeal joint of the index finger. It corresponds to the outer border of the central portion of the palmar fascia, and is produced by the special movement of opposition of the thumb to the other fingers. A second line (*linea cephalica*) commences at the termination of the first, and extends obliquely across the palm, upwards and inwards, to the ulnar margin about the middle of the fifth metacarpal bone. A third (*linea mensalis*) commences at the ulnar border of the hand, about an inch below the termination of the linea cephalica, and extends outwards across the palm over the heads of the third, fourth, and fifth metacarpal bones. The last two lines are caused by flexion of the fingers at the metacarpo-phalangeal joint. From the linea mensalis, furrows pass vertically downwards along each finger, corresponding to the lines of attachment of the skin to the sheaths of the Flexor tendons. These are called *valleculæ*, and between them are small projections or hillocks, caused by bulging of the subcutaneous tissues when the tendons are stretched. They are named, from the thumb to the little finger, *eminentia Veneris, Jovis, Saturni, Solis*, and *Mercurii*. Over the fingers the skin again becomes thinner, especially at the flexures of the joints; and over the terminal phalanges it is thrown into numerous ridges, in consequence of the arrangement of the papillæ in it. These ridges form, in different individuals, distinctive and permanent patterns, which may be used for purposes of identification. The superficial fascia in the palm is made up of dense fibro-fatty tissue. This tissue binds down the skin so firmly to the deep palmar fascia that very little movement is permitted between the two.

Surgical Anatomy.—The student, having completed the dissection of the muscles of the upper extremity, should consider the effects likely to be produced by the action of the various muscles in fracture of the bones.

In considering the actions of the various muscles upon fractures of the upper extremity, the most common forms of injury have been selected both for illustration and description.

Fracture of the *middle of the clavicle* (fig. 438) is always attended with considerable displacement of the outer fragment, which is drawn downwards and inwards, and at the same time rotated, so that its outer end is carried forwards and its inner end backwards.

The displacement is produced as follows: the outer fragment is drawn *downwards* by the weight of the arm, the Trapezius not being able to support the weight of the limb. It is drawn *inwards* by the Subclavius and Pectoralis minor, possibly assisted by the Pectoralis major and Latissimus dorsi; and is rotated on an axis drawn through it own centre by the Serratus magnus, which causes the scapula to rotate on the wall of the chest, and carries the acromion and outer end of the outer fragment of the clavicle forwards, and so carries the inner end of the outer portion backwards. The depression of the whole outer fragment is produced by the weight of the arm and by the contraction of the Deltoid. The causes of displacement having been ascertained, it is easy to apply the appropriate treatment. The outer fragment is to be drawn outwards, and, together with the scapula, raised upwards to a level with the inner fragment, and retained in that position.

Fig. 438.—Fracture of the middle of the clavicle.

In fracture of the *acromial end of the clavicle*, between the conoid and trapezoid ligaments, only slight displacement occurs, as these ligaments, from their oblique insertion, serve to hold both portions of the bone in apposition. Fracture, also, of the *sternal end*, internal to the costo-clavicular ligament, is attended with only slight displacement, this ligament serving to retain the fragments in close apposition.

Fracture of the *acromion process* outside the ligaments usually arises from violence applied to the upper and outer part of the shoulder. There is great displacement; the outer fragment being drawn downwards by the weight of the arm, and rotated forwards and inwards, so that it forms a right angle with the rest of the bone.

Fracture of the *coracoid process* is an extremely rare accident, and is usually caused by a sharp blow on the point of the shoulder. In many cases there appears to be little or no displacement, from the fact that the coraco-clavicular ligament remains intact, and keeps the separated fragment from displacement. But in some cases displacement does occur, the fragment being drawn downwards and forwards by the Coraco-brachialis and Biceps, and inwards by the Pectoralis minor. In order to relax these muscles and replace the fragments in close apposition, the forearm should be flexed so as to relax the Biceps, and the arm drawn forwards and inwards across the chest so as to relax the Coraco-brachialis; the humerus should then be pushed upwards against the coraco-acromial ligament, and the arm retained in that position.

Fig. 439.—Fracture of the surgical neck of the humerus.

Fracture of the *surgical neck of the humerus* (fig. 439) is very common, is attended with considerable displacement, and its appearances correspond somewhat with those of dislocation of the head of the humerus into the axilla. The upper fragment is slightly elevated under the coraco-acromial ligament by the muscles attached to the greater and lesser tuberosities; the lower fragment is drawn inwards by the Pectoralis major, Latissimus dorsi, and Teres major; and the humerus is thrown obliquely outwards from the side by the Deltoid, and occasionally elevated so as to cause the upper end of the lower fragment to project beneath and in front of the coracoid process. The deformity is reduced by fixing the shoulder, and drawing the arm outwards and downwards. To counteract the opposing muscles, and to keep the fragments in position, a conical-shaped pad should be placed in the axilla, and the arm bandaged to the side by a broad roller passed round the chest, in such a manner that the elbow is carried slightly forwards, so as to throw the upper end of the lower fragment backwards and outwards

towards the head of the bone. The whole is then covered with a carefully moulded guttapercha or poroplastic shoulder-cap.

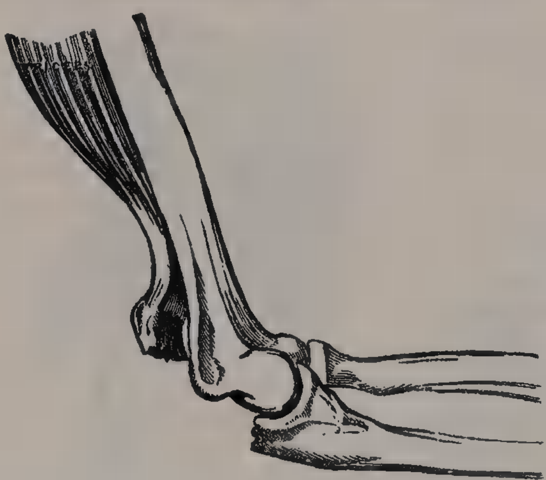
In fracture of the *shaft of the humerus* below the insertion of the Pectoralis major, Latissimus dorsi, and Teres major, and above the insertion of the Deltoid, there is also considerable deformity, the upper fragment being drawn inwards by the first-mentioned muscles, and the lower fragment upwards and outwards by the Deltoid, producing shortening of the limb, and a considerable prominence at the seat of fracture, from the fractured ends of the bone riding over one another, especially if the fracture takes place in an oblique direction. The fragments may be brought into apposition by extension from the elbow, and retained in that position by adopting the same means as in the preceding injury.

Fig. 440.—Fracture of the humerus above the condyles.

In fractures of the *shaft of the humerus* immediately below the insertion of the Deltoid, the amount of deformity depends greatly upon the direction of the fracture. If it occurs in a transverse direction, only slight displacement takes place, the upper fragment being drawn a little forwards; but in oblique fracture, the combined actions of the Biceps and Brachialis anticus muscles in front, and the Triceps behind, draw upwards the lower fragment, causing it to glide over the upper fragment, either backwards or forwards, according to the direction of the fracture. Simple extension reduces the deformity, and the application of a shoulder cap and splints to the arm will retain the fragments in apposition (see page 279). Care should be taken not to raise the elbow; but the forearm and hand may be supported in a sling.

Fracture of the *humerus* (fig. 440) immediately above the condyles deserves very attentive consideration, as the general appearances correspond somewhat with those produced by separation of the epiphysis of the humerus, and with those of dislocation of the radius and ulna backwards. If the direction of the fracture is oblique, from above, downwards and forwards, the lower fragment is drawn upwards by the Brachialis anticus and Biceps in front, and the Triceps behind; and at the same time is drawn backwards behind the upper fragment by the Triceps. This injury may be diagnosed from dislocation by the increased mobility in fracture, the existence of crepitus, and the fact of the deformity being remedied by extension, on the discontinuance of which it is reproduced. The age of the patient is of importance in distinguishing this form of injury from separation of the epiphysis. In some cases where the injury has been produced by falls on the elbow, the lower fragment is drawn upwards and forwards, causing a considerable prominence in front; and the upper fragment projects backwards beneath the tendon of the Triceps muscle.

Fig. 441.—Fracture of the olecranon.



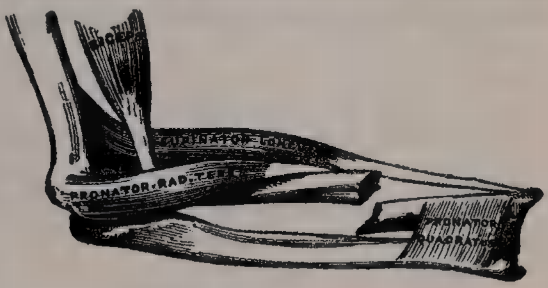
Fracture of the *olecranon process* (fig. 441) is a frequent accident. The detached fragment is displaced upwards, by the action of the Triceps muscle, from half an inch to two inches; the prominence of the elbow is consequently lost, and a deep hollow is felt at the back part of the joint, which is much increased on flexing the limb. The patient at the same time loses, more or less, the power of extending the forearm. The treatment consists in wiring the fragments together; but if for some reason this operation is not desirable, the fragments should be approximated by strapping or a figure-of-8 bandage, and the arm put up in an extended position in order to relax the Triceps. Massage and passive movements must be employed, for fear of ankylosis. Union is generally ligamentous.

Fracture of the *neck of the radius* is an exceedingly rare accident, and is usually caused by direct violence. Its diagnosis is somewhat obscure, on account of the slight deformity visible, the injured part being surrounded by a large number of muscles; but the movements of pronation and supination are entirely lost. The lower fragment is

drawn forwards and slightly upwards by the Biceps, and inwards by the Pronator radii teres, its displacement forwards and upwards being counteracted in some degree by the Supinator brevis. The treatment essentially consists in relaxing the Biceps, Supinator brevis, and Pronator radii teres muscles, by flexing the forearm, and placing it in a position midway between pronation and supination, extension having been previously made so as to bring the parts in apposition.

In fracture of the *radius* below the insertion of the Biceps, but above the insertion of the Pronator radii teres, the upper fragment is strongly supinated by the Biceps and Supinator brevis, and at the same time drawn forwards and flexed by the Biceps; the lower fragment is pronated and drawn inwards towards the ulna by the pronators. Thus there is extreme displacement with very little deformity. In treating such a fracture the arm must be put up in a position of supination, otherwise union will take place with great impairment of the movements of the hand. In fractures of the radius below the insertion of the Pronator radii teres (fig. 442), the upper fragment is drawn upwards by the Biceps, and inwards by the Pronator radii teres, holding a position midway between pronation and supination, and a degree of fulness in the upper half of the forearm is thus produced: the lower fragment is drawn downwards and inwards towards the ulna by the Pronator quadratus, and thrown into a state of pronation by the same muscle; at the same time, the Supinator longus, by elevating the styloid process, into which it is inserted, will serve to depress the upper end of the lower fragment still more towards the ulna. In order to relax the opposing muscles the forearm should be bent, and the limb placed in a position midway between pronation and supination; the fracture is then easily reduced by extension from the wrist and elbow: well-padded splints should be applied on both sides of the forearm from the elbow to the wrist; the hand being allowed to fall will, by its own weight, counteract the action of the Pronator quadratus and Supinator longus, and elevate the lower fragment to the level of the upper one.

Fig. 442.—Fracture of the shaft of the radius.



In fracture of the *shaft of the ulna* the upper fragment retains its usual position, but the lower fragment is drawn outwards towards the radius by the Pronator quadratus, producing a well-marked depression at the seat of fracture, and some fulness on the dorsal and palmar surfaces of the forearm. The fracture is easily reduced by extension from the wrist and forearm. The forearm should be flexed, and placed in a position midway between pronation and supination, and well-padded splints applied from the elbow to the ends of the fingers.

In fracture of the *shafts of the radius and ulna together*, the lower fragments are drawn upwards, sometimes forwards, sometimes backwards, according to the direction of the fracture, by the combined actions of the Flexor and Extensor muscles, producing a degree of fulness on the dorsal or palmar surface of the forearm; at the same time the lower fragments are drawn into contact by the Pronator quadratus, the radius being in a state of pronation: the upper fragment of the radius is drawn upwards and inwards by the Biceps and Pronator radii teres to a higher level than the ulna; the upper portion of the ulna is slightly elevated by the Brachialis anticus. The fracture may be reduced by extension from the wrist and elbow, and the forearm should be placed in the same position as in fracture of the ulna.

Fig. 443.—Fracture of the lower end of the radius.

In fracture of the *lower end of the radius* (fig. 443) the displacement which is produced is very considerable, and bears some resemblance to dislocation of the carpus backwards,

from which it should be carefully distinguished. The lower fragment is displaced backwards and upwards, but this displacement is probably due to the force of the blow driving the portion of the bone into this position and not to any muscular influence. The upper fragment projects forwards, often lacerating the substance of the Pronator quadratus, and is drawn by this muscle into close contact with the lower end of the ulna, causing a projection on the anterior surface of the forearm, immediately above the carpus, from the Flexor tendons being thrust forwards. This fracture may be distinguished from dislocation by the deformity being removed on making sufficient extension, when crepitus may be occasionally detected; at the same time, on extension being discontinued, the parts immediately resume their deformed appearance (see also page 290). The age of the patient will assist in determining whether the injury is fracture or separation of the epiphysis. The treatment consists in flexing the forearm, and making powerful extension from the wrist and elbow, depressing at the same time the radial side of the hand, and retaining the parts in that position by well-padded *pistol-shaped* splints.

MUSCLES AND FASCIÆ OF THE LOWER EXTREMITY

The Muscles of the Lower Extremity are subdivided into groups, corresponding with the different regions of the limb.

I. Iliac Region

Psoas magnus.
Psoas parvus.
Iliacus.

II. Thigh

1. *Anterior Femoral Region*

Tensor fasciæ femoris.
Sartorius.
Quadriceps extensor { Rectus femoris. Vastus externus. Vastus internus. Crureus.
Subcrureus.

2. *Internal Femoral Region*

Gracilis.
Pectineus.
Adductor longus.
Adductor brevis.
Adductor magnus.

3. *Gluteal Region*

Gluteus maximus.
Gluteus medius.
Gluteus minimus.
Pyriformis.
Obturator internus.
Gemellus superior.
Gemellus inferior.
Quadratus femoris.
Obturator externus.

4. *Posterior Femoral Region*

Biceps.
Semitendinosus.
Semimembranosus.

III. Leg

5. *Anterior Tibio-fibular Region*

Tibialis anticus.
Extensor proprius hallucis.
Extensor longus digitorum.
Peroneus tertius.

6. *Posterior Tibio-fibular Region*

Superficial Layer

Gastrocnemius.
Soleus.
Plantaris.

Deep Layer

Popliteus.
Flexor longus hallucis.
Flexor longus digitorum.
Tibialis posticus.

7. *Fibular Region*

Peroneus longus.
Peroneus brevis.

IV. Foot

8. *Dorsal Region*

Extensor brevis digitorum.

9. *Plantar Region*

First Layer

Abductor hallucis.
Flexor brevis digitorum.
Abductor minimi digiti.

Second Layer

Flexor accessorius.
Lumbricales.

Third Layer

Flexor brevis hallucis.
Adductor obliquus hallucis.
Flexor brevis minimi digiti.
Adductor transversus hallucis

Fourth Layer

The Interossei.

I. Muscles and Fasciæ of the Iliac Region

Psoas magnus. Psoas parvus. Iliacus.

Dissection.—No detailed description is required for the dissection of these muscles. On the removal of the viscera from the abdomen, they are exposed, covered by the peritoneum and a thin layer of fascia, the iliac fascia.

The **Fascia covering the Psoas and Iliacus** is the aponeurotic layer which lines the back part of the abdominal cavity, and covers the Psoas and Iliacus muscles throughout their whole extent. It is thin above, and becomes gradually thicker below as it approaches Poupart's ligament.

The *portion covering the Psoas* is thickened above to form the ligamentum arcuatum internum, which stretches from the transverse process of the first lumbar vertebra to the body of the second; internally, it is attached by a series of arched processes to the intervertebral discs, and prominent margins of the bodies of the vertebræ, and to the upper part of the sacrum; the intervals so left, opposite the constricted portions of the bodies, transmitting the lumbar arteries and veins and filaments of the sympathetic cord. Externally, above the crest of the ilium, this portion of the fascia is continuous with the anterior lamella of the lumbar fascia covering the front of the Quadratus lumborum (see page 470), but below the crest of the ilium it is continuous with the fascia covering the Iliacus.

The *portion investing the Iliacus* (Fascia iliaca*) is connected, externally, to the whole length of the inner border of the crest of the ilium; and internally, to the brim of the true pelvis, where it is continuous with the periosteum; and at the ilio-pectineal eminence it receives the tendon of insertion of the Psoas parvus, when that muscle exists. External to the femoral vessels, this fascia is intimately connected to the posterior margin of Poupart's ligament, and is continuous with the fascia transversalis. Immediately to the outer side of the femoral vessels the fascia iliaca is prolonged backwards and inwards from Poupart's ligament as a band, the *ilio-pectineal ligament*, which is attached to the ilio-pectineal eminence. This ligament divides the space between Poupart's ligament and the innominate bone into two parts, the inner of which transmits the femoral vessels, the outer the ilio-psoas and the anterior crural nerve (fig. 360). Internal to the vessels the iliac fascia is attached to the ilio-pectineal line behind the conjoined tendon, where it is again continuous with the transversalis fascia; and corresponding to the point where the femoral vessels pass into the thigh, this fascia descends behind them forming the posterior wall of the femoral sheath. This portion of the iliac fascia which passes behind the femoral vessels is also attached to the ilio-pectineal line beyond the limits of the attachment of the conjoined tendon; at this part it is continuous with the pubic portion of the fascia lata of the thigh. The external iliac vessels lie in front of the iliac fascia, but all the branches of the lumbar plexus behind it; it is separated from the peritoneum by a quantity of loose areolar tissue.

The **Psoas magnus** (fig. 445) is a long fusiform muscle placed on the side of the lumbar region of the spine and margin of the pelvis. It arises from the front of the bases and lower borders of the transverse processes of the lumbar vertebræ by five fleshy slips; also from the sides of the bodies, and the corresponding intervertebral substances of the last dorsal and all the lumbar vertebræ. The muscle is connected to the bodies of the vertebræ by five slips; each slip is attached to the upper and lower margins of two vertebræ, and to the intervertebral substance between them; the slips themselves being connected by tendinous arches which extend across the constricted part of the bodies, and beneath which pass the lumbar arteries and veins and filaments of the sympathetic cord. These tendinous arches also give origin to muscular fibres, and protect the blood-vessels and nerves from pressure during the action of the muscle. The first slip is attached to the contiguous margins of the last dorsal and first lumbar vertebræ; the last to the contiguous margins of the fourth and fifth lumbar vertebræ, and to the intervertebral substance. From these points the muscle proceeds downward across the brim of the pelvis, and, diminishing gradually in size, passes beneath Poupart's ligament, and

* The student must not confound this fascia with the *iliac portion of the fascia lata* (see page 545).

terminates in a tendon, which, after receiving nearly the whole of the fibres of the Iliacus, is inserted into the lesser trochanter of the femur.

Relations.—In the lumbar region: By its *anterior surface*, with the ligamentum arcuatum internum, the iliac fascia, the extra-peritoneal fat and peritoneum, the kidney, Psoas parvus, renal vessels, ureter, spermatic vessels, genito-crural nerve, and the colon. By its *posterior surface*, with the transverse processes of the lumbar vertebræ, and the Quadratus lumborum, from which it is separated by the anterior lamella of the lumbar fascia. The lumbar plexus is situated in the posterior part of the substance of the muscle. By its *inner side*, the muscle is in relation with the bodies of the lumbar vertebræ, the lumbar arteries, the ganglia of the sympathetic nerve, and their branches of communication with the spinal nerves; the lumbar glands; the vena cava inferior on the right, and the aorta on the left side, and along the brim of the pelvis with the external iliac artery. In the thigh it is in relation, in front, with the fascia lata; behind, with the capsular ligament of the hip, from which it is separated by a synovial bursa, which frequently communicates with the cavity of the joint through an opening of variable size; by its *inner border*, with the Pectineus and internal circumflex artery, and also with the femoral artery, which slightly overlaps it; by its *outer border*, with the anterior crural nerve and Iliacus muscle.

The **Psoas parvus** is a long slender muscle, placed in front of the Psoas magnus. It arises from the sides of the bodies of the last dorsal and first lumbar vertebræ and from the intervertebral substance between them. It forms a small muscular bundle, which terminates in a long flat tendon, inserted into the ilio-pectineal line and eminence, and, by its outer border, into the fascia iliaca. This muscle is often absent, and, according to Cruveilhier, sometimes double.

Relations.—The Psoas parvus is covered by the peritoneum, and, at its origin, by the ligamentum arcuatum internum; it rests on the Psoas magnus.

The **Iliacus** is a flat, triangular muscle, which fills up the whole of the iliac fossa. It arises from the upper two-thirds of this fossa, and from the inner margin of the crest of the ilium; behind, from the anterior sacro-iliac and the ilio-lumbar ligaments, and base of the sacrum; in front, it reaches as far as the anterior superior and anterior inferior spinous processes of the ilium, and the notch between them. The fibres converge to be inserted into the outer side of the tendon of the Psoas, some of them being prolonged on to the shaft of the femur for about an inch below and in front of the lesser trochanter.*

Relations.—Within the abdomen: By its *anterior surface*, with the iliac fascia, which separates the muscle from the extra-peritoneal fat and peritoneum, and with the external cutaneous nerve; on the right side, with the cæcum; on the left side, with the sigmoid flexure of the colon. By its *posterior surface*, with the iliac fossa. By its *inner border*, with the Psoas magnus, and anterior crural nerve. In the thigh, it is in relation, by its *anterior surface*, with the fascia lata, Rectus, Sartorius, and profunda femoris artery; behind, with the capsule of the hip-joint, a synovial bursa common to it and the Psoas magnus being interposed.

Nerves.—The Psoas magnus is supplied by the anterior branches of the second and third lumbar nerves; the Psoas parvus, when it exists, is supplied by the anterior branch of the first lumbar nerve; and the Iliacus by the anterior branches of the second and third lumbar nerves through the anterior crural.

Actions.—The Psoas and Iliacus muscles, acting from above, flex the thigh upon the pelvis: acting from below, the femur being fixed, the muscles of both sides bend the lumbar portion of the spine and pelvis forwards. They also serve to maintain the erect position, by supporting the spine and pelvis upon the femur, and assist in raising the trunk when the body is in the recumbent posture.

The *Psoas parvus* is a tensor of the iliac fascia.

Surgical Anatomy.—In the iliac fascia there is no definite septum between the portions of fascia covering the Psoas and Iliacus respectively, and the fascia is only connected to the subjacent muscles by a quantity of loose connective tissue. When an abscess forms beneath this fascia, as it is very apt to do, the matter is contained in an osseo-fibrous cavity

* The Psoas and Iliacus are sometimes regarded as a single muscle, the *Ilio-psoas*, having two heads of origin and a single insertion.

which is closed on all sides within the abdomen, and is open only at its lower part, where the fascia is prolonged over the muscle into the thigh.

Abscess within the sheath of the Psoas muscle (*Psoas abscess*) is generally due to tuberculous caries of the bodies of the lower dorsal and lumbar vertebræ. When the disease is in the dorsal region, the matter tracks down the posterior mediastinum, in front of the bodies of the vertebræ, and, passing beneath the Ligamentum arcuatum internum, enters the sheath of the Psoas muscle, down which it passes as far as the pelvic brim; it then gets beneath the iliac portion of the fascia, and fills up the iliac fossa. In consequence of the attachment of the fascia to the pelvic brim, it rarely finds its way into the pelvis, but passes by a narrow opening under Poupart's ligament into the thigh, to the outer side of the femoral vessels. It thus follows that a Psoas abscess may be described as consisting of four parts: (1) a somewhat narrow channel at its upper part, in the Psoas sheath; (2) a dilated sac in the iliac fossa; (3) a constricted neck under Poupart's ligament; and (4) a dilated sac in the upper part of the thigh. When the lumbar vertebræ are the seat of the disease, the matter finds its way directly into the substance of the muscle. The muscular fibres are destroyed, and the nervous cords contained in the abscess are isolated and exposed in its interior; the femoral vessels which lie in front of the fascia remain intact, and the peritoneum seldom becomes implicated. All Psoas abscesses do not, however, pursue this course: the matter may leave the sheath of the muscle above the crest of the ilium, and tracking backwards may point in the loin (*lumbar abscess*); or it may point above Poupart's ligament in the inguinal region; or it may follow the course of the iliac vessels into the pelvis, and, passing through the great sacro-sciatic notch, discharge itself on the back of the thigh; or it may open into the bladder, or find its way into the perinæum.

II. Muscles and Fasciæ of the Thigh

1. *Anterior Femoral Region*

Tensor fasciæ femoris.
Sartorius.

Quadriceps extensor:
- Rectus femoris.
- Vastus externus.
- Vastus internus.
- Crureus.

Subcrureus.

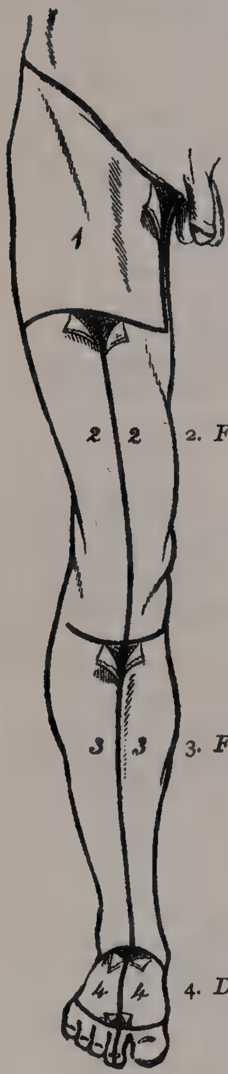
Dissection.—To expose the muscles and fasciæ in this region, make an incision along Poupart's ligament, from the anterior superior spine of the ilium to the spine of the os pubis; a vertical incision from the centre of this, along the middle of the thigh to below the knee-joint; and a transverse incision from the inner to the outer side of the leg, at the lower end of the vertical incision. The flaps of integument having been removed, the superficial and deep fasciæ should be examined. The more advanced student should commence the study of this region by an examination of the anatomy of femoral hernia, and Scarpa's triangle, the incisions for the dissection of which are marked out in fig. 444.

The **superficial fascia** forms a continuous layer over the whole of the thigh, consisting of areolar tissue, containing in its meshes much fat, and capable of being separated into two or more layers, between which are found the superficial vessels and nerves. It varies in thickness in different parts of the limb; in the groin it is thick, and the two layers are separated from one another by the superficial inguinal lymphatic glands, the internal saphenous vein, and several smaller vessels. One of these two layers, the superficial, is continuous above with the superficial fascia of the abdomen. The deep layer of the superficial fascia is a very thin, fibrous layer, best marked on the inner side of the long saphenous vein and below Poupart's ligament. It is placed beneath the subcutaneous vessels and nerves and upon the surface of the fascia lata. It is intimately adherent to the fascia lata a little below Poupart's ligament. It covers the saphenous opening in the fascia lata, being closely united to its circumference, and is connected to the sheath of the femoral vessels, corresponding to its under surface. The portion of fascia covering this aperture is perforated by the internal saphenous vein and by numerous blood and lymphatic vessels, hence it has been termed the *cribriform fascia*, the openings for these vessels having been likened to the holes in a sieve. The cribriform fascia adheres closely both to the superficial fascia and to the fascia lata, so that it is described by some anatomists as part of the fascia lata, but is usually considered as belonging to the superficial fascia. It is not until the cribriform fascia has been cleared away that the saphenous opening is seen, so that this opening does not in ordinary cases exist naturally, but is the result of dissection. Callender, however, speaks of cases in which, probably as the result of pressure from enlarged inguinal lymphatic glands, the fascia has become

atrophied, and a saphenous opening exists independent of dissection. A femoral hernia in passing through the saphenous opening receives the cribriform fascia as one of its coverings. A large subcutaneous bursa is found in the superficial fascia over the patella.

The **deep fascia** of the thigh is exposed on the removal of the superficial fascia, and is named, from its great extent, the *fascia lata*; it constitutes a uniform investment for the whole of this region of the limb, but varies in thickness in different parts; thus, it is thicker in the upper and outer part of the thigh, where it receives a fibrous expansion from the Gluteus maximus muscle, and where the Tensor fasciæ femoris is inserted between its layers: it is very thin behind and at the upper and inner part, where it covers the Adductor muscles, and again becomes stronger around the knee, receiving fibrous expansions from the tendon of the Biceps externally, and from the Sartorius internally, and Quadriceps extensor cruris in front. The fascia lata is attached, above and behind, to the back of the sacrum and coccyx; externally, to the crest of the ilium; in front, to Poupart's ligament, and to the body of the os pubis; and internally, to the descending ramus of the os pubis, to the ramus and tuberosity of the ischium, and to the lower border of the great sacro-sciatic ligament. From its attachment to the crest of the ilium it passes down over the Gluteus medius muscle to the upper border of the Gluteus maximus, where it splits into two layers, one passing superficial to and the other beneath this muscle. At the lower border of the muscle the two layers reunite. Externally, the fascia lata receives the greater part of the tendon of insertion of the Gluteus maximus, and becomes proportionately thickened. The portion of the fascia lata attached to the front part of the crest of the ilium, and corresponding to the origin of the Tensor fasciæ femoris, passes down the outer side of the thigh as two layers, one superficial to and the other beneath this muscle; these at the lower end of the muscle become blended together into a thick and strong band, having first received the insertion of the muscle. This band is continued downwards, under the name of the *ilio-tibial band*, to be inserted into the external tuberosity of the tibia. The part of the ilio-tibial band which lies beneath the Tensor fasciæ femoris is prolonged upwards to the capsule of the hip, with the outer part of which it becomes continuous. Below, the fascia lata is attached to all the prominent points around the knee-joint, viz. the condyles of the femur, tuberosities of the tibia, and head of the fibula. On each side of the patella it is strengthened by transverse fibres given off from the lower part of the Vasti muscles, which are attached to and support this bone. Of these the outer are the stronger, and are continuous with the ilio-tibial band. From the inner surface of the fascia lata are given off two strong intermuscular septa, which are attached to the whole length of the linea aspera and its prolongations above and below: the external and stronger one, which extends from the insertion of the Gluteus maximus to the outer condyle, separates the Vastus externus in front from the short head of the Biceps behind, and gives partial origin to these muscles; the inner one, the thinner of the two, separates the Vastus internus from the Adductor and Pectineus muscles. Besides these

Fig. 444.—Dissection of lower extremity. Front view.



there are numerous smaller septa, separating the individual muscles, and enclosing each in a distinct sheath.

The Saphenous Opening.—At the upper and inner part of the thigh, a little below the inner end of Poupart's ligament, a large oval-shaped aperture is observed after the superficial fascia has been cleared off: it transmits the internal saphenous vein, and other smaller vessels, and is termed the *saphenous opening.* In order to consider more correctly the mode of formation of this aperture, the fascia lata in this part of the thigh is described as consisting of two portions, an iliac portion and a pubic portion.

The *iliac portion* is the part of the fascia lata on the outer side of the saphenous opening. It is attached, externally, to the crest of the ilium and its anterior superior spine, to the whole length of Poupart's ligament, and to the pectineal line in conjunction with Gimbernat's ligament. From the spine of the os pubis it is reflected downwards and outwards, forming an arched margin, the *falciform process* or boundary of the saphenous opening; this margin overlies and is adherent to the anterior layer of the sheath of the femoral vessels: to its edge is attached the cribriform fascia. The upward and inward prolongation of the falciform process is named the *superior cornu*; its downward and inward prolongation, the *inferior cornu.* The latter is well defined, and is continuous behind the saphenous vein with the pubic portion of the fascia lata.

The *pubic portion* is situated at the inner side of the saphenous opening; at the lower margin of this aperture it is continuous with the iliac portion; traced upwards, it covers the surface of the Pectineus, Adductor longus, and Gracilis muscles, and, passing behind the sheath of the femoral vessels, to which it is closely united, is continuous with the fascia iliaca, and is attached above to the ilio-pectineal line. From this description it may be observed that the iliac portion of the fascia lata passes in front of the femoral vessels, and the pubic portion behind them, so that an apparent aperture exists between the two, through which the internal saphenous passes to join the femoral vein.

The fascia should now be removed from the surface of the muscles. This may be effected by pinching it up between the forceps, dividing it, and separating it from each muscle in the course of its fibres.

The **Tensor fasciæ femoris** arises from the anterior part of the outer lip of the crest of the ilium, from the outer surface

Fig. 445.—Muscles of the iliac and anterior femoral regions.

of the anterior superior spinous process, and part of the outer border of the notch below it, between the Gluteus medius and Sartorius, and from the inner surface of the fascia lata. It is inserted between two layers of the fascia lata about the junction of the middle and upper thirds of the thigh. From the point of insertion the fascia is continued downwards to the external tuberosity of the tibia as a thickened band, the *ilio-tibial band.*

Relations.—By its *superficial surface,* with the fascia lata and the integument. By its *deep surface,* with the Gluteus medius, Rectus femoris, Vastus externus, and the ascending branches of the external circumflex artery. By its *anterior border,* with the Sartorius, from which it is separated below by a triangular space, in which is seen the Rectus femoris. By its *posterior border,* with the Gluteus medius.

The **Sartorius,** the longest muscle in the body, is flat, narrow, and ribbon-like; it arises by tendinous fibres from the anterior superior spinous process of the ilium and the upper half of the notch below it, passes obliquely across the upper and anterior part of the thigh, from the outer to the inner side of the limb, then descends vertically, as far as the inner side of the knee, passing behind the inner condyle of the femur, and terminates in a tendon; this curves obliquely forwards and expands into a broad aponeurosis, which is inserted, in front of the Gracilis and Semitendinosus, into the upper part of the inner surface of the shaft of the tibia, nearly as far forwards as the crest. The upper part of the aponeurosis is curved backwards over the upper edge of the tendon of the Gracilis so as to be inserted behind it. An offset, derived from its upper margin, blends with the fibrous capsule of the knee-joint, and another, given off from its lower border, blends with the fascia on the inner side of the leg.

The relations of this muscle to the femoral artery should be carefully examined, as it constitutes the chief guide in tying the vessel. In the upper third of the thigh it forms the outer side of a triangular space, *Scarpa's triangle,* the inner side of which is formed by the inner border of the Adductor longus, and the base, turned upwards, by Poupart's ligament; the femoral artery passes perpendicularly through the middle of this space from its base to its apex. In the middle third of the thigh, the femoral artery is contained in Hunter's canal, on the roof of which lies the Sartorius.

Relations.—By its *superficial surface,* with the fascia lata and integument. By its *deep surface,* with the Rectus, Iliacus, Vastus internus, anterior crural nerve, sheath of the femoral vessels, Adductor longus, Adductor magnus, Gracilis, Semitendinosus, long saphenous nerve, and internal lateral ligament of the knee-joint.

The **Quadriceps extensor** includes the four remaining muscles on the front of the thigh. It is the great Extensor muscle of the leg, forming a large fleshy mass, which covers the front and sides of the femur, being united below into a tendon, attached to the patella, and above, subdivided into separate portions, which have received distinct names. Of these, one occupying the middle of the thigh, connected above with the ilium, is called the *Rectus femoris,* from its straight course. The other divisions lie in immediate connection with the shaft of the femur, which they cover from the trochanters to the condyles. The portion on the outer side of the femur is termed the *Vastus externus*; that covering the inner side, the *Vastus internus*; and that in front, the *Crureus.*

The **Rectus femoris** is situated in the middle of the anterior region of the thigh; it is fusiform in shape, and its superficial fibres are arranged in a bipenniform manner, the deep fibres running straight down to the deep aponeurosis. It arises by two tendons: one, the anterior or straight, from the anterior inferior spinous process of the ilium; the other, the posterior or reflected tendon, from a groove above the brim of the acetabulum; the two unite at an acute angle, and spread into an aponeurosis, which is prolonged downwards on the anterior surface of the muscle and from which the muscular fibres arise.* The muscle terminates in a broad and thick aponeurosis, which occupies the lower two-thirds of its

* W. R. Williams, in an interesting paper in the *Journ. of Anat. and Phys.* vol. xiii. p. 204, points out that the reflected tendon is the real origin of the muscle, and is alone present in early fœtal life. The direct tendon is merely an accessory band of condensed fascia. The paper will well repay perusal, though in some particulars the description in the text is more generally accurate.

posterior surface, and, gradually becoming narrowed into a flattened tendon, is inserted into the patella in common with the Vasti and Crureus.

Relations.—By its *superficial surface*, with the anterior fibres of the Gluteus minimus, the Tensor fasciæ femoris, the Sartorius, and the Iliacus; by its lower three-fourths, with the fascia lata. By its *posterior surface*, with the hip-joint, the external circumflex vessels, branches of the anterior crural nerve, and the Crureus and Vasti muscles.

The **Vastus externus** is the largest part of the Quadriceps extensor. It arises by a broad aponeurosis, which is attached to the upper half of the anterior intertrochanteric line, to the anterior and inferior borders of the root of the great trochanter, to the outer lip of the gluteal ridge, and to the upper half of the outer lip of the linea aspera: this aponeurosis covers the upper three-fourths of the muscle, and from its inner surface many fibres take origin. A few additional fibres arise from the tendon of the Gluteus maximus, and from the external intermuscular septum between the Vastus externus and short head of the Biceps. The fibres form a large fleshy mass, which is attached to a strong aponeurosis, placed on the under surface of the muscle at its lower part: this becomes contracted and thickened into a flat tendon, which is inserted into the outer border of the patella, blending with the great Extensor tendon, and giving an expansion to the capsule of the knee-joint.

Relations.—By its *superficial surface*, with the Rectus, the Tensor fasciæ femoris, the fascia lata, and the tendon of the Gluteus maximus, from which it is separated by a synovial bursa. By its *deep surface*, with the Crureus, some large branches of the external circumflex artery and anterior crural nerve being interposed.

The **Vastus internus** and **Crureus** appear to be inseparably united, but when the Rectus femoris has been reflected a narrow interval will be observed extending upwards from the inner border of the patella between the two muscles. Here they can be separated, and the separation should be continued upwards as far as the lower part of the anterior intertrochanteric line, where, however, the two muscles are frequently continuous.

The **Vastus internus** arises from the lower half of the anterior intertrochanteric line, the spiral line, the inner lip of the linea aspera, the upper part of the internal supracondylar line, and the tendons of the Adductor longus and Adductor magnus and internal intermuscular septum. Its fibres are directed downwards and forwards, and are chiefly attached to an aponeurosis which lies on the deep surface of the muscle and is inserted into the inner border of the patella and the Quadriceps extensor tendon, an expansion being sent to the capsule of the knee-joint.

The **Crureus** arises from the front and outer aspect of the shaft of the femur in its upper two-thirds and from the lower part of the external intermuscular septum. Its fibres end in a superficial aponeurosis, which forms the deep part of the Quadriceps extensor tendon.

Relations.—The inner edge of the Crureus is in contact with the anterior edge of the Vastus internus, but when separated from each other, as directed above, the latter muscle is seen merely to overlap the inner aspect of the femoral shaft without taking any fibres of origin from it. The Vastus internus is partly covered by the Rectus and Sartorius, but where these separate near the knee it becomes superficial, and produces a well-marked prominence above the inner aspect of the knee. In the middle third of the thigh it forms the outer wall of Hunter's canal, which contains the femoral vessels and the long saphenous nerve—the roof of the canal being formed by a strong fascia (derived from the membranous expansion of the fascia lata, which lies beneath the Sartorius) which extends from the Vastus internus to the Adductores longus and magnus. The Crureus is almost completely hidden by the Rectus femoris and Vastus externus. The deep surface of the two muscles is in relation to the femur and Subcrureus muscle. A synovial bursa is situated between the femur and the portion of the Quadriceps extensor tendon above the patella; in the adult it usually communicates with the synovial cavity of the knee-joint.

The *tendons* of the different portions of the Quadriceps extensor unite at the lower part of the thigh, so as to form a single strong tendon, which is inserted into the upper part of the patella, some few fibres passing over it to blend with the Ligamentum patellæ. More properly, the patella may be regarded as a

sesamoid bone, developed in the tendon of the Quadriceps; and the Ligamentum patellæ, which is continued from the lower part of the patella to the tuberosity of the tibia, as the proper tendon of insertion of the muscle, the lateral patellar ligaments (see page 403) being fascial expansions from its borders. A synovial bursa is interposed between the tendon and the upper part of the front of the tibia; and another, the *pre-patellar bursa*, is placed over the patella itself. This latter bursa often becomes enlarged, constituting 'housemaid's knee.'

The **Subcrureus** is a small muscle, usually distinct from the Crureus, but occasionally blended with it, which arises from the anterior surface of the lower part of the shaft of the femur, and is inserted into the upper part of the synovial membrane of the knee-joint. It sometimes consists of several separate muscular bundles.

Nerves.—The Tensor fasciæ femoris is supplied by the fourth and fifth lumbar and first sacral nerves through the superior gluteal nerve; the other muscles of this region, by the second, third, and fourth lumbar nerves, through branches of the anterior crural.

Actions.—The Tensor fasciæ femoris is a tensor of the fascia lata; continuing its action, the oblique direction of its fibres enables it to abduct and to rotate the thigh inwards. In the erect posture, acting from below, it will serve to steady the pelvis upon the head of the femur; and by means of the ilio-tibial band it steadies the condyles of the femur on the articular surfaces of the tibia, and assists the Gluteus maximus in supporting the knee in the extended position. The Sartorius flexes the leg upon the thigh, and, continuing to act, flexes the thigh upon the pelvis; it next abducts and rotates the thigh outwards. It was formerly supposed to adduct the thigh, so as to cross one leg over the other, and hence received its name of Sartorius, or tailor's muscle (*sartor*, a tailor), because it was supposed to assist in crossing the legs in the squatting position. When the knee is bent, the Sartorius assists the Semitendinosus, Semimembranosus, and Popliteus in rotating the tibia inwards. Taking its fixed point from the leg, it flexes the pelvis upon the thigh, and, if one muscle acts, assists in rotating the pelvis. The Quadriceps extensor extends the leg upon the thigh. The Rectus muscle assists the Psoas and Iliacus in supporting the pelvis and trunk upon the femur. It also assists in flexing the thigh on the pelvis, or if the thigh is fixed it will flex the pelvis. The Vastus internus draws the patella inwards as well as upwards.

Surgical Anatomy.—A few fibres of the Rectus muscle are occasionally ruptured from severe strain. This accident is especially liable to occur during the games of football and cricket, and is sometimes known as 'cricket thigh.' The patient experiences a sudden pain in the part, as if he had been struck, and the Rectus muscle stands out and is felt to be tense and rigid. The accident is often followed by considerable swelling from inflammatory effusion. Occasionally the Quadriceps extensor may be torn away from its insertion into the patella; or the tendon of the patella may be ruptured about an inch above the bone. This accident is caused in the same manner as fracture of the patella by muscular action, viz. by a violent muscular effort to prevent falling while the knee is in a position of semiflexion. A distinct gap can be felt above the patella, and, owing to the retraction of the muscular fibres, union may fail to take place.

2. *Internal Femoral Region*

Gracilis. Adductor longus.
Pectineus. Adductor brevis.
Adductor magnus.

Dissection.—These muscles are at once exposed by removing the fascia from the fore part and inner side of the thigh. The limb should be abducted, so as to render the muscles tense and easier of dissection.

The **Gracilis** (figs. 445, 448) is the most superficial muscle on the inner side of the thigh. It is thin and flattened, broad above, narrow and tapering below. It arises by a thin aponeurosis from the lower half of the margin of the symphysis and the anterior half of the pubic arch. The fibres pass vertically downwards, and terminate in a rounded tendon, which passes behind the internal condyle of the femur, and, curving round the inner tuberosity of the tibia, becomes flattened, and is inserted into the upper part of the inner surface of the shaft of the tibia, below the tuberosity. A few of the fibres of the lower part of the tendon are

prolonged into the deep fascia of the leg. The tendon of this muscle is situated immediately above that of the Semitendinosus, and its upper edge is overlapped by the tendon of the Sartorius with which it is in part blended. As it passes across the internal lateral ligament of the knee-joint, it is separated from it by a synovial bursa common to it and the Semitendinosus muscle.

Relations.—By its *superficial surface*, with the fascia lata and the Sartorius below; the internal saphenous vein crosses it obliquely near its lower part, lying superficial to the fascia lata. The internal saphenous nerve emerges between its tendon and that of the Sartorius. By its *deep surface*, with the Adductor brevis and the Adductor magnus, and the internal lateral ligament of the knee-joint.

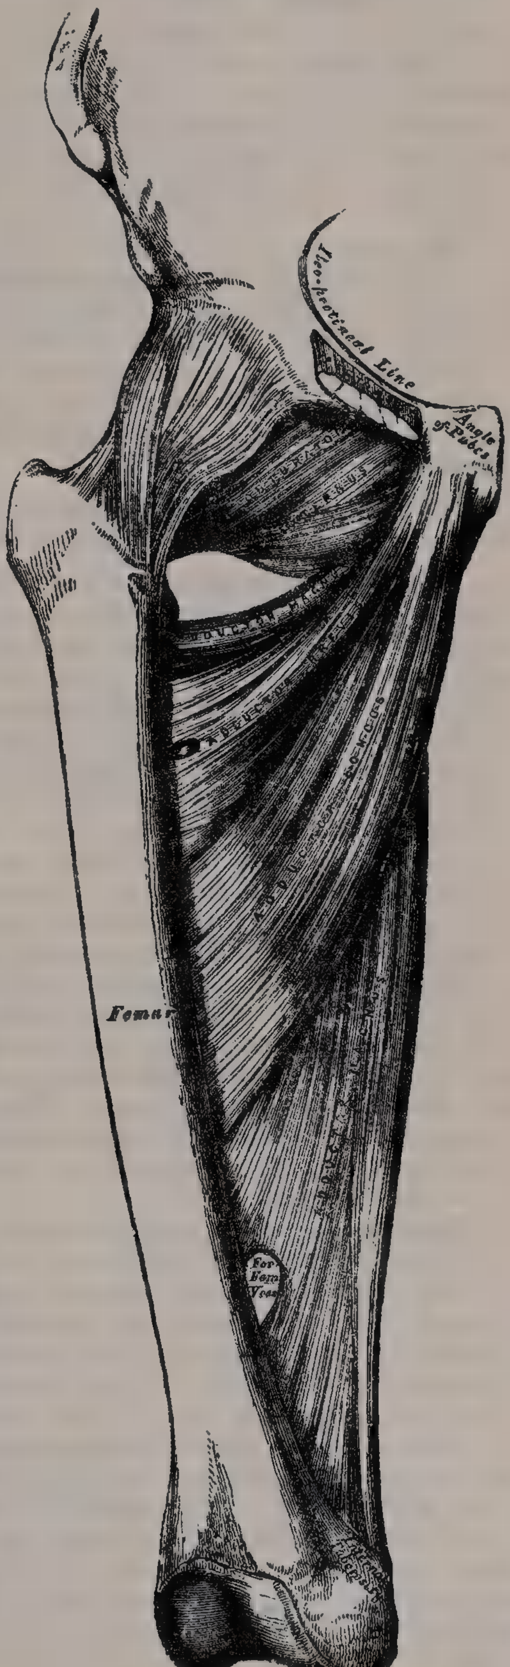
The **Pectineus** (fig. 445) is a flat, quadrangular muscle, situated at the anterior part of the upper and inner aspect of the thigh. It arises from the linea ilio-pectinea, and to a slight extent from the surface of bone in front of it, between the pectineal eminence and spine of the os pubis, and from the fascia covering the anterior surface of the muscle; the fibres pass downwards, backwards, and outwards, to be inserted into a rough line leading from the small trochanter to the linea aspera.

Relations.—By its *anterior surface*, with the pubic portion of the fascia lata, which separates it from the femoral vessels and internal saphenous vein. By its *posterior surface*, with the capsular ligament of the hip-joint, the Adductor brevis and Obturator externus muscles, the obturator vessels and nerve being interposed. By its *outer border*, with the Psoas, a cellular interval separating them, through which pass the internal circumflex vessels. By its *inner border*, with the margin of the Adductor longus.

The **Adductor longus**, the most superficial of the three Adductors, is a flat triangular muscle, lying on the same plane as the Pectineus. It arises, by a flat, narrow tendon, from the front of the os pubis, at the angle of junction of the crest with the symphysis; and soon expands into a broad fleshy belly, which, passing downwards, backwards, and outwards, is inserted, by an aponeurosis, into the linea aspera, between the Vastus internus and the Adductor magnus, with both of which it is usually blended.

Relations.—By its *anterior surface*, with the fascia lata, the Sartorius, and, near its insertion, with the femoral artery and vein. By its *posterior surface*, with the Adductor brevis and magnus, the anterior division of the obturator nerve, and with the profunda artery and vein

Fig. 446.—Deep muscles of the internal femoral region.



near its insertion. By its *outer border*, with the Pectineus. By its *inner border*, with the Gracilis.

The Pectineus and Adductor longus should now be divided near their origin, and turned downwards, when the Adductor brevis and Obturator externus will be exposed.

The **Adductor brevis** is situated immediately behind the two preceding muscles. It is somewhat triangular in form, and arises by a narrow origin from the outer surface of the body and descending ramus of the os pubis, between the Gracilis and Obturator externus. Its fibres, passing backwards, outwards, and downwards, are inserted, by an aponeurosis, into the line leading from the small trochanter to the linea aspera and into the upper part of the linea aspera, immediately behind the Pectineus and upper part of the Adductor longus.

Relations.—By its *anterior surface*, with the Pectineus, Adductor longus, profunda femoris artery, and anterior division of the obturator nerve. By its *posterior surface*, with the Adductor magnus, and posterior division of the obturator nerve. By its *outer border*, with the internal circumflex artery, the Obturator externus, and conjoined tendon of the Psoas and Iliacus. By its *inner border*, with the Gracilis and Adductor magnus. This muscle is pierced, near its insertion, by the second or first and second perforating branches of the profunda femoris artery.

The Adductor brevis should now be cut away near its origin, and turned outwards when the entire extent of the Adductor magnus will be exposed.

The **Adductor magnus** is a large triangular muscle, forming a septum between the muscles on the inner and those on the back of the thigh. It arises from a small part of the descending ramus of the os pubis, from the ramus of the ischium, and from the outer margin of the inferior part of the tuberosity of the ischium. Those fibres which arise from the ramus of the os pubis are very short, horizontal in direction, and are inserted into the rough line leading from the great trochanter to the linea aspera, internal to the Gluteus maximus; those from the ramus of the ischium are directed downwards and outwards with different degrees of obliquity, to be inserted, by means of a broad aponeurosis, into the linea aspera and the upper part of its internal prolongation below. The internal portion of the muscle, composed principally of those fibres which arise from the tuberosity of the ischium, forms a thick fleshy mass consisting of coarse bundles which descend almost vertically, and terminate about the lower third of the thigh in a rounded tendon, which is inserted into the adductor tubercle on the inner condyle of the femur, being connected by a fibrous expansion to the line leading upwards from the tubercle to the linea aspera. At the insertion of the muscle, a series of osseo-aponeurotic openings, formed by tendinous arches attached to the bone, is seen. The upper four openings are small, and give passage to the perforating branches of the profunda femoris artery. The lowest is of large size, and transmits the femoral vessels from Hunter's canal to the popliteal space.

Relations.—By its *anterior surface*, with the Pectineus, Adductor brevis, Adductor longus, and the femoral and profunda vessels and obturator nerve. By its *posterior surface*, with the great sciatic nerve, the Gluteus maximus, Biceps, Semitendinosus, and Semimembranosus. By its *superior* or *shortest border*, it lies parallel with the Quadratus femoris, the internal circumflex artery passing between them. By its *internal* or *longest border*, with the Gracilis, Sartorius, and fascia lata. By its *external* or *attached border*, it is inserted into the femur behind the Adductor brevis and Adductor longus, which separate it from the Vastus internus; and in front of the Gluteus maximus and short head of the Biceps, which separate it from the Vastus externus.

Nerves.—The three Adductor muscles and the Gracilis are supplied by the third and fourth lumbar nerves through the obturator nerve; the Adductor magnus receiving an additional branch from the sacral plexus through the great sciatic. The Pectineus is supplied by the second, third, and fourth lumbar nerves through the anterior crural, and by the accessory obturator, from the third lumbar, when it exists. Occasionally it receives a branch from the obturator nerve.*

* Paterson describes the Pectineus as consisting of two incompletely separated strata, of which the outer or dorsal stratum, which is constant, is supplied by the anterior

Actions.—The Pectineus and three Adductors adduct the thigh powerfully; they are especially used in horse exercise, the sides of the horse being grasped between the knees by the contraction of these muscles. In consequence of the obliquity of their insertion into the linea aspera, they rotate the thigh outwards, assisting the external Rotators, and when the limb has been abducted, they draw it inwards, carrying the thigh across that of the opposite side. The Pectineus and Adductor brevis and longus assist the Psoas and Iliacus in flexing the thigh upon the pelvis. In progression, also, all these muscles assist in drawing forwards the hinder limb. The Gracilis assists the Sartorius in flexing the leg and rotating it inwards; it is also an adductor of the thigh. If the lower extremities are fixed, these muscles may take their fixed point from below and act upon the pelvis, serving to maintain the body in an erect posture; or, if their action is continued, to flex the pelvis forwards upon the femur.

Surgical Anatomy.—The Adductor longus is liable to be severely strained in those who ride much on horseback, or its tendon to be ruptured by suddenly gripping the saddle. And, occasionally, especially in cavalry soldiers, the tendon may become ossified, constituting the 'rider's bone.'

3. *Gluteal Region*

Gluteus maximus.	Obturator internus.
Gluteus medius.	Gemellus superior.
Gluteus minimus.	Gemellus inferior.
Pyriformis.	Quadratus femoris.

Obturator externus.

Dissection (fig. 447).—The subject should be turned on its face, a block placed beneath the pelvis to make the buttocks tense, and the limbs allowed to hang over the end of the table, with the foot inverted, and the thigh abducted. Make an incision through the integument along the crest of the ilium to the middle of the sacrum and thence downwards to the tip of the coccyx, and carry a second incision from that point obliquely downwards and outwards to the outer side of the thigh, four inches below the great trochanter. The portion of integument included between these incisions is to be removed in the direction shown in the figure.

The **Gluteus maximus** (fig. 448), the most superficial muscle in the gluteal region, is a very broad and thick fleshy mass, of a quadrilateral shape, which forms the prominence of the nates. Its large size is one of the most characteristic points in the muscular system in man, connected as it is with the power he has of maintaining the trunk in the erect posture. In structure the muscle is remarkably coarse, being made up of muscular fasciculi lying parallel with one another, and collected together into large bundles, separated by deep cellular intervals. It arises from the superior curved line of the ilium, and the portion of bone, including the crest, immediately above and behind it; from the posterior surface of the lower part of the sacrum, the side of the coccyx; the aponeurosis of the Erector spinæ muscle, the great sacro-sciatic ligament, and the fascia (gluteal aponeurosis) covering the Gluteus medius. The fibres are directed obliquely downwards and outwards; those forming the upper and larger portion of the muscle, together with the superficial fibres of the lower portion, terminate in a thick tendinous lamina, which passes across the great trochanter, and is inserted into the fascia lata covering the outer side of the thigh; the deeper fibres of the lower portion of the muscle are inserted into the rough line leading from the great trochanter to the linea aspera between the Vastus externus and Adductor magnus.

Three *synovial bursæ* are usually found in relation with the deep surface of this muscle. One of these, of large size, and generally multilocular, separates it from the great trochanter. A second, often wanting, is situated on the tuberosity of the ischium. A third is found between the tendon of the muscle and the Vastus externus.

Relations.—By its *superficial surface*, with a thin fascia, which separates it from the subcutaneous tissue. By its *deep surface*, from above downwards, with the ilium, sacrum, coccyx, and great sacro-sciatic ligament, part of the Gluteus

crural nerve, or in its absence by the accessory obturator, with which it is intimately related; while the inner or ventral stratum, when present, is supplied by the obturator nerve.—*Journal of Anatomy and Physiology*, vol. xxvi. p. 43.

medius; Pyriformis, Gemelli, Obturator internus, Quadratus femoris, the tuberosity of the ischium, great trochanter, the origin of the Biceps, Semitendinosus, Semimembranosus, and Adductor magnus muscles. The superficial part of the gluteal artery reaches the deep surface of the muscle by passing between the Pyriformis and the Gluteus medius; the sciatic and internal pudic vessels and nerves, and muscular branches from the sacral plexus issue from the pelvis below the Pyriformis. The first perforating artery and the terminal branches of the internal circumflex artery are also found under cover of the muscle. Its *upper border* is thin, and connected with the Gluteus medius by the fascia lata. Its *lower border* is free and prominent and is crossed by the fold of the nates.

FIG. 447.—Dissection of lower extremity. Posterior view.

Dissection.—Divide the Gluteus maximus near its origin by a vertical incision carried from its upper to its lower border; a cellular interval will be exposed, separating it from the Gluteus medius and External rotator muscles beneath. The upper portion of the muscle is to be altogether detached, and the lower portion turned outwards; the loose areolar tissue filling up the interspace between the trochanter major and tuberosity of the ischium being removed, the parts already enumerated as exposed by the removal of this muscle will be seen.

The **Gluteus medius** is a broad, thick, radiating muscle, situated on the outer surface of the pelvis. Its posterior third is covered by the Gluteus maximus; its anterior two-thirds by the fascia lata, which separates it from the superficial fascia and integument. It arises from the outer surface of the ilium, between the superior and middle curved lines, and from the outer lip of that portion of the crest which is between them; it also arises from the dense fascia (gluteal aponeurosis) covering its outer surface. The fibres converge to a strong flattened tendon, which is inserted into the oblique ridge which runs downwards and forwards on the outer surface of the great trochanter. A synovial bursa separates the tendon of the muscle from the surface of the trochanter in front of its insertion.

Relations.—By its *superficial surface*, with the Gluteus maximus behind, the Tensor fasciæ femoris and deep fascia in front. By its *deep surface*, with the Gluteus minimus, deep branches of the gluteal vessels, and the superior gluteal nerve. It *anterior border* is blended with the Gluteus minimus. Its *posterior border* lies parallel with the Pyriformis, the superficial branches of the gluteal vessels intervening.

This muscle should now be divided near its insertion and turned upwards, when the Gluteus minimus will be exposed.

The **Gluteus minimus**, the smallest of the three Glutei, is placed immediately beneath the preceding. It is fan-shaped, arising from the outer surface of the ilium, between the middle and inferior curved lines, and behind, from the margin of the great sacro-sciatic notch: the fibres converge to the deep surface of a radiated aponeurosis, which, terminating in a tendon, is inserted into an impression on the anterior border of the great trochanter, and gives an expansion to the capsule of the hip-joint. A synovial bursa is interposed between the tendon and the great trochanter.

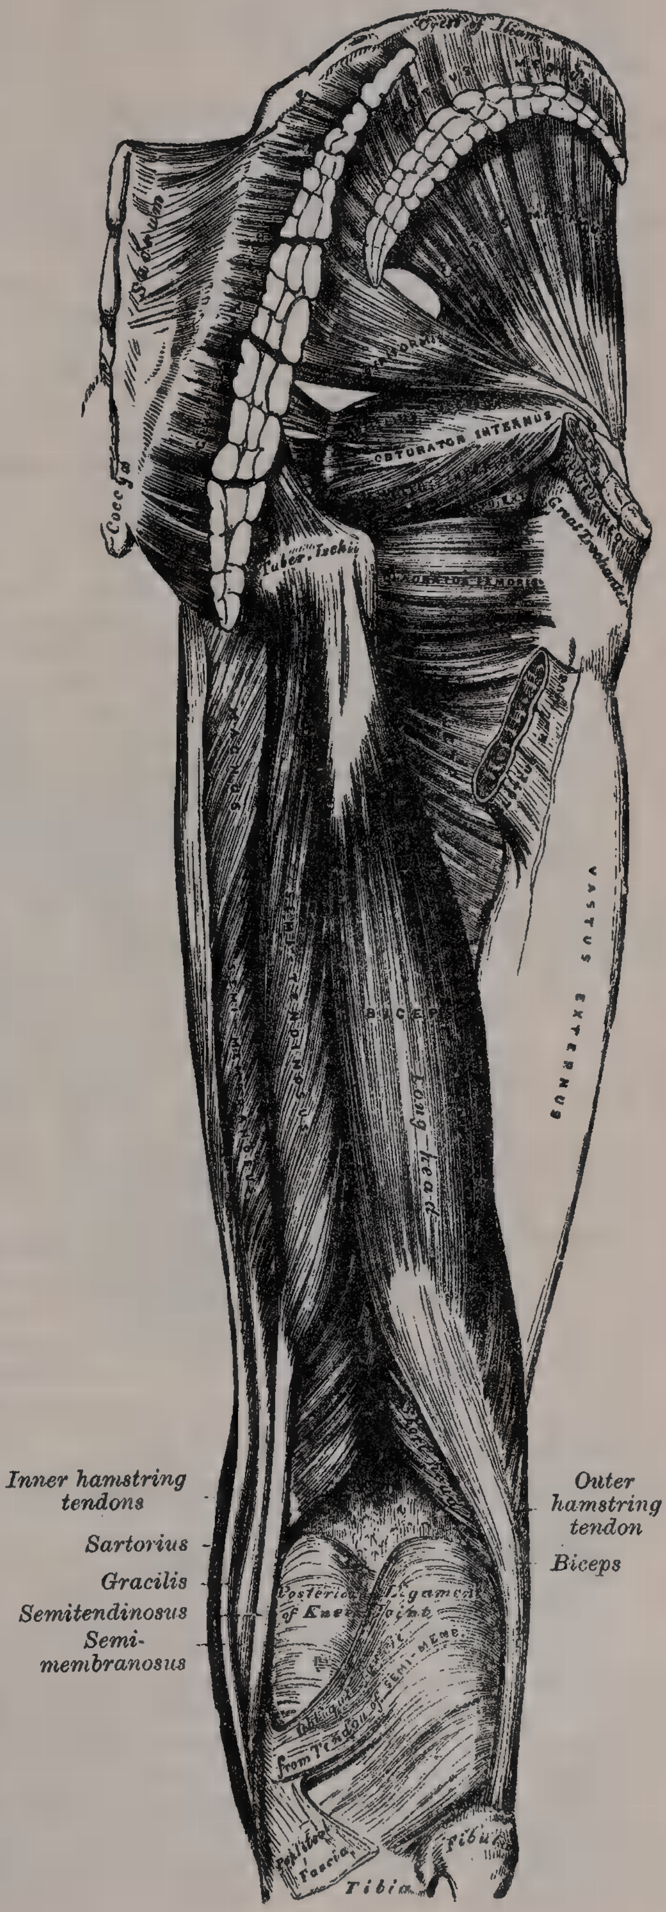
Relations.—By its *superficial surface*, with the Gluteus medius, and the gluteal vessels and superior gluteal nerve. By its *deep surface*, with the ilium,

the reflected tendon of the Rectus femoris, and capsular ligament of the hip-joint. Its *anterior margin* is blended with the Gluteus medius. Its *posterior margin* is in contact and sometimes joined with the tendon of the Pyriformis.

The **Pyriformis** is a flat muscle, pyramidal in shape, lying almost parallel with the posterior margin of the Gluteus medius. It is situated partly within the pelvis against its posterior wall, and partly at the back of the hip-joint. It arises from the front of the sacrum by three fleshy digitations, attached to the portions of bone between the first, second, third, and fourth anterior sacral foramina, and also from the grooves leading from the foramina: a few fibres also arise from the margin of the great sacro-sciatic foramen, and from the anterior surface of the great sacro-sciatic ligament. The muscle passes out of the pelvis through the great sacro-sciatic foramen, the upper part of which it fills, and is inserted by a rounded tendon into the upper border of the great trochanter, behind, but often partly blended with, the tendon of the Obturator internus and Gemelli muscles.

Relations.—By its *anterior surface, within the pelvis*, with the Rectum (especially on the left side), the sacral plexus of nerves, and the branches of the internal iliac vessels; *external to the pelvis*, with the posterior surface of the ischium and capsular ligament of the hip-joint. By its *posterior surface, within the pelvis*, with the sacrum; and *external to it*, with the Gluteus maximus. By its *upper border*, with the Gluteus medius, and the gluteal vessels and superior gluteal nerve. By its *lower border*, with the Gemellus superior and Coccygeus; the sciatic vessels and nerves, the internal pudic vessels and nerve, and muscular branches from

Fig. 448.—Muscles of the hip and thigh.



the sacral plexus, passing from the pelvis in the interval between the two muscles. The muscle is frequently pierced by the external popliteal nerve.

The **obturator membrane** (fig. 360) is a thin layer of interlacing fibres, which closes the obturator foramen. It is attached, externally, to the margin of the foramen; internally, to the posterior surface of the ischio-pubic ramus, below and internal to the margin of the foramen. It is occasionally incomplete, and presents at its upper and outer part a small canal, which is bounded below by a thickened band of fibres, for the passage of the obturator vessels and nerve (see page 306). Both Obturator muscles are connected with this membrane.

Dissection.—The next muscle, as well as the origin of the Pyriformis, can only be seen when the pelvis is divided and the viscera removed.

The **Obturator internus,** like the preceding muscle, is situated partly within the cavity of the pelvis, and partly at the back of the hip-joint. It arises from the inner surface of the anterior and external wall of the pelvis, where it surrounds the greater part of the obturator foramen, being attached to the descending ramus of the os pubis and the ramus of the ischium, and at the side to the inner surface of the innominate bone below and behind the pelvic brim, reaching from the upper part of the great sacro-sciatic foramen above and behind to the thyroid foramen below and in front. It also arises from the inner surface of the obturator membrane except at its posterior part, from the tendinous arch which completes the canal for the passage of the obturator vessels and nerve and to a slight extent from the obturator layer of the pelvic fascia, which covers it. The fibres converge rapidly, and are directed backwards and downwards, and terminate in four or five tendinous bands, which are found on its deep surface; these bands are reflected at a right angle over the grooved surface of the ischium between its spine and tuberosity. This bony surface is covered by smooth cartilage, which is separated from the tendon by a synovial bursa, and presents one or more ridges which correspond with the furrows between the tendinous bands. These leave the pelvis by the lesser sacro-sciatic foramen and unite into a single flattened tendon, which passes horizontally outwards, and, after receiving the attachment of the Gemelli, is inserted into the fore part of the inner surface of the great trochanter in front of the Pyriformis. A synovial bursa, narrow and elongated in form, is usually found between the tendon of this muscle and the capsular ligament of the hip: it occasionally communicates with the bursa between the tendon and the tuberosity of the ischium, the two forming a single sac.

In order to display the peculiar appearances presented by the tendon of this muscle, it must be divided near its insertion and reflected inwards.

Relations.—*Within the pelvis,* this muscle is in relation, by its *anterior surface,* with the obturator membrane and inner surface of the anterior wall of the pelvis; by its *posterior surface,* with the pelvic and obturator fasciæ, which separate it from the Levator ani; and it is crossed by the internal pudic vessels and nerve. This surface forms the outer boundary of the ischio-rectal fossa. *External to the pelvis,* it is covered by the Gluteus maximus, crossed by the great sciatic nerve, and rests on the back part of the hip-joint. As the tendon of the Obturator internus emerges from the lesser sacro-sciatic foramen it is overlapped by the two Gemelli, while nearer its insertion the Gemelli pass in front of it and form a groove in which the tendon lies.

The **Gemelli** are two small muscular fasciculi, accessories to the tendon of the Obturator internus, which is received into a groove between them. They are called *superior* and *inferior.*

The **Gemellus superior,** the smaller of the two, arises from the outer surface of the spine of the ischium, and passing horizontally outwards becomes blended with the upper part of the tendon of the Obturator internus, and is inserted with it into the inner surface of the great trochanter. This muscle is sometimes wanting.

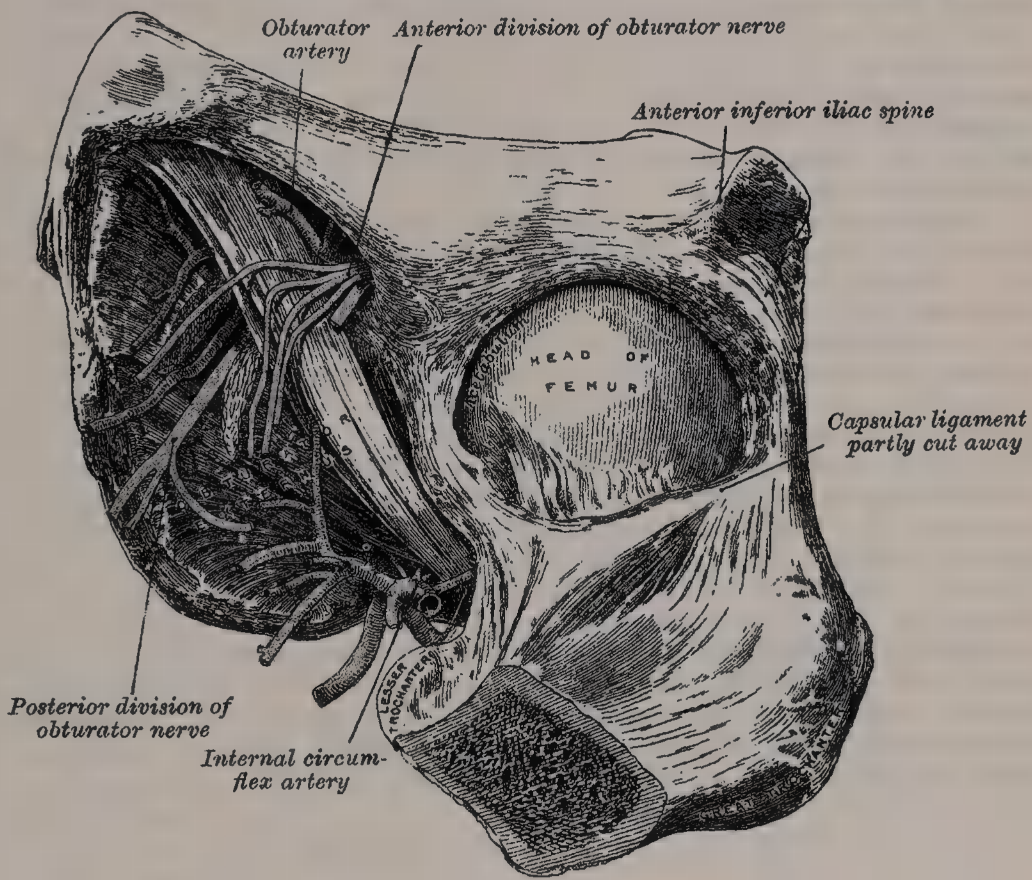
Relations.—By its *superficial surface,* with the Gluteus maximus and the sciatic vessels and nerves. By its *deep surface,* with the capsule of the hip-joint. By its *upper border,* with the lower margin of the Pyriformis. By its *lower border,* with the tendon of the Obturator internus.

The **Gemellus inferior** arises from the upper part of the tuberosity of the ischium, where it forms the lower edge of the groove for the Obturator internus tendon, and, passing horizontally outwards, is blended with the lower part of the tendon of the Obturator internus, and inserted with it into the inner surface of the great trochanter.

Relations.—By its *superficial surface,* with the Gluteus maximus and the sciatic vessels and nerves. By its *deep surface,* with the capsular ligament of the hip-joint. By its *upper border,* with the tendon of the Obturator internus. By its *lower border,* with the tendon of the Obturator externus and Quadratus femoris.

The **Quadratus femoris** is a short, flat muscle, quadrilateral in shape (hence its name), situated between the Gemellus inferior and the upper margin of the Adductor magnus. It arises from the upper part of the external lip of the tuberosity of the ischium, and, proceeding horizontally outwards, is inserted

Fig. 449.—Obturator externus muscle.
(From a preparation in the museum of the Royal College of Surgeons of England.)



into the upper part of the linea quadrata—that is, the line which crosses the posterior intertrochanteric line. A synovial bursa is often found between the under surface of this muscle and the small trochanter, which it covers.

Relations.—By its *posterior surface,* with the Gluteus maximus and the sciatic vessels and nerves. By its *anterior surface,* with the tendon of the Obturator externus and small trochanter, and with the capsule of the hip-joint. By its *upper border,* with the Gemellus inferior. Its *lower border* is separated from the Adductor magnus by the terminal branches of the internal circumflex vessels.

Dissection.—In order to expose the next muscle (the Obturator externus), it is necessary to remove the Psoas, Iliacus, Pectineus, and Adductores brevis and longus muscles from the front and inner side of the thigh; and the Gluteus maximus and Quadratus femoris from the back part. Its dissection should, consequently, be postponed until the muscles of the anterior and internal femoral regions have been examined.

The **Obturator externus** (fig. 449) is a flat, triangular muscle, which covers the outer surface of the anterior wall of the pelvis. It arises from the margin of

bone immediately around the inner side of the obturator foramen, viz. from the body and ramus of the os pubis, and the ramus of the ischium; it also arises from the inner two-thirds of the outer surface of the obturator membrane, and from the tendinous arch which completes the canal for the passage of the obturator vessels and nerves. The fibres from the pubic arch extend on to the inner surface of the bone, from which they obtain a narrow origin between the margin of the foramen and the attachment of the membrane. The fibres converging pass backwards, outwards, and upwards, and terminate in a tendon which runs across the back part of the hip-joint, and is inserted into the digital fossa of the femur.

Relations.—By its *anterior surface*, with the Psoas, Iliacus, Pectineus, Adductor magnus, and Adductor brevis; and more externally, with the neck of the femur and capsule of the hip-joint. The obturator artery and vein lie between this muscle and the obturator membrane; the superficial part of the obturator nerve lies above the muscle, and the deep branch perforates it. By its *posterior surface*, with the obturator membrane and Quadratus femoris.

Nerves.—The Gluteus maximus is supplied by the fifth lumbar and first and second sacral nerves through the inferior gluteal nerve from the sacral plexus; the Gluteus medius and minimus, by the fourth and fifth lumbar and first sacral nerves through the superior gluteal; the Pyriformis is supplied by the first and second sacral nerves; the Gemellus inferior and Quadratus femoris by the last lumbar and first sacral nerve; the Gemellus superior and Obturator internus by the first, second, and third sacral nerves, and the Obturator externus by the third and fourth lumbar nerves through the obturator.

Actions.—The Gluteus maximus, when it takes its fixed point from the pelvis, extends the femur and brings the bent thigh into a line with the body. Taking its fixed point from below, it acts upon the pelvis, supporting it and the trunk upon the head of the femur, which is especially obvious in standing on one leg. Its most powerful action is to cause the body to regain the erect position after stooping, by drawing the pelvis backwards, being assisted in this action by the Biceps, Semitendinosus, and Semimembranosus. The Gluteus maximus is a tensor of the fascia lata, and by its connection with the ilio-tibial band it steadies the femur on the articular surface of the tibia during standing, when the Extensor muscles are relaxed. The lower part of the muscle also acts as an adductor and external rotator of the limb. The Gluteus medius and minimus abduct the thigh, when the limb is extended, and are principally called into action in supporting the body on one limb, in conjunction with the Tensor fasciæ femoris. Their anterior fibres, by drawing the great trochanter forwards, rotate the thigh inwards, in which action they are also assisted by the Tensor fasciæ femoris. The remaining muscles are powerful rotators of the thigh outwards. In the sitting posture, when the thigh is flexed upon the pelvis, their action as rotators ceases, and they become abductors, with the exception of the Obturator externus, which still rotates the femur outwards.

4. *Posterior Femoral Region*

Biceps. Semitendinosus. Semimembranosus.
(*Hamstring muscles.*)

Dissection (fig. 447).—Make a vertical incision along the middle of the back of the thigh, from the lower fold of the nates to about three inches below the back of the knee-joint, and there connect it with a transverse incision, carried from the inner to the outer side of the leg. Make a third incision transversely at the junction of the middle with the lower third of the thigh. The integument having been removed from the back of the knee, and the boundaries of the popliteal space examined, the removal of the integument from the remaining part of the thigh should be continued, when the fascia and muscles of this region will be exposed.

The **Biceps** (*Biceps flexor cruris*) is a large muscle, of considerable length, situated on the posterior and outer aspect of the thigh (fig. 448). It has two heads of origin: one, the long head, from the lower and inner impression on the back part of the tuberosity of the ischium, by a tendon common to it and the Semitendinosus, and from the lower part of the great sacro-sciatic ligament; the other, or short head, from the outer lip of the linea aspera, between the

Adductor magnus and Vastus externus, extending up almost as high as the insertion of the Gluteus maximus; from the outer prolongation of the linea aspera to within two inches of the outer condyle; and from the external intermuscular septum. The fibres of the long head form a fusiform belly, which, passing obliquely downwards and a little outwards, terminates in an aponeurosis which covers the posterior surface of the muscle, and receives the fibres of the short head: this aponeurosis becomes gradually contracted into a tendon, which is inserted into the outer side of the head of the fibula, and by a small slip into the lateral surface of the external tuberosity of the tibia. At its insertion the tendon divides into two portions, which embrace the long external lateral ligament of the knee-joint. From the posterior border of the tendon a thin expansion is given off to the fascia of the leg. The tendon of this muscle forms the outer hamstring.

Relations.—By its *superficial surface*, with the Gluteus maximus, and the small sciatic nerve, the fascia lata, and integument. By its *deep surface*, with the Semimembranosus, Adductor magnus, and Vastus externus, the great sciatic nerve, and, near its insertion, with the external head of the Gastrocnemius, Plantaris, the superior external articular artery, and the external popliteal nerve.

The **Semitendinosus,** remarkable for the great length of its tendon, is situated at the posterior and inner aspect of the thigh. It arises from the lower and inner impression on the tuberosity of the ischium, by a tendon common to it and the long head of the Biceps; it also arises from an aponeurosis which connects the adjacent surfaces of the two muscles to the extent of about three inches after their origin. It forms a fusiform muscle, which, passing downwards and inwards, terminates a little below the middle of the thigh in a long round tendon which lies along the inner side of the popliteal space, then curves around the inner tuberosity of the tibia, and is inserted into the upper part of the inner surface of the shaft of that bone, nearly as far forwards as its anterior border. At its insertion it gives off from its lower border a prolongation to the deep fascia of the leg. This tendon lies behind the tendon of the Sartorius, and below that of the Gracilis, to which it is united. A tendinous intersection is usually observed about the middle of the muscle.

Relations.—By its *superficial surface*, with the Gluteus maximus and fascia lata. By its *deep surface*, with the Semimembranosus, Adductor magnus, inner head of the Gastrocnemius, and internal lateral ligament of the knee-joint, the last being separated from the tendon by a bursa.

The **Semimembranosus,** so called from its membranous tendon of origin, is situated at the back part and inner side of the thigh. It arises by a thick tendon from the upper and outer impression on the back part of the tuberosity of the ischium, above and to the outer side of the Biceps and Semitendinosus, and is inserted into the groove on the inner and back part of the inner tuberosity of the tibia. The tendon of the muscle at its origin expands into an aponeurosis, which covers the upper part of its anterior surface: from this aponeurosis muscular fibres arise, and converge to another aponeurosis which covers the lower part of its posterior surface and contracts into the tendon of insertion. The tendon of the muscle at its insertion gives off certain fibrous expansions: one of these, of considerable size, passes upwards and outwards to be inserted into the back part of the outer condyle of the femur, forming part of the posterior ligament of the knee-joint; a second is continued downwards to the fascia which covers the Popliteus muscle; while a few fibres join the internal lateral ligament of the joint.

The tendons of the two preceding muscles form the inner hamstrings.

Relations.—By its *superficial surface*, with the Gluteus maximus, Semitendinosus, Biceps, and fascia lata. By its *deep surface*, with the origin of the Quadratus femoris, popliteal vessels, Adductor magnus, and inner head of the Gastrocnemius, from which it is separated by a synovial bursa. By its *inner border*, with the Gracilis. By its *outer border*, with the great sciatic nerve, and its internal popliteal branch.

Nerves.—The muscles of this region are supplied by the fourth and fifth lumbar and the first, second, and third sacral nerves through the great sciatic nerve.

Actions.—The hamstring muscles flex the leg upon the thigh. When the knee is semiflexed, the Biceps, in consequence of its oblique direction downwards

and outwards, rotates the leg slightly outwards; and the Semitendinosus, and to a slight extent the Semimembranosus, rotate the leg inwards, assisting the Popliteus. Taking their fixed point from below, these muscles serve to support the pelvis upon the head of the femur, and to draw the trunk directly backwards, as in raising it from the stooping position or in feats of strength, when the body is thrown backwards in the form of an arch. When the leg is extended on the thigh they limit the amount of flexion of the trunk on the lower limbs.

Surgical Anatomy.—In disease of the knee-joint, contraction of the hamstring tendons is a frequent complication; this causes flexion of the leg, and a partial dislocation of the tibia backwards, with a slight degree of rotation outwards, probably due to the action of the Biceps muscle. The hamstring tendons occasionally require subcutaneous division in some forms of spurious ankylosis of the knee-joint dependent upon permanent contraction and rigidity of the Flexor muscles, or from stiffening of the ligamentous and other tissues surrounding the joint, the result of disease. This is effected by putting the tendon upon the stretch, and inserting a narrow, sharp-pointed knife between it and the skin: the cutting edge being then turned towards the tendon, it should be divided, taking care that the wound in the skin is not at the same time enlarged. The relation of the external popliteal nerve, which lies in close apposition to the inner border of the tendon of the Biceps, must always be borne in mind in dividing this tendon; and probably, in unskilled hands, a free incision and exposure of the tendon, before division, is a safer proceeding.

III. Muscles and Fasciæ of the Leg

The muscles of the leg may be divided into three groups: those on the anterior, those on the posterior, and those on the outer side.

5. *Anterior Tibio-fibular Region*

Tibialis anticus.	Extensor longus digitorum.
Extensor proprius hallucis.	Peroneus tertius.

Dissection (fig. 444).—The knee should be bent, a block placed beneath it, and the foot kept in an extended position; then make an incision through the integument in the middle line of the leg to the ankle, and continue it along the dorsum of the foot to the toes. Make a second incision transversely across the ankle, and a third in the same direction across the bases of the toes; remove the flaps of integument included between these incisions in order to examine the deep fascia of the leg.

The **Deep Fascia of the Leg** forms a complete investment to the muscles, but is not continued over the subcutaneous surfaces of the bones. It is continuous above with the fascia lata, and is attached around the knee to the patella, the ligamentum patellæ, the tubercle and tuberosities of the tibia, and the head of the fibula. Behind, it forms the popliteal fascia, covering in the popliteal space; here it is specially thick, being strengthened by transverse fibres, and is perforated by the external saphenous vein. It receives an expansion from the tendon of the Biceps on the outer side, and from the tendons of the Sartorius, Gracilis, and Semitendinosus on the inner side; in front, it blends with the periosteum covering the subcutaneous surface of the tibia, and with that covering the head and external malleolus of the fibula; below, it is continuous with the annular ligaments of the ankle. It is thick and dense in the upper and anterior part of the leg, and gives attachment, by its deep surface, to the Tibialis anticus and Extensor longus digitorum muscles; but thinner behind, where it covers the Gastrocnemius and Soleus muscles. Its deep surface gives off, on the outer side of the leg, two strong intermuscular septa, which enclose the Peronei muscles, and separate them from the muscles on the anterior and posterior tibial regions and several smaller and more slender processes, which enclose the individual muscles in each region; at the same time a broad transverse intermuscular septum, called the *deep transverse fascia of the leg*, intervenes between the superficial and deep muscles in the posterior tibio-fibular region.

Remove the fascia by dividing it in the same direction as the integument, excepting opposite the ankle, where it should be left intact. Commence the removal of the fascia from below, opposite the tendons, and detach it in the line of direction of the muscular fibres.

The **Tibialis anticus** is situated on the outer side of the tibia; it is thick and fleshy at its upper part, tendinous below. It arises from the outer tuberosity and upper half or two-thirds of the external surface of the shaft of the tibia; from the adjoining part of the interosseous membrane; from the deep surface of the fascia; and from the intermuscular septum between it and the Extensor longus digitorum: the fibres pass vertically downwards, and terminate in a tendon, which is apparent on the anterior surface of the muscle at the lower third of the leg. After passing through the innermost compartment of the anterior annular ligament, it is inserted into the inner and under surface of the internal cuneiform bone, and base of the metatarsal bone of the great toe.

Relations.—By its *anterior surface*, with the fascia, and with the annular ligament. By its *posterior surface*, with the interosseous membrane, tibia, ankle-joint, and inner side of the tarsus: this surface also overlaps the anterior tibial vessels and nerve in the upper part of the leg. By its *inner surface*, with the tibia. By its *outer surface*, with the Extensor longus digitorum, and Extensor proprius hallucis, and the anterior tibial vessels and nerve.

The **Extensor proprius hallucis** is a thin, elongated, and flattened muscle, situated between the Tibialis anticus and Extensor longus digitorum. It arises from the anterior surface of the fibula for about the middle two-fourths of its extent, its origin being internal to that of the Extensor longus digitorum; it also arises from the interosseous membrane to a similar extent. The fibres pass downwards, and terminate in a tendon, which occupies the anterior border of the muscle, passes through a distinct compartment in the lower portion of the annular ligament, crosses the anterior tibial vessels near the bend of the ankle, and is inserted into the base of the last phalanx of the great toe. Opposite the metatarso-phalangeal articulation, the tendon gives off a thin prolongation on each side, which covers the surface of the joint. It usually sends an expansion, from the inner side of the tendon, to be inserted into the base of the first phalanx.

Relations.—By its *anterior surface*, with the fascia, and the anterior annular ligament. By its *posterior surface*, with the interosseous membrane, fibula, tibia, and ankle-joint. By its *outer side*, with the Extensor longus digitorum above, the dorsalis pedis vessels, anterior tibial nerve, and Extensor brevis digitorum below. By its *inner side*, with the Tibialis anticus and the anterior tibial vessels above. The muscle is external to the anterior tibial vessels in the upper part of the leg; but in the lower third its tendon crosses over them, so that it lies internal to them on the dorsum of the foot.

Fig. 450.—Muscles of the front of the leg.

The **Extensor longus digitorum** is an elongated, flattened, penniform muscle, situated at the outer part of the front of the leg. It arises from the outer tuberosity of the tibia; from the upper three-fourths of the anterior surface of the shaft of the fibula; from the interosseous membrane; from the deep surface of the fascia; and from the intermuscular septa between it and the Tibialis anticus on the inner, and the Peronei on the outer side. The tendon passes under the annular ligament in company with the Peroneus tertius, and divides into four slips, which run forward on the dorsum of the foot, and are inserted into the second and third phalanges of the four lesser toes. The mode in which the tendons are inserted is the following: each of the three inner tendons, opposite the metatarso-phalangeal articulation, is joined, on its outer side, by a tendon of the Extensor brevis digitorum. Each receives a fibrous expansion from the Interossei and Lumbricales, and then spreads out into a broad aponeurosis, which covers the dorsal surface of the first phalanx: this aponeurosis, at the articulation of the first with the second phalanx, divides into three slips, a middle one, which is inserted into the base of the second phalanx; and two lateral slips, which, after uniting on the dorsal surface of the second phalanx, are continued onwards, to be inserted into the base of the third.

Relations.—By its *anterior surface*, with the fascia and the annular ligament. By its *posterior surface*, with the fibula, interosseous membrane, ankle-joint, and Extensor brevis digitorum. By its *inner side*, with the Tibialis anticus, Extensor proprius hallucis, and anterior tibial vessels and nerve. By its *outer side*, with the Peroneus longus and brevis.

The **Peroneus tertius** is a part of the Extensor longus digitorum, and might be described as its fifth tendon. The fibres belonging to this tendon arise from the lower third or more of the anterior surface of the fibula; from the lower part of the interosseous membrane; and from an intermuscular septum between it and the Peroneus brevis. The tendon, after passing through the same canal in the annular ligament as the Extensor longus digitorum, is inserted into the dorsal surface of the base of the metatarsal bone of the little toe. This muscle is sometimes wanting.

Nerves.—These muscles are supplied by the fourth and fifth lumbar and first sacral nerves through the anterior tibial nerve.

Actions.—The Tibialis anticus and Peroneus tertius are the direct flexors of the foot at the ankle-joint; the former muscle, when acting in conjunction with the Tibialis posticus, raises the inner border of the foot (i.e. inverts the foot); and the latter, acting with the Peroneus brevis and longus, raises the outer border of the foot (i.e. everts the foot). The Extensor longus digitorum and Extensor proprius hallucis extend the phalanges of the toes, and, continuing their action, flex the foot upon the leg. Taking their fixed point from below, in the erect posture, all these muscles serve to fix the bones of the leg in the perpendicular position, and give increased strength to the ankle-joint.

6. *Posterior Tibio-fibular Region*

Dissection (fig. 447).—Make a vertical incision along the middle line of the back of the leg, from the lower part of the popliteal space to the heel, connecting it below by a transverse incision extending between the two malleoli; the flaps of integument being removed, the fascia and muscles should be examined.

The muscles in this region of the leg are subdivided into two layers—superficial and deep. Those of the superficial layer constitute a powerful muscular mass, forming the calf of the leg. Their large size is one of the most characteristic features of the muscular apparatus in man, and bears a direct relation to his ordinary attitude and mode of progression.

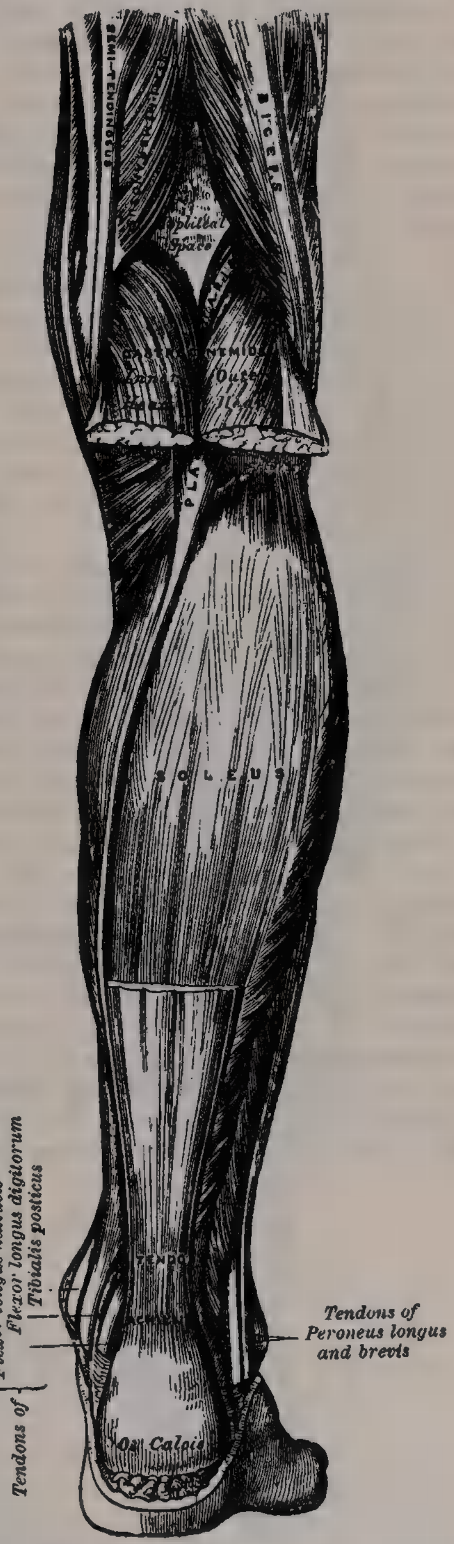
Superficial Layer

Gastrocnemius.	Soleus.	Plantaris.

The **Gastrocnemius** is the most superficial muscle, and forms the greater part of the calf. It arises by two heads, which are connected to the condyles of the femur by two strong flat tendons. The inner and larger head takes its origin from a

depression at the upper and back part of the inner condyle and from the adjacent part of the femur. The outer head arises from an impression on the outer side of the external condyle and from the posterior surface of the femur immediately above the outer part of the condyle. Both heads, also, arise from the subjacent part of the capsular ligament of the knee. Each tendon spreads out into an aponeurosis, which covers the posterior surface of that portion of the muscle to which it belongs. From the anterior surface of these tendinous expansions, muscular fibres are given off; those of the inner head being thicker and extending lower than those of the outer. The fibres in the median line unite at an angle in a median tendinous raphé, which expands into a broad aponeurosis on the anterior surface of the muscle, and into this the remaining fibres are inserted. The aponeurosis, gradually contracting, unites with the tendon of the Soleus, and forms with it the tendo Achillis.

Fig. 451.—Muscles of the back of the leg Superficial layer.



Relations.—By its *superficial surface*, with the fascia of the leg, which separates it from the external saphenous vein and nerve. By its *deep surface*, with the posterior ligament of the knee-joint, the Popliteus, Soleus, Plantaris, popliteal vessels, and internal popliteal nerve. Beneath the tendon of the inner head is a synovial bursa, which, in some cases, communicates with the cavity of the knee-joint. The tendon of the outer head sometimes contains a sesamoid fibro-cartilage or bone, where it plays over the corresponding outer condyle; and one is occasionally found in the tendon of the inner head.

The Gastrocnemius should be divided across, just below its origin, and turned downwards, in order to expose the next two muscles.

The **Soleus** is a broad flat muscle situated immediately beneath the Gastrocnemius. It has received its name from its resemblance in shape to a sole-fish. It arises by tendinous fibres from the back part of the head of the fibula, and from the upper third of the posterior surface of its shaft; from the oblique line of the tibia, and from the middle third of its internal border; some fibres also arise from a tendinous arch placed between the tibial and fibular origins of the muscle, beneath which the popliteal vessels and internal popliteal nerve run. The fibres pass backwards to an aponeurosis which covers the posterior surface of the muscle, and this gradually becoming thicker and narrower, joins with the tendon of the Gastrocnemius, and forms with it the tendo Achillis.

Relations.—By its *superficial surface*, with the Gastrocnemius and Plantaris. By its *deep surface*, with the Flexor longus digitorum, Flexor longus hallucis,

Tibialis posticus, and posterior tibial vessels and nerve, from which it is separated by the transverse intermuscular septum or deep transverse fascia of the leg.

The **tendo Achillis,** the common tendon of the Gastrocnemius and Soleus, is the thickest and strongest tendon in the body. It is about six inches in length, and commences near the middle of the leg, but receives fleshy fibres on its anterior surface, almost to its lower end. Gradually becoming contracted below, it is inserted into the middle part of the posterior surface of the os calcis, a synovial bursa being interposed between the tendon and the upper part of this surface. The tendon spreads out somewhat at its lower end, so that its narrowest part is about an inch and a half above its insertion. The tendon is covered by the fascia and the integument, and is separated from the deep muscles and vessels by a considerable interval filled up with areolar and adipose tissue. Along its outer side, but superficial to it, is the external saphenous vein.

The **Plantaris** is an extremely diminutive muscle, placed between the Gastrocnemius and Soleus, and remarkable for its long and delicate tendon. It arises from the lower part of the outer prolongation of the linea aspera, and from the posterior ligament of the knee-joint. It forms a small fusiform belly, about three or four inches in length, terminating in a long slender tendon which crosses obliquely between the two muscles of the calf, and, running along the inner border of the tendo Achillis, is inserted with it into the posterior part of the os calcis. This muscle is sometimes double, and at other times wanting. Occasionally, its tendon is lost in the internal annular ligament, or in the fascia of the leg.

Nerves.—The Gastrocnemius is supplied by the first and second sacral nerves, and the Plantaris by the fourth and fifth lumbar and first sacral nerves through the internal popliteal. The Soleus is supplied by the first and second sacral nerves through the internal popliteal and posterior tibial.

Actions.—The muscles of the calf are the chief extensors of the foot at the ankle-joint. They possess considerable power, and are constantly called into use in standing, walking, dancing, and leaping; hence the large size they usually present. In walking, these muscles draw powerfully upon the os calcis, raising the heel from the ground; the body being thus supported on the raised foot, the opposite limb can be carried forwards. In standing, the Soleus, taking its fixed point from below, steadies the leg upon the foot and prevents the body from falling forwards, to which there is a constant tendency from the superincumbent weight. The Gastrocnemius, acting from below, serves to flex the femur upon the tibia, assisted by the Popliteus. The Plantaris is the rudiment of a large muscle which exists in some of the lower animals, and is continued over the os calcis to be inserted into the plantar fascia. In man it is an accessory to the Gastrocnemius, extending the ankle if the foot is free, or bending the knee if the foot is fixed. Possibly, acting from below, by its attachment to the posterior ligament of the knee-joint, it may pull that ligament backwards during flexion, and so protect it from being compressed between the two articular surfaces.

Deep Layer (fig. 452)

Popliteus.	Flexor longus digitorum.
Flexor longus hallucis.	Tibialis posticus.

Dissection.—Detach the Soleus from its attachment to the fibula and tibia, and turn it downwards, and the deep layer of muscles is exposed, covered by the deep transverse fascia of the leg.

The **Deep Transverse Fascia** of the leg is a transversely placed, intermuscular septum, between the superficial and deep muscles in the posterior tibio-fibular region. On either side it is connected to the margins of the tibia and fibula. Above, where it covers the Popliteus, it is thick and dense, and receives an expansion from the tendon of the Semimembranosus; it is thinner in the middle of the leg; but below, where it covers the tendons passing behind the malleoli, it is thickened and continuous with the internal annular ligament.

This fascia should now be removed, commencing from below opposite the tendons, and detaching it from the muscles in the direction of their fibres.

The **Popliteus** is a thin, flat, triangular muscle, which forms the lower part of the floor of the popliteal space. It arises by a strong tendon about an inch in length, from a depression at the anterior part of the popliteal groove on the outer side of the external condyle of the femur, and to a small extent from the posterior ligament of the knee-joint; and is inserted into the inner two-thirds of the triangular surface above the oblique line on the posterior surface of the shaft of the tibia, and into the tendinous expansion covering the surface of the muscle.

Fig. 452.—Muscles of the back of the leg. Deep layer.

Relations.—The tendon of the muscle is covered by that of the Biceps and by the external lateral ligament of the knee-joint; it grooves the posterior border of the external semilunar fibro-cartilage, and is invested by the synovial membrane of the knee-joint. The fascia covering the muscle separates it from the Gastrocnemius, Plantaris, popliteal vessels, and internal popliteal nerve. The deep surface of the muscle is in contact with the knee-joint and back of the tibia.

The **Flexor longus hallucis** is situated on the fibular side of the leg, and is the largest and most superficial of the three next muscles. It arises from the lower two-thirds of the posterior surface of the shaft of the fibula, with the exception of an inch at its lowest part; from the lower part of the interosseous membrane; from an intermuscular septum between it and the Peronei, externally; and from the fascia covering the Tibialis posticus internally. The fibres pass obliquely downwards and backwards, and terminate in a tendon which occupies nearly the whole length of the posterior surface of the muscle. This tendon lies in a groove on the posterior surface of the lower end of the tibia; it then grooves the posterior surface of the astragalus, and the under aspect of the sustentaculum tali of the os calcis, and passes into the sole of the foot, where it runs forwards between the two heads of the Flexor brevis hallucis, and is inserted into the base of the last phalanx of the great toe. The grooves on the astragalus and os calcis, which contain the tendon of the muscle, are converted by tendinous fibres into distinct canals, lined by synovial membrane. As the tendon passes forwards in the sole of the foot, it is situated above, and crosses from without inwards, the tendon of the Flexor longus digitorum, to which it is connected by a tendinous slip.

Relations.—By its *superficial surface*, with the Soleus and tendo Achillis, from which it is separated by the deep transverse fascia. By its *deep surface*, with the fibula, Tibialis posticus, the peroneal vessels, the lower part of the interosseous membrane, and the ankle-joint. By its *outer border*, with the Peronei. By its *inner border*, with the Tibialis posticus, and posterior tibial vessels and nerve.

The **Flexor longus digitorum** (*flexor perforans*) is situated on the tibial side of the leg. At its origin it is thin and pointed, but gradually increases in size as it

descends. It arises from the posterior surface of the shaft of the tibia, from immediately below the oblique line to within three inches of its extremity, internal to the tibial origin of the Tibialis posticus; some fibres also arise from the fascia covering the Tibialis posticus. The fibres terminate in a tendon, which runs nearly the whole length of the posterior surface of the muscle. This tendon passes behind the internal malleolus, in a groove, common to it and the Tibialis posticus, but separated from the latter by a fibrous septum; each tendon being contained in a special sheath lined by a separate synovial membrane. It then passes obliquely forwards and outwards, superficial to the internal lateral ligament into the sole of the foot (fig. 454), where it crosses the tendon of the Flexor longus hallucis,* lying on its plantar aspect and receiving from it a strong tendinous slip; it then becomes expanded and is joined by the Flexor accessorius, and finally divides into four tendons, which are inserted into the bases of the last phalanges of the four lesser toes, each tendon passing through an opening in the tendon of the Flexor brevis digitorum opposite the base of the first phalanx.

Relations.—In the leg: By its *superficial surface*, with the posterior tibial vessels and nerve, and the deep transverse fascia, which separates it from the Soleus muscle; by its *deep surface*, with the tibia and Tibialis posticus. In the foot, it is covered by the Abductor hallucis and Flexor brevis digitorum, and crosses superficial to the Flexor longus hallucis.

The **Tibialis posticus** lies between the two preceding muscles, and is the most deeply seated of all the muscles in the leg. It commences above by two pointed processes, separated by an angular interval, through which the anterior tibial vessels pass forwards to the front of the leg. It arises from the whole of the posterior surface of the interosseous membrane, excepting its lowest part; from the outer portion of the posterior surface of the shaft of the tibia, between the commencement of the oblique line above and the junction of the middle and lower third of the shaft below; and from the upper two-thirds of the internal surface of the fibula; some fibres also arise from the deep transverse fascia, and from the intermuscular septa separating it from the adjacent muscles on either side. This muscle, in the lower fourth of the leg, passes in front of the Flexor longus digitorum, and terminates in a tendon, which lies in a groove behind the inner malleolus, with the tendon of that muscle, but enclosed in a separate sheath; it then passes through another sheath, over the internal lateral ligament into the foot, and then beneath the inferior calcaneo-navicular ligament, and is inserted into the tuberosity of the navicular bone. The tendon of this muscle contains a sesamoid fibro-cartilage, as it runs under the inferior calcaneo-navicular ligament, and gives off fibrous expansions, one of which passes backwards to the sustentaculum tali of the os calcis, others forwards and outwards to the three cuneiforms, the cuboid, and the bases of the second, third, and fourth metatarsal bones (fig. 455).

Relations.—By its *superficial surface*, with the soleus, from which it is separated by the deep transverse fascia, the Flexor longus digitorum, the posterior tibial vessels and nerve, and the peroneal vessels. By its *deep surface*, with the interosseous ligament, the tibia, fibula, and ankle-joint.

Nerves.—The Popliteus is supplied by the fourth and fifth lumbar and first sacral nerves, through the internal popliteal; the Flexor longus digitorum and Tibialis posticus by the fifth lumbar and first sacral; and the Flexor longus hallucis by the fifth lumbar, and first and second sacral nerves through the posterior tibial.
